ful examination of the body by a person competent to form an intelligent opinion. Certain cases arise in the experience of every physician in which the operation performed amounts practically to taking a surgical chance in hopeless diseases. If also in such a case a large fee is charged, surgery is apt to be brought into more or less disrepute. Before an operation a thorough inquiry should be made as to drugs which have been taken or administered. This is especially true in those cases in which the debatable point concerns nervous diseases. It is a complaint of some surgeons that cases of malignant growth are brought to them at a late stage. Time is a great aid in establishing the diagnosis, and oftentimes a case which is obscure to the medical predecessor is cleared up for the one who succeeds him. The question of cardiac strength is often as interesting to the surgeon as to the physician. Many people fear heart failure under anesthesia. Observation has shown that many patients with heart lesions have undergone operative procedures most satisfactorily. It is always well to emphasize to a patient the importance of employing a thoroughly competent anesthetist. In cases of prolonged jaundice the physician has the responsibility of considering the danger of hemorrhage which might lead to a fatal result after operation. The writer is impressed, however, with the necessity of early operation in suitable cases. Kidney disease is no longer considered such a drawback to surgical procedures as it once was. The writer admits that he does not feel inclined to urge a patient to undergo dubious palliative treatment. — *Medical Record*, March 17, 1906.

Correspondence.

EUTHANASIA — DEGENERATED SYMPATHY.

BOSTON, February, 1906.

Mr. Editor: The subject of "Degenerated Sympathy," discussed and dismissed very briefly by a leading medical journal, is too important to be put aside with a sneer, and is worthy of more extended and respectful consideration than was there given it.

The propositions alluded to in this article seem to indicate a wider spread of sentiments, neither new nor obsolete, than has been hitherto apparent upon the surface. They are not entertained solely by the immoral, insensible, cranky or degenerate, nor are they so rare among the medical profession, in a class much higher than that of the common hangman, as some of the comments would lead one to suppose.

The discussion of them is most appropriate in the journals which bring the great problems of life, death, suffering and crime most nearly home to the men who are in daily contact with them and whose work is their relief.

Reference is made to the recommendation of a "reforming woman to kill off the incurables" and of another to "murder the children in the slums" and to the "moral aberration" of Professor Norton who proposes to make away with the "hopelessly insane, diseased and injured." Since the article appeared there have been many comments upon a bill introduced (and rejected) in the Ohio legislature giving permission to physicians to fatally anesthetize persons hopelessly ill who ask for the privilege. A bill has been introduced into the New York legislature making any advocacy of such propositions a felony. Just

where any of these or similar schemes would stop is a matter which may be passed over until it is settled that we have any right to carry them out under any circumstances.

Although the responsibility for terminating useless, painful and harmful lives would not rest upon physicians as such, yet the practical application of it would depend largely upon their opinions and they would see much more of its workings than any other class. Beside this, although the duty of the physician is towards his patient first of all, and always as against any adverse interest, he is often called upon to consider the welfare of friends; while outside of professional relations he has the same rights and duties toward the community that any other citizen has.

We all know what the moral and legal rule is at present; that the life of the individual is to be sustained as long as possible without regard to its value to the possessor, his friends or the community, even when the possessor would be gladly released from the intolerable burden; that the taking of a life which is surely near its end of suffering is just as much a homicide as if it were one of prospective happiness and of the greatest value to the world.

What, I think we should ask calmly and without prejudice, is whether, in the interests of humanity and mercy as well as of the welfare of the community, we are not justified in adopting some modification in rendering it less absolute.

The whole conduct of life, by the normal as well as the degenerate, consists in the balancing of probabilities, and we have a right to take into the account probabilities, possibilities and prospects when there is thrown upon us a more or less complete responsibility for others. We value a life now for what it offers to its possessor or his friends in the way of development and enjoyment, and to the community in usefulness or, perhaps, on the other hand, in harm and danger.

The right to take the life of another is recognized in the individual who is threatened with the loss of his own, and in the community when that of a criminal becomes a menace.

The right of the community to accept the sacrifice of life from members is admitted in the endangering of it by almost any great industrial enterprise. We admit the hideous sacrifices of war, for which we select the best and reject many who could well be spared, and in times of stress do not wait for the sacrifice to be a voluntary one. A few workmen must fall from the bridge that the multitude need not suffer the inconvenience of the ferry. Crowds throng to exhibitions in which the principal object of attraction is the chance of the performer being killed. We are by no means careful of life in general.

It is only when the question comes to the life of some definite individual, when it is our friend, or some one on whom the community focuses its attention, when it is the one man or one woman about whom the papers and the public are for the moment talking, and not merely the undetermined few taken at random from among unknown thousands, — that the sacredness of life comes to the front for practical recognition.

I may not knowingly administer a fatal dose of morphine to the anencephalous monster, but I may without legal restraint distribute the same drug wholesale among normal persons so long as no one can point out which particular ones will have the possibilities of a useful life destroyed. A courageous governor may not order the carrying into execution of a just sentence upon an acknowledged murderer of the lowest type without awakening horror-stricken comments and protests, but he might with approval have vetoed a bill which would protect the lives of thousands of travelers if his decision were in the interests of commercial prosperity.

In fact, life in the abstract, a percentage of life in a mass, weighs but lightly in the balance against other considerations which involve its destruction, but when the necessity or policy of its loss narrows down to the one selected life, then the pity, conscience and religious sentiment of the community go out in an instinctive repugnance to the taking of it.

This reverence for the individual human life without regard to its value, this respect for the mere functions of respiration and heart beat which may go on without the

least trace of consciousness, and with an intelligence which can by no possibility be made to rise to that of a brute (so called), or which has fallen hopelessly below it; this moral and religious principle, as we consider it, is in reality a sentiment, based indeed for the most part upon a principle, but not a reasoned or reasonable conviction which should be allowed to control in all cases the sense of humanity to the patient or the welfare of the community.

It is the deeply rooted and admirable instinct—mother-instinct, if you will, of protection to the helpless, which preserves the existence of the lowest of beings in the human form and which prolongs the stay of those dear to us after they themselves have ceased from all the higher functions or are carrying a burden which they would gladly lay down.

That there exists in some minds a rudimentary perception of our right to consider in our treatment the value of individual lives may be seen in the impression, of which the physician sometimes becomes aware, that it is his duty to take away at birth the life of certain monsters, and he may be reproached for not having done so by those who would not take the responsibility themselves.

This right or duty, although in every respect contributory to the public welfare, has never been conceded by the code of professional ethics. In the case of the anencephalous fetus the question is of no great importance practically, for nature soon settles it, but from this up an unbroken series can be formed through human infants whose mental and moral characteristics must always remain below those of the brutes but whose viability may be equal to the normal.

At the other end of life we may arrive at a stage when all cerebral structure will have degenerated, when mental, moral and emotional action will have ceased, and there remains nothing but the external form with its associations of memory to show that it has been the abiding place of a soul now evicted. Would it not be a more respectful treatment of the loved ones, a more dignified ending of a worthy life, if respiration were allowed to cease when all higher functions have irrevocably departed? Would not memories associated with a previous life of its fullness and beauty be more precious than these dependent upon the prolongation of the lowest animal existence?

To those who are in full possession of their psychic functions, but to whom life can never be anything but a prolongation of suffering, the physician and surgeon are constantly offering the chance of relief at the price of danger to life. They undertake the operation or the administration of the drug which they know will bring relief to pain, which they hope will prolong life a little, but which both patient and surgeon know may bring death sooner than it would otherwise come. It is their duty to do it. The surgeon is shirking his duty if he refuses to give the relief which an operation would afford for fear of the death which would impair his statistics. Is it not as humane, as merciful, and just as reasonable to select for death those who are longing for it and for whom we know that life has nothing to offer but a prolongation of suffering, as to distribute the chances of it over many days and months?

The proposed "murder of the children in the slums" of the writer be correctly quoted. I admit the full lucidness of, but not having seen the original proposition I venture to suggest that it is quite likely that the writer used this expression as a rhetorical exaggeration to express her horror of slums, an energetic protest against their existence, rather than as a serious plan to do away with their effects.

The objections to any such plans upon the practical side are at once obvious in the abuses which might come in the hands of the unscrupulous, but it is, it seems to me, the ethical question rather than the practical one which should first be brought to some agreement among those who are neither unscrupulous nor reckless, or devoid of conscience or natural affections. If the principle were admitted by such it would not be difficult to surround its application with as many safeguards as are now thrown around that deprivation of liberty and the pursuit of happiness which equally with life are supposed to be our constitutional rights which have now involved in sending a patient to an asylum.

It is not necessary to go back many years to arrive at a

time when the same sort of accusations of abuse were made in regard to this procedure, which we now look upon as an immense advance upon the system which gave the care of such cases to families and almshouses.

Certainly, precautions much less stringent than those now employed for keeping the murderer from his just doom would make abuse quite as near to impossibility.

I should like to call your attention and that of some of the secular papers to an editorial on Euthanasia in the *New York Medical Record* of some twenty years ago. It shows that the proposition of introduction into the Ohio legislature, which has called out so many unfavorable comments from the lay press, was no novelty, but that its author was simply a man who had the courage of his convictions and the convictions of many others.

It seems to me very clear from this article, as well as from conversations with physicians and others, that it is the feeling of dislike and aversion to a direct, definite and complete responsibility for the taking of life, which makes men decline to take 100% of it when they are fully convinced, and show by their deeds that they are aware of their duty to take 99% in behalf of their suffering patients.

It is the same feeling which at a military execution leads one gun of the firing party with blank cartridge in order that each one, who perhaps would have no hesitation about pouring a storm of bullets from an almost unaiming machine into a crowd of his fellow men, may flatter himself that he has not the death of a comrade upon his conscience.

Very truly yours,

..

"THE MEDICAL PROFESSION AND THE MEDICAL JOURNALS IN RELATION TO NOSTRUMS."

THE MEDICAL SOCIETY OF THE COUNTY OF WILSON.
THE COUNTY BOARD OF HEALTH.

CAMDEN, ATLANTA, March 10, 1906.

Mr. Editor: I have just read with a great deal of interest the article under the head of "The Medical Profession and the Medical Journals in Relation to NostRUMS" in your issue of March 1, 1906. As one who fills his own prescriptions, as a necessity, not choice, I find that there are among the proprietary medicines, so-called nostrums, some which are of such excellent therapeutic qualities that to discard them would be doing an injustice to the patient, for the reason that there are not 10% of the country physicians who are qualified to fill any prescription that requires the amount of skill these do. If they attempted to make any internal antiseptic solution like the one in mind, I fear that they would fail or if they wanted a solution of iron, potassium and manganese, could they make it? If not, why not use the best, which is a proprietary medicine? The author criticizes this preparation on account of its mal-formed name, not its inefficacy. All of us have heard our grandmothers suggest clay for bruises, sprains, etc., and now that we can get clay as an elegant preparation, should we not take advantage of it? There are a few other preparations of equal efficiency that should be retained as a part of our armamentarium. As for the advertisements of these preparations in the medical journals, does the doctor think that if the journals refuse to accept the advertisements, all of the firms selling proprietary are going out of business? On the contrary, they will form a journal of their own, procure the services of a Board of Editors composed of physicians, and continue to put their preparations before the eye of the profession or what is worse, they will send advertisers to the Editor through the mails and newspapers. Is it not far better to have the dealer under the control of the profession, as they now are, than to force them to look to the people for support? We can choose the efficient preparation and discard the inefficient ones. The latter will not use such discretion, but will accept them according to their own all-around ideas. Shall the physician accept badly prepared proprietary or shall the people procure a better one?

R. O. SEYMOUR, M.D., Editor.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING MARCH 17, 1906.

H. A. DUNN, passed assistant surgeon. Detached from the naval proving ground, Indian Head, Md., and ordered to the "Princeton."

J. D. MANCHESTER, assistant surgeon. Detached from the "Princeton" and ordered home to wait orders.

M. W. BAKER, passed assistant surgeon. Detached from the Naval Hospital, Washington, D. C., and ordered to the Naval Hospital, New York, N. Y.

F. D. CHAPPELEAR, acting assistant surgeon. Ordered to the Naval Hospital, Washington, D. C.

C. D. LANGHORNE, surgeon. Detached from the "Denver" and ordered home to wait orders.

G. P. LUNDEN, surgeon. Detached from the "Olympia," when put out of commission, and ordered to the "Minneapolis."

O. D. NORTON, surgeon. Detached from the "Minneapolis" and ordered home to wait orders.

R. W. PLUMMER, passed assistant surgeon. Detached from the naval sub-recruiting station, St. Joseph, Mo., and ordered to the "Denver."

W. B. SMITH, assistant surgeon. Detached from the "Olympia," when put out of commission, and ordered to the "Hancock."

I. F. CONE, J. FLINT, assistant surgeons. Appointed assistant surgeons with rank of lieutenant, junior grade, from Feb. 28, 1906.

APPOINTMENT.

CHARLES HARRINGTON, M.D., Secretary of the Mass. State Board of Health, has been appointed Professor of Hygiene in the Medical School of Harvard University.

RECENT DEATHS.

DR. LEOPOLD HIRSCHMANN of New York died on March 15, at the age of thirty-five years. He was born in Germany and was a graduate of Cornell University and of the Cornell Medical School.

DR. SAMUEL H. FREEMAN of Albany, N. Y., died on March 15.

DR. LAWRENCE J. GEROLD, assistant surgeon of the State Soldiers' Home Hospital at Bath, N. Y., died from cardiac disease on March 16. He was forty-one years of age, and was formerly assistant physician at the Kings Park branch of the Long Island State Hospital for the Insane.

DR. PETER V. P. HEWLETT of Newark, N. J., county physician of Essex County, died on March 13, at the age of fifty-nine years.

BOOKS AND PAMPHLETS RECEIVED.

Movable Kidney. A Cause of Insanity, Headache, Neurasthenia, Insomnia, Mental Failure and Other Disorders of the Nervous System. A Cause also of Dilatation of the Stomach. By C. W. Suckling, M.D. (Lond.). M.R.C.P. Illustrated. London: H. K. Lewis. 1905.

Radiotherapy in Skin Disease. By Dr. J. Belot. With a Preface by Dr. L. Brocq. Translated by W. Deane Butcher, M.R.C.S. Only authorized translation from the second French edition. Illustrated. London: Rebusan, Limited. New York: Rebusan Co. 1905.

New York State Library Year-book of Legislation. 1904. Edited by Robert H. Whitten, Sociology Librarian. Albany. 1905.

The Practitioner's Visiting List. Philadelphia and New York: Lea Brothers & Co. 1906.

Thirty-sixth Annual Report of the State Board of Health of Massachusetts. 1905.

Studies from the Rockefeller Institute for Medical Research. Reprints. Vol. III, 1905.

Studies in the Surgical Anatomy of the Small Intestine and its Mesentery. By George H. Monks, M.D. Reprint.

Clinical and Pathological Papers from the Lakeside Hospital, Cleveland. Series II, 1905.

The Harvard Embryological Collection. By Charles Sedgwick Minot, LL.D., D.Sc. Reprint.

Veneral Phylaxis. By Albert E. Carrier. Reprint.

Materia Medica for Nurses. By John E. Groff, Ph.G. Third edition, revised, with an appendix giving list of questions for self-examination. Based upon eighth decennial revision of the U. S. Pharmacopoeia. Philadelphia: P. Blakiston's Son & Co. 1905.

Clinical Obstetrics. By Robert Jardine, M.D. Edin., M.R.C.S. Eng., F.F.P., & S. Glas., F.R.S. Edin. Second edition. Illustrated. London: Rebusan Limited. New York: Rebusan Company. 1905.

Bulletin of the Massachusetts Institute of Technology. Catalogue, December, 1905.

Lectures on Clinical Psychiatry. By Dr. Emil Kraepelin. Authorized translation from the second German edition. Revised and edited by Thomas Johnstone, M.D. Edin., M.R.C.P. Lond. Second edition. New York: William Wood & Co. 1906.

The Diagnosis of Tuberculosis of the Lung, with Special Reference to the Early Stages. By Dr. K. Turban. With an introduction by Sir Dyce Duckworth, M.D., LL.D., F.R.C.P. Translated by Herbert C. Morland, M.D., B. Sc. Lond. New York: William Wood & Co. 1906.

Clinical Sanitary Science. A Handbook for the Public Health Laboratory. By David Sommerville, B.A., M.D., D.P.H. (Camb.), M.R.C.P. (Lond.) Illustrated. New York: William Wood & Co. 1906.

Transactions of the Association of American Physicians. Twentieth Session, held at Washington, D. C., May 16 and 17, 1905.

Military Hygiene. By Robert Caldwell, F.R.C.S., D.P.H., Lieut.-Colonel Royal Army Medical Corps. Illustrated. New York: William Wood & Co. 1905.

University of California Publications. Physiology. Studies on the Toxicity of Sea-Water for Fresh-Water Animals (Gammarus pulex de Geer). By C. W. Wolfgang Ostwald.

On the Validity of Plüger's Law for the Galvanotropic Reactions of Paramecium. By Frank W. Bancroft.

Saunders' Question Compend. No. 7. Essentials of Materia Medica and Prescription Writing. Arranged in the form of Questions and Answers prepared especially for Students of Medicine. By Henry Morris, M.D. Seventh edition, thoroughly revised, by W. A. Bastedo, Ph.G., M.D. Philadelphia and London: W. B. Saunders & Co. 1905.

Blakiston's Quiz-Compend. A Compend of Medical Chemistry. Inorganic and organic, including urinary analysis. By Henry Leffmann, A.M., M.D. Fifth edition, revised. Philadelphia: P. Blakiston's Son & Co. 1905.

The Office Treatment of Diseases of the Rectum, with a Description of Some New Methods. By Charles B. Kelsey, M.D. Reprint.

Nervous and Mental Diseases. By Archibald Church, M.D., and Frederick Peterson, M.D. Fifth edition, thoroughly revised. Illustrated. Philadelphia and London: W. B. Saunders & Co. 1905.

Official Register of Harvard University. The Harvard University Catalogue. 1905-6.

THE VALUE OF DRUGS IN THERAPEUTICS.*

BY FREDERICK C. SHATTUCK, M.D., BOSTON.

Jackson Professor of Clinical Medicine in Harvard University

I do not believe that King David meant to be taken in absolute seriousness when he classed all men alike as liars; nor do I believe that Dr. Holmes, had it come to the point, would have cast every drug into the deep.¹ Ten righteous men would have saved Sodom, than which the Pharmacopœia is less sinful in that most of its inhabitants are negative characters like Kipling's Tomlinson — neither fit for heaven nor ripe for hell. Even if the Pharmacopœia were as bad as Sodom it would be easily saved by a score or more agents which the world could ill spare. Moreover, who can foretell what chemistry is still to do for us?

Dr. Holmes's statement was made at a time when the only drugs in use were those pretty directly derived from the mineral or vegetable kingdoms. The rising sun of science had scarcely reached the valley of therapeutics, though the keen vision of Jacob Bigelow penetrated deep enough into the gloom to see that many diseases are self-limited, and curable rather through that which is in the patient than what we put into him. To-day new compounds are made and tested, compounds which, as far as we know, never existed before. The vast majority of them are of little or no value as remedies for disease, but some useful synthetic compounds have been discovered, and more will be discovered. Who can count the number of cases of typhoid which have originated through the urine of a previous patient? This is a danger against which urotropin, rightly used, seems to afford absolute protection. For the past eight years my typhoid patients have all had 7 to 10 gr. of urotropin three daily, two successive days of each week, until convalescence was complete. In no case has harm resulted. Were the practice universal there would be less typhoid, the prevalence of which among us is a reproach to our civilization.

Bigelow and Holmes were among the early protestants against the irrational and indiscriminate therapy which had ruled the medical world since the time of Galen. Here and there a Sydenham had risen above authority but was ahead of his time. To-day, thanks to a scientific spirit and saner methods, we believe food, sleep and fresh air to be the trinity of health, and that if we can regulate the lives of our patients we can largely dispense with drugs. It is true that we have a few specifics, as quinine for malarial fever, and, to a less degree, for amebic dysentery. We also have mercury and the robes for syphilis. The salivæ compounds, great as their control is over the articular manifestations and fever of what we call rheumatism, can scarcely be classed among the specifics until the evidence is clearer than it seems at present that they prevent or

control the heart involvement, so much more serious in its effects than the joint inflammation. Our knowledge of these agents, as of most of the other useful drugs to which I shall allude, is purely empirical. Diphtheria antitoxin and thyroid extract are not, properly speaking, drugs, though they are remedial agents of the first importance, and there is sharp contrast between their birth and that of quinine or mercury.

It may be broadly stated that drugs are in the main adjuvants only; that such beneficial effects as belong to them lie in their power to alleviate some untoward symptom like indigestion, insomnia, pain, which retards or prevents recovery. This is eminently true of those acute and chronic general infections, for which we have, as yet, no antidote, such as typhoid, pneumonia, the exanthemata and tuberculosis. In these the action of drugs at present known can be only indirect. All that we can do now is to put the patient under the most favorable conditions possible in order that we may help him to manufacture his own antidote. Many a case of acute infection especially, goes through our hands without getting any drug at all. If we use a drug it is purely symptomatically.

Take again diseases which, in our present ignorance, are incurable. Among these I shall speak only of cancer and pernicious anemia. In certain forms and in certain stages of cancer surgery may be curative. Drugs, opium especially, may here, judiciously used, promote comfort (no mean boon) and prolong life. That is all drugs can do. In pernicious anemia experience teaches me that the down follows the up wave sooner or later, neither wave nor interval being capable of influence for good through drugs unless, possibly, to a slight degree by arsenic. Injudicious medication may do the patient harm. The fundamental good which judicious medication can do is problematical.

Again, there are maladies more or less local in their character in the successful treatment of many cases of which drugs may be practically indispensable. Myocardial disease furnishes a good illustration. I feel as sure as I can of almost anything in medicine that there are cases where hygiene and every other therapeutic agent fails without digitalis. Twice in the past two years I have sent back to Nova Scotia a live and greatly improved cardiac patient whose doctor and friends expected him to return in a coffin. The determining factor was a fairly bold use of an efficient preparation of digitalis, a drug the occasional or continuous use of which may enable a person to lead a relatively active and useful life, perhaps for years. It may be regarded as practically curative, and when well directed we could all dispense with it.

There are, furthermore, a number of disorders which a skilled practitioner can so modify by drugs, which will often be taken while we give general advice which will be left unheeded, as to increase the efficiency of life and the joy of living. An illustration which comes readily to mind is what was called biliousness, now more generally

* Read at the meeting of the Boston Homœopathic Medical Society, March 1, 1906.

¹ See he is generally quoted. But he expressly excepts opium, a few specifics, wine and ether.

known as auto-intoxication, and the effect upon it of an efficient purge. Calomel is a favorite nowadays. It is interesting to recall that the indiscriminate and excessive use of calomel and blue mass in former times led to their practical abandonment. Calomel was used irrationally. It is now used rationally in the main.

In gastric indigestion our chief reliance must be on diet and mode of life. They alone will usually right the mischief. But time can often be saved and an irritable be converted into a complacent member of the household more quickly by an acid, an alkali, bismuth or some other well selected drug or combination of drugs. The bromides seem clearly to allay reflex excitability, and often thus are of use in dyspepsia, palpitation of the heart and genital disturbance, in so far as these are due mainly to faulty innervation based upon nothing worse than what we call functional disorder.

The temporary or occasional use of a bromide or of one of the other more modern hypnotics can greatly help nature by securing sleep; but we must never forget the danger of the use, or too constant use, of these remedies. Each new hypnotic which comes out is at first called harmless; but we have all seen addiction to chloral, paraldehyde, amylene hydrate, sulfonal and trional. Veronal has scarcely had time to show its hand. Prophecy is dangerous, but I do not believe that a drug will ever be found which will cause a really natural sleep and can thus be used day after day indefinitely with safety. Some of the modern coal tar antineuralgics when rightly used are potent for good; but unless their sale as headache powders and bracers over every drug counter and in every bar-room can be stopped I think, on the whole, the world would be better without them. They are not as innocent as they are believed to be, and in so far as are more dangerous than opium, care in the use of which is generally recognized as desirable. I have by no means exhausted the list of drugs which I believe in themselves to be really active and thus capable of rendering good service to diseased and ailing humanity; but I think I have said enough for my purpose, which is to sketch rather than to attempt a finished picture, however small.

Therapeutic truth lies at the bottom of a very deep well, deeper than the medicine and food manufacturers who leave us samples realize themselves, or would like to have us realize. It is very easy for us to connect sequent events as cause and effect, though they may stand in no such relation to one another. Let us be on our guard, not only against our own credulity (and we are all infected more or less, either generally or locally, constantly or occasionally), but also against that of our patients. The power of suggestion may, nay, so very often does, play the leading part, whether we recognize the fact or not. When the good clergyman in the midst of his sermon said, "My friends, it is not so much the well from which we draw the water as it is the spirit with which we take it that counts,"

some of his congregation were amused. We may not altogether blame their levity, however firmly convinced we are of the truth of the statement. The same remedy in the same case at practically the same time may be of great service in the hands of one practitioner and fail utterly in the hands of another. To how many cases in which benefit has been and is attributed to drugs, do the words of Christ to the menorrhagic woman apply, "Thy faith hath made thee whole"? Mind cure, faith cure and Christian Science are simply new manifestations of the old, old human nature which is intolerant of the slow evolution of accurate knowledge, which must cling to something, and which thinks if it has a new name it has a new thing. As drugs in general have lost the pre-eminence in the treatment of disease which they once enjoyed, and as faith in old religious dogma has weakened, disease and the demand for its cure persisting all the time, faith, which also persists, seeks new channels. This need not disturb us at all, nor should it lead us to slacken our constant effort to think straight. Let us use suggestion as far as is necessary to subserve the best interests of our patients; but let us strive without ceasing to separate in our own minds mere suggestion from actual drug action. Few are capable of either imparting or receiving suggestion strong enough to prevent a hypodermic of apomorphia from producing active emesis, or zinc sulphate given by the mouth for that matter. But we have all seen cases in which the patient was relieved by a hypodermic of plain water which he—or she—believed to contain morphia.

I well remember, when interne at the Massachusetts General Hospital a third of a century ago a liniment introduced by a member of the staff who was of a skeptical turn of mind. It was a solution of common salt in water colored with some ink which had been bought by the hospital and which proved of poor quality for writing purposes. It was called *linimentum salis*, and more than one patient who had used it in the hospital came back for it after discharge, having found it useful and being unable to get it in any drug store. Rubbing is as useful as it ever was. To-day we call it massage. Some call it osteopathy. The element of suggestion enters more or less, I suppose, into the action of most applications to the seat of pain or disease. In recent years certain clay preparations mildly scented have attained much vogue. The thought of being smeared with such stuff adds a new terror to illness. Primitive people prefer medicines with taste and odor even if not agreeable. An Adirondack guide of mine replied, when I asked him how he liked some claret I gave him, "Well, I guess it's healthy." I have an impression that homeopathy has not made as much headway among the farming and laboring classes as among the more educated classes with a different kind of an imagination. The late Dr. T. B. Curtis remarked to me once that it is impossible to underrate the intelligence of the most intelligent classes in matters of physical

science. They do not know what constitutes growing knowledge, and most of

Therapeuti deep well, d manufacturei themselves, o very easy fo cause and ef such relation guard, not o we are all in or locally, co against that suggestion n the leading p not. When of his sermon the well from the spirit with

science. They do not know what constitutes evidence here or how to weigh it.

It seems to me that the leading therapeutic principles can be stated somewhat as follows:

First. Do no harm. This principle seems to be well met by the homoeopathist who uses the infinitesimal dose. He does no harm save in so far as he may miss doing good.

Second. Try to see as clearly as possible just why you give a drug, your purpose in giving it, whether as a specific, curative, palliative or as a placebo.

Third. As far as you can, give a drug uncombined. This is a general rule subject to many exceptions. Rules, however, are made to break. They are our servants, though we too often allow them to be our masters. But in breaking rules we must use our brains, an exercise which most of us avoid as far as we can.

Fourth. In using an efficient drug be as sure as you can of a good preparation, and then give it until something happens, — either the desired effect or evidence appears that the limit of toleration has been reached, what is called the physiological, but what I should prefer to call the toxic effect. Disregard of this law is, I believe, responsible for many therapeutic failures. Allow me to mention two remedies in this connection: Nitroglycerin is not to be thrown aside as useless until its dose has been pushed to the point of headache or flushing of the face without relief. In syphilis of the nervous system I share the belief of those whose experience in that line has been far greater than mine, that the dose of potassic iodide should be rapidly pushed, even once in a while, to 3 oz. a day. It is rarely necessary to go as high as this, but 1 to 4 dr. three times a day are not infrequently needed, unless I am more credulous than I think I am.

All that I have said may be summed up in the statement that our knowledge of drugs as therapeutic agents rests mainly on an empirical basis, and that in drawing conclusions we must be keenly alive to the manifold sources of error which encompass us on every side. Here judgment is indeed difficult.

I venture now to add a few words which I am sure you will take in the friendly spirit in which they are said. Why is the noun *curatives* not broad enough for any one? What is the reason to-day for any adjective? Scientific medicine is younger than homoeopathy, which is one of the forces that has led to the more rational use of drugs, in conjunction with the truly scientific spirit and with modern chemistry, which has separated the wheat from the chaff, and given us efficient agents, pleasing to the eye and inoffensive to the palate.

There is really no room in medicine for sects. There is less excuse for the *Odium Scientificum* than for the *Odium Theologicum*, in that scientific questions are more capable of demonstration. In matters of faith one man's opinion may be as good as another's — ay, be better for him. Not so in matters open to direct experimentation. It is mainly the imperfection of our constantly

growing knowledge, and, may I add, the frailty of our tempers and our narrowness of view which produce apparent discord. In essentials you and I agree, I think. As far as the selection of the drug and size of the dose go, unless my observation is woefully at fault, we are daily coming closer together. I frankly state, that in my opinion, homoeopathy has done its work. You and I are really separated in name rather than in fact, and, though I am no longer young, I hope and expect to see a single State Medical Society, comprising within its ranks the great majority of all well educated and honorable physicians, animated by the sole desire to advance knowledge, elevate the profession of medicine and serve the best interests of the community.

According to my thinking a grave mistake was made when the Massachusetts Medical Society years ago expelled reputable, well trained men whose only offense was that they used homoeopathic remedies homoeopathically. This mistake was made practically at the behest of the American Medical Association. Had the Massachusetts Medical Society simply stood pat it would have been justified by time as well as by its conscience. To-day the American Medical Association is more liberal; but the portal of entry into the American Medical Association is through the state societies, and a By-Law of the Massachusetts Medical Society prevents your joining it should you be so minded unless you sever your present affiliations and sign a statement that you do not "profess to cure disease by, nor intend to practice, spiritualism, homoeopathy, allopathy, Thomsonianism, eclecticism or any other irregular or exclusive system," etc. On spiritualism we need waste no words in this connection. Allopathy has never existed. Thomsonianism and eclecticism are dead.

Mine eyes hope to see the glory of the coming of the Lord. The true physician is simply seeking the truth as God gives him power to see it, and it is the truth which sets men free. Homoeopathy, in its early days especially, was too much dominated by its theories of selection and dosage. One result is a tendency to devote too exclusive attention to the study and nature of symptoms, too little attention to thorough physical examination, which, with proper methods and correct reasoning, lead to diagnosis.

Within ten years a lady who had been under the care of one of your leading members for three years, and who had obtained no relief for severe pruritus, consulted an eminent dermatologist, who referred her to me. Itching was due to chronic retention of bile which discolored the urine more profoundly than the skin or sclera, and which was due to biliary cirrhosis of the liver. Hanot's cirrhosis. The liver was very large, and the outlines of the lower edge could be felt with the greatest ease. The lady, who seemed a cool headed and credible person, assured me that her attendant had never examined her during the three years she had been going to his office. I do not know any member of the Massachusetts Medical Society who could hold a patient

three years under the same circumstances without examination.

Undue attention to the symptoms of disease has resulted in neglect of deep study into the nature of disease. If any really important contribution to the advance of medical science has come from a homeopathic physician I am ignorant of it, but am more than ready to learn.

Scientific medicine is open to the danger of going to the extreme of therapeutic nihilism, of disregarding the individual, of forgetting that, while our knowledge is imperfect and the big thing is to find out the true nature and cause of disease, the present day sufferer demands and has a right to demand all the aid that our knowledge, imperfect as it is, permits.

Peace and concord we enjoy. Let us, imbued with charity rather than prejudice, strive for unity.

THE HOMEOPATHIC PRINCIPLE.*

BY FREDERICK B. FERRY, M.D.,

Professor of Materia Medica, Boston University School of Medicine.

TRANSITION periods in medicine have always been epochal. Great men possessed of great and candid minds have in every age and generation struggled with the problem of drug influence in disease. System has followed system; theory, theory; all alike to disappear and be forgotten. From Hippocrates, the father of medicine, who said at the close of his life in speaking of disease, "Such are the causes, such the course, such the termination, alas, of all the diseases of my day; but if you ask me how to cure them then I must close my mouth; I did my best with the rough means at my disposal," down through the various schools of Aesclepiades, Galen, Paracelsus, Stahl, Sylvius, Boerhaave, Brown, Haller, and up to the time of Hahnemann, doubt and uncertainty prevailed as to the power of drugs. Some years before the promulgation of the law of similars Hahnemann thus voiced his opinion of the practice of medicine: "A number of causes — I dare not count them up — have for centuries been dragging down the dignity of that divine science of practical medicine, and have converted it into a miserable grabbing for bread, a mere cloaking of symptoms, a degrading prescription trade, a very God-forgotten handiwork, so that the real physicians are hopelessly jumbled together with a heap of befrilled medicine mongers. How seldom it is possible for a straight-forward man by means of his great knowledge of the sciences, and by his talents to raise himself above the crowd of mediocasters, and to throw such a pure, bright sheen upon the healing art at whose altar he ministers that it becomes impossible even for the common herd to mistake a glorious, benign evening star for a mere vapory sky-fall. How seldom is such a phenomenon seen, and hence how difficult it is to obtain for a purified science of medicine a renewal of her musty letters of nobility." Who was this man Hahnemann? Let me quote

from a contemporary and one opposed to his convictions in medicine: "No careful observer of his actions, or candid reader of his writings, can hesitate for a moment to admit that he was a very extraordinary man — one whose name will descend to posterity as the exclusive excogitator and founder of an original system of medicine, as ingenious as many that preceded it, and destined, probably, to be the remote, if not the immediate, cause of more important fundamental changes in the practice of the healing art than have resulted from any promulgated since the days of Galen himself. Hahnemann was undoubtedly a man of genius and a scholar; a man of indefatigable industry, of undaunted energy. In the history of medicine his name will appear in the same list with those of the greatest systematists and theorists; unsurpassed by few in the originality and ingenuity of his views, superior to most in having substantiated and carried out his doctrines into actual and most extensive practice." What thought this wonderful man of the value of medicine in the days preceding the birth of the law of similars? It was because of serious illness in his own family when, uncertain as to the methods to be employed for their relief, he thus expressed himself: "Eight years of scrupulously careful practice have shown me the nothingness of ordinary curative means; my sad experience has taught me but too well what may be expected from the advice of the greatest men. However, it is, perhaps, in the very nature of medicine, as many great men have already said, to be unable to arrive to a very high degree of certainty." In the middle of the last century Sir John Forbes thus wrote: "The same truth, as to the uncertainty of practical medicine generally, and the utter insufficiency of the ordinary evidence to establish the efficacy of many of our remedies, as was stated above, has almost always been attained to by philosophical physicians of experience in the course of long practice, and has resulted, in general, in a mild, tentative, or expectant mode of practice in their old age, whatever may have been the vigorous or heroic doings of their youth. Who among us, in fact, of any considerable experience, and who has thought somewhat as well as prescribed, but is ready to admit that, — in a large proportion of the cases he treats, whether his practice, in individual instances, be directed by precept and example, by theory, by observation, by experiment, by habit, by accident, or by whatsoever principle of action, — he has no positive proof, or rather no proof whatever, often indeed very little probability, that the remedies administered by him exert any beneficial influence over the disease? We often may hope, and frequently believe, and sometimes feel confident, that we do good, even in this class of cases; but the honest, philosophical thinker, the experienced, scientific observer, will hesitate, even in the best cases, ere he commit himself by the positive assertion, that the good done has been done by him. When physicians of this stamp have met in consultation in any doubtful case, and when they have chanced

* Read at the meeting of the Boston Homeopathic Medical Society, March 1, 1906.

to be startled out of their conventionalities by the bold doubt, or bolder query, of some frank brother of the craft, has not the confession, like the confidence, been mutual?"

It was, then, following these years of skepticism and after years of careful, painstaking experiment, that Samuel Hahnemann gave to the world his principle of *similia similibus curentur*; and through all the years which have passed his followers have shown no abatement of their enthusiasm in their faith in this law of cure. You may, if you like, attribute to others priority in the thought of first ascertaining the effects of drugs on the human body before using them in disease, yet as Rutherford Russell has well said: "The inductive philosophy of Bacon and Hahnemann and the application of its truths were necessary to the establishment of this law." What is it to believe in a law and practice it? "To believe or not to believe in a philosophical point of view, and apart from the theological acceptance of the term, signifies to give or withhold one's approval after having fully and seriously examined every new idea that bears the stamp of truth."

To practice it presupposes a thorough knowledge of the subject and a careful following out of its principles. What, briefly, are the essentials of the law of cure, for such we deem it to be?

First. That every drug should be thoroughly tested upon the healthy human body, and that facts thus elicited shall be supplemented by further experiments upon animals, and also by the results of poisoning when that is possible.

Second. That the conditions thus occasioned are those which when present in diseased states will be cured by these same drugs.

Third. That the dose to accomplish this must be sufficiently minute to occasion no aggravation of the symptoms present.

What are the advantages to be gained from using drugs in this way?

(1) Simplicity in form and administration, the single remedy its natural corollary.

(2) Precision.

(3) It assists nature, does not thwart or check her, and thereby fulfils that most important essential of all cures.

You may naturally ask what is the basis of its action, and I can do no better than to quote from a recent article by Dr. Villechaux: "To explain homeopathic cures Hahnemann evolved a certain number of theories. At first he considered that the organism was much more sensitive to drug-action than to disease, that drug-action was absolute; disease-action but relative. Then he concluded, that to induce a cure a slight aggravation was essential. Later he argued that the drug-disease was substituted for the natural disease and in turn vanquished by the reactive powers of the organism. This is the 'substitution method,' borrowed by Tronseau from Hahnemann. These theories lack solid scientific foundation, and Hahnemann finally said that the law being an established fact, its explanation

was of lesser moment. However, when this law shall be scientifically explained, homeopathy will become omnipotent in medicine and the most prejudiced mind will be forced to accept it."

I have purposely ignored certain features of homeopathy as not germane to the subject. That homeopathy is capable of curing *tuto cito et jucunde* is to us perfectly self-evident, but to the seeker after truth this is a thing to be proven. As a recent editorial rightly has said: "Drug giving may or may not be a permanent factor in the art of medicine; that is an open question; we who are homeopathic specialists believe, and with the soundest reason, that it is a factor far yet from being outworn. Be that as it may, we repeat, drug giving is not synonymous with the art of medicine. It may rise or fall; the art of medicine only declines when the physician's means of healing the sick decline in number or in power. Has this been the case in the last twenty years? Is there anyone who would seriously make a claim so instantly refutable? We need cite but a few shining instances in disproof. What of diphtheria, fatal, twenty years ago, in from 10% to 60% of the cases attacked, to-day treated in hundreds of consecutive cases without a death? What of tuberculosis, whose mortality, in the city of Boston alone, has been reduced 50% in the last quarter century? What of the once incurable headache, now easily diagnosed as due to eye-strain, and as easily cured? What of the innumerable hay fevers, reflex coughs, and their kin, disappearing promptly after removal of nasal growths and hypertrophies? What of the regaining of lost nervous balance, under the various forms of rest cure? What of the once lethal cyclone of 'peritonitis' cases, to-day recognized and relieved as appendicitis? What of the vastly more intelligent treatment of anemia, possible on the knowledge obtainable by the 'laboratory student' of to-day as to whether the case be one of chlorosis, leukemia, or primary or secondary anemia? We surely need not multiply proof. Even superficial study of that already adduced must convince any impartial investigator that the art of healing—the important true synonym of the art of medicine—is not declining, but progressing—and that, with beneficent speed."

Let us admit from the beginning that in the cure of the sick many influences must be considered:

- (a) Natural history of morbid processes.
- (b) The recuperative energies of the organism.
- (c) The favorable agencies of hygiene.
- (d) The power of personal magnetism in the practitioner.
- (e) Suggestion and a patient's suggestion.
- (f) Faith.
- (g) Courage.
- (h) Drugs.

Here then is the problem which faces every far-minded man, to apportion to each of these influences its due weight. It is not strange that there have been differences of opinion, no two cases are alike as no two individuals are alike,

and it does seem as though in certain carefully well selected cases we should possess definite information as to how much or how little drugs are factors. It would not be difficult in functional diseases to determine this factor; but in self-limited diseases the problem is a different one. Homeopathy has won its successes in the treatment of epidemic disorders, and we point with pride to those statistics so long ago offered by Fleischman in the successful treatment of pneumonia. The time has come and is not far distant when such tests of the remedial power of homeopathic drugs as shall silence all doubt will be made. It is the truth that we seek; self-deception must not longer rule us, and suffering humanity will be the gainer. The weakness of homeopathy lies in the crude and imperfect application of its principles, and in that most important defect, lack of entire faith in its adaptability. Polypharmacy in the minds of most of the new school is an anachronism, a thing not to be tolerated; and yet with us it is even now a menacing evil. This, gentlemen, is not homeopathy, give it some other name if you wish to adopt it; but leave to us the single remedy and the approval of an honest mind. As Dr. Elbridge C. Price has well said: "Do not forget, however, that since the days when Hahnemann wrote his 'Organon,' the world has progressed, arts have become more vital and effective, and the ever-multiplying branches of science have evolved into varied systems of learning of which the sages of the eighteenth century could have no conception. Do not forget that it is quite possible for many of the unessentials which have grown up beside the vital law, to be proven to be without foundation in fact, and that it is unHahnemannian in men of to-day to refuse to recognize the demonstrable facts of science. And finally, do not forget that nothing ever yet has modified in the slightest the truth of that eternal verity, the law of similars, and, to judge from the sublime verdict of the ages, nothing ever will. Its roots dip deep beneath the dust of remotest antiquity, and its branches reach out into the empyrean of coming time, bearing its leaves to all the ends of the earth for the healing of all the unborn nations of all futurity."

AN INEXPENSIVE MECHANICAL TREATMENT FOR ANTERIOR METATARSALGIA.

BY ERNEST BOYEN YOUNG, M.D., BOSTON.

Second Assistant Visiting Physician for Diseases of Women, Boston City Hospital; Assistant in Gynecology, Harvard Medical School.

ORTHOPEDIC surgery and gynecology would seem, at first glance, to be almost too widely separated in their scope to have any interdependence; but there is a class of cases, coming, as a rule, to the specialist in diseases of women, in which pain is referred to the pelvis, lower back and hips, for which pelvic examination shows no adequate cause. Poor muscular development and improper shoes have seemed to be very often at the bottom of these difficulties. As a conse-

quence, faulty methods of standing and walking, induced by the attempt to gain relief, have usually been manifest.

Some of these have been entirely relieved by suitable shoes and education as to the proper methods of standing; and others by muscular exercises of various kinds. Among those with indefinite pains about the pelvis have been a number suffering from lowering of the anterior transverse arch of the foot.

In experimenting to convince myself that the pains were not of pelvic origin, the discomforts due to the breaking down of the transverse arch have been relieved by such simple devices; that it seems worth while to publish them, in order that others may have the benefit; if they prove as satisfactory in their hands, as in my own.

The inside sole and plate are both somewhat costly, and often necessitate the purchase of larger shoes, in order that they may be worn with comfort. The method adopted in my own cases does away with these drawbacks, and will be found acceptable to many of moderate means.

Fig I Fig II Fig III Fig IV
Diagram of different methods of applying support.

A piece of sole leather of the thickness required is cut into the shape indicated in the illustration (Fig. 1). The edges are beveled, and the leather is touched on one side with a few drops of liquid glue. It is then placed on the sole of the boot, to which it adheres, in about the required position, *i. e.*, so that its pressure is exerted just behind the heads of the metatarsal bones. The situation in which it gives relief is marked with pencil, and the leather nailed in position by a shoemaker. It can also be inserted under the sole (Fig. 2), by raising the posterior edge of the sole and nailing it again in place.

If there is too much pressure, the leather is pared to the requisite thickness, as indicated by the comfort of the wearer.

The increased depth, at the point where the leather is inserted, raises the sole over this area and slightly beyond, whenever the patient steps — this in turn supporting the anterior arch.

Experiments have also been made with the leather and rubber buttons (Fig. 4) which are manufactured for use upon the bottoms of chair legs. While they answer the purpose when screwed to the bottom of the shoe, they are not so firm, and distributing the pressure over a smaller area, are less comfortable than the leather

tongue. However, they will be found useful occasionally, as they can be fitted in the office by the same methods as the leather tongue, and fixed in place immediately upon any thick-soled shoe. It is always necessary to shorten the screws somewhat, in order not to perforate the bottom of the boot. It is also possible to pare them down after they are in position, until the pressure exerted is acceptable to the patient. Still another means of accomplishing the same result, and one which is especially applicable to shoes which are to withstand severe wear, is shown in Fig. 3. The leather strip raises all the metacarpals slightly, and, at the same time, by varying the angle at which it is placed on the shoe, it may be made to aid in raising the inner side of a pronated foot. In mild cases this works exceedingly well. The proper slant and thickness are adjusted to the comfort of the patients as they stand upon the leather strip. Naturally, suitable exercises should be carried out in every case.

Suffering from metatarsalgia I have tested these different methods upon myself, with relief, and, therefore, feel that I can recommend them from personal experience. They are not advocated for all types; but it is possible by these means to give relief to many at a moderate cost, who would find the purchase of new shoes, plates and pads a strain upon their small financial resources.

Boston City Hospital.

CLINICAL MEETING, JAN. 11, 1906.

Dr. HENRY JACKSON, chairman; Dr. L. R. G. CRANDON, secretary.

DISLOCATION OF SHOULDER WITH CONTUSION OF BRACHIAL PLEXUS

By L. R. G. CRANDON, M.D.

A MAN of fifty-four years fell sideways to the ground, striking on his right elbow. He came to the hospital complaining of the usual disability of shoulder dislocation, together with numbness of the hand and fingers.

Examination showed a subcoracoid dislocation of the right shoulder with paresis and numbness of right hand.

The shoulder was easily reduced by the Kocher method at the first attempt. The evidence of nerve injury continued, namely, wrist drop, entire loss of all finger motions, anesthesia over the whole "glove" area, and partial anesthesia over front and back of forearm and of anterior aspect of arm.

Diagnosis: Contusion of part of brachial plexus.

At the end of one month, having received electricity and massage, condition is considerably improved, but the power of the hand is far from being normal.

This case has great medico-legal value, in my opinion, since if a careful physical examination at the time of entrance had not been made it might have been concluded, to the detriment of the operator, that the manipulations of reduction had caused the nerve injury.

FIBROIDS AND PREGNANCY, EXTRA- AND INTRA-UTERINE PREGNANCY

By ERNEST B. YOUNG, M.D.

I. A case in which delivery by version, on account of eclampsia, was obstructed by multiple fibroids. The mother recovered, although there was some disturbance of the circulation of the tumors, and the premature child survived.

II. Specimens from a case of coincident extra- and intra-uterine pregnancy. The extra-uterine pregnancy ruptured and patient was operated upon for relief of hemorrhage. Pregnancy advanced to about the sixth week.

A TUMOR OF THE KIDNEY SHOWN BY MICROSCOPIC EXAMINATION TO BE HYPERNEPHROMA

By J. C. HERRARD, M.D.

W. G., male, fifty-six years old; married.

Family History.—Father died of old age at eighty-four. Mother at fifty-five from some injury to her side. Two sisters at about thirty-five who had both been sick about two years. One sister and three brothers alive and well.

Previous history.—Patient, when young was not considered healthy but was always, nevertheless, able to do hard work. Has had no sickness of any consequence or venereal disease. For a period previous to nine years ago was at intervals a hard drinker.

Present illness.—Two years ago last April was seized with a sudden pain in right side severe enough to double him up. The attack was followed immediately by blood in the urine. From this time has had attacks of bloody urine at intervals. At first every four or five weeks but steadily growing more frequent. Sometimes they were accompanied by pain sometimes not. At first the blood lasted for a day or two. With the succeeding attacks it lasted longer and longer, a week at a time. Has had at times difficulty in passing urine from clogging of the urethra with blood clots. There has been no expedient loss of weight noticed. Feels somewhat weaker than usual.

Physical examination.—Well developed and nourished man. Radial artery somewhat hard but the pulse tension not high. An enlarged lymph gland in right axilla, otherwise no increase in the size of the superficial glands. Chest negative. Liver dullness extended from the fourth space in the mammary line to two fingers' breadth below the rib margin. Its edge was plainly palpable, not irregular. Spleen and left kidney not palpable. Hemoglobin 90%. In the region of the right kidney there was a firm, evenly rounded tumor, moving with respiration independently of the liver. Feels similar to the kidney in shape but larger. Not tender. No other tumor masses felt in the abdomen.

Urine passed immediately after the examination was almost pure blood. That examined several days later was as follows: Acid, color normal, 1018 albumin large trace to 1-10%, sugar absent. Microscopic examination of the sediment: Much blood, normal or only slightly abnormal, few leucocytes, many round cells slightly larger than leucocytes, many with several nuclei of fat drops, no crystals or casts.

Operation.—Lith.

Patient was placed on left side on pillow. The incision ran from the outer part of the twelfth rib parallel to the spine down to the crest of the ilium. The peritoneal fat, which was of small amount, was opened, and the kidney freed with the hand. There were a number of adhesions which were broken by the hand. The hemorrhage was very free but it never

became alarming. The ureter was divided between clamps and its end touched with carbolic acid and alcohol. Several of the more firm adhesions, one of which it seemed on the chances should contain the vessels, were divided between clamps. The vessels were, however, not seen. After the tumor was entirely free it was so large that the incision had to be enlarged along the crest of the ilium before it could be delivered. Only after careful search on the tumor were the ends of the divided vessels found. There was practically no bleeding from the wound in the loin from which the tumor had come, although the renal vessels had not been tied or clamped. After searching here and comparing the position of the divided vessels on the tumor with the place where they should be in the wound a small vein was found which was ligated. Nothing was found to correspond to the renal artery. The wound was closed in layers leaving a small gauze wick to the bottom of the cavity.

By afternoon of the same day the dressings had soaked through and were changed. The gauze wick was removed after twenty-four hours and provisional stitches tied. The convalescence was uneventful and the patient was out of bed on the sixteenth day, the wound having healed by first intention.

The tumor weighed 2 lb. and on microscopic examination was found to be a hypernephroma. At one end of the tumor there was some kidney tissue and it was to this portion that the greatly atrophied vessels went.

PROSTATIC HYPERTROPHY, PERINEAL PROSTATECTOMY. RECOVERY. IMMEDIATE RESULT CURE.

BY F. S. WATSON, M.D.

This patient is shown principally to illustrate two things, the first being the admirable result of an operation rendered grave by virtue of the patient's previous condition, and the other being the necessity which the surgeon labors under, of being forced by the circumstances of the patient's and his surroundings to perform a radical operation in spite of its being contra-indicated from the surgical point of view. With respect to the latter, the patient's conditions of life, his lack of intelligence, and unsteadiness of hand made it impossible for the man to employ a catheter treatment without involving greater danger to life, though, perhaps, not such immediate danger than was, I believed, to be encountered by subjecting him to the removal of his prostate, which gland was the source of his suffering and played a large part in promoting the steady decline of his health. The event has justified that opinion.

With respect to the nature of the surgical contra-indications, they were as follows: Marked senile debility; the patient was so weak that he tottered as he walked, and a heart which suggested that it was very liable to stop at any time under the influence of but a slight cause of any kind. The pulse was weak and intermittent, and became very irregular whenever he sat up in bed, and the heart sounds were very feeble. He had also a chronic bronchitis and lungs which invited post-operative complications, which is one of the four most frequent causes of death in connection with operations requiring anesthesia. The single encouraging feature was the fact that the urine was clear and showed no evidence of serious functional disability of the kidneys.

In connection with this case I would call attention once more to the fact which is very difficult

to impress upon the profession, viz., that operative treatment of prostatic hypertrophy is less dangerous than the catheter treatment, if only we can apply it before the patients have been made septic by the catheter or their kidneys injured by long delay in applying the surgical remedy.

The relief afforded to this patient whose sufferings were severe and increasing has been complete. He has entire control of the bladder. The urine is clear and there is but one half an ounce of residual urine. In short, the immediate result of the operation is cure in the strictest sense of the word. It is very rare that we find in our experience of these operations, that the patient, who obtains such a successful result as this one has done at the beginning, fails to maintain the same excellence of condition thereafter.

PYOPNEUMO-THORAX. OPERATION, OPENING INTO THE PLEURAL CAVITY THROUGH AN INTERCOSTAL SPACE, DONE TO AVERT IMMINENT DANGER ARISING FROM INCREASINGLY GREAT PRESSURE OF AIR WITHIN THE PLEURAL CAVITY UPON THE HEART, AND THE SERIOUS DISPLACEMENT OF THE LATTER ORGAN THEREBY, AND FOR THE RELIEF OF DISTRESSING DYSPNEA FROM WHICH THE PATIENT WAS SUFFERING. IMMEDIATE RELIEF OF THE LATTER SYMPTOM AND DANGER AVERTED FROM THE CONDITION PER SE.

This patient is shown in order to illustrate the benefit that may be gained from the above operation in these most distressing conditions. And to serve as an example demonstrating the ability to gain this relief by surgical intervention, contrary to the established tradition and practice in these cases. The operation is one that it is just as rational, it seems to me, to perform for the purpose of allowing the escape of intra-thoracic pressure from air as is that of opening the chest wall for the purpose of relieving the same pressure when it is due to collection of fluid.

GENERAL PURULENT PERITONITIS WITHOUT OBVIOUS CAUSE; SECONDARY ENTEROSTOMY.

BY DAVID D. SCANNELL, M.D.

From the service of Dr. H. W. Cushing. Female, aged twenty; six days before entrance, general abdominal pain associated with chill, nausea, vomiting and constipation; gradual localization of most acute pain in right lower quadrant; more or less continual vomiting, fever and complete cessation of bowel movements for three days prior to admission. On entrance, facies was strongly suggestive of general peritonitis. Temperature, 102; pulse, 136; of fair volume and tension. Abdomen, slightly distended, with dullness in flanks, general involuntary spasm with tenderness most marked over appendix region. Vaginal examination, negative. Operation by Dr. Monks: Right rectus incision; immediate escape of large amount of highly turbid fluid, coming from all parts of the general cavity; appendix injected, but apparently not the cause of the peritonitis; careful examination of the other common sources of peritonitis, viz., tubes, perforated gut or stomach, gall bladder, etc., failed to show the cause. Abdomen washed out with many quarts of salt solution and drained. After this operation progressive

change for the worse with incessant and exhausting vomiting of greenish watery fluid; complete stoppage of bowels, marked abdominal distension, producing embarrassed respiration, rising and occasionally intermittent pulse and marked restlessness. The patient seemed to be going the way of most cases of general peritonitis in the adult. Fifty-two hours after the first operation, an enterostomy was done by Dr. Scannell under 1% cocaine anesthesia, the incision being made in the median line just below the umbilicus; light adhesions were everywhere present; these were easily broken up by the finger and the force of the irrigating fluid; a loop of ileum was then brought up. Practically nothing was given by mouth for five days; bowels moved by enemata and calomel on the third day and after; practically no post-operative nausea or vomiting; no distension.

(Case shown at meeting fourteen days after operation.)

GENERAL PURULENT PERITONITIS WITHOUT OBVIOUS CAUSE.

BY DAVID D. McANNEEL, M.D.

From the service of Dr. W. P. Bolles. Female, aged seventeen. Negative past history; twenty-four hours before admission, acute general abdominal pain associated with nausea, vomiting and constipation; gradual localization in right lower quadrant. At entrance relevant physical examination was as follows: Pulse, 100; of good volume and tension; temperature, 101; facies not peritonitic; tongue coated; abdomen not distended; moderate general involuntary spasm, most marked in lower half of abdomen and especially in right lower quadrant; no epigastric spasm; tenderness marked in area corresponding to spasm, with most acute pain over McBurney's point. Graham incision over appendix area; immediate escape of fairly thick pus; no adhesions; appendix practically normal except for deep injection of serosa, removed, however; intestines everywhere distended; peritoneum throughout deeply injected, and more or less irregularly covered with plaques of thick fibrin; careful exploration of small gut from ileo-cecal valve up to the beginning of the jejunum, this being facilitated by a second median incision from above the umbilicus down to pubes; gut at no point collapsed, or showing evidence of ulcerative enteric conditions; pelvic organs, normal; stomach contained a small amount of fluid with no obvious point of perforation, kidneys normal to palpation. The patient's condition not justifying further search, the general cavity was washed out with twelve to fourteen quarts of salt solution, with careful sponging of ileum (which showed the most evidence of peritoneal injection) in particular. Median incision closed, and wicks placed in pelvic, subcostal, umbilical and subhepatic regions through the appendix wound; sutured to the abdominal wall, and immediately opened; escape of large amount of gas and greenish watery feces, the patient was turned on the side and the inside of the gut in both directions was washed out with salt solution. At the conclusion of this procedure, the patient's condition was certainly no worse than before. Subsequently, the fecal discharge through the enterostomy became profuse, the distension gradually went down, relieving the respiration, the vomiting ceased and there was a return of the pulse and temperature to the normal, in five days practically all danger was past. During these five days the patient was given, once daily, sub-mucous injections of one quart of 1:50,000 adrenalin chloride in salt solution, always with marked benefit. The enterostomy closed spontaneously about one month.

(Case shown ten months after operation.)

LACERATED WOUND OF FOOT; GAS BACILLUS INFECTION.

SERVICE of Dr. W. P. Bolles, M.D. Male, aged forty-five; laborer; two weeks before entrance, patient sustained severe crush as to left foot in cogs of donkey-engine. On admission to Relief Station, patient presented an extensively lacerated wound, extending transversely across the entire dorsum of left foot at the metatarsophalangeal level, through the extensor tendons, and accompanied by fractures of the second, third and fourth metatarsals near their heads, the little toe being completely crushed. Under ether, parts thoroughly cleaned; little toe amputated; wound loosely sutured, after reduction of metatarsal fractures. Twenty-four hours later, local evidence of infection by bacillus aerogenes capsulatus; crepitation in soft parts; rapid sloughing of tissues; slightly foul odor to discharge; cultures taken at this time showed the presence of the gas bacillus; temperature and pulse both slightly elevated; almost no constitutional reaction; local swelling confined to dorsum of foot; no lymphangitis nor inguino-femoral lymphoditis. Treatment consisted in chlorinated soda soaks and dressings. On fourth day normal pulse and temperature, and disappearance of crepitation.

(Case shown two weeks after injury.)

ADENOCARCINOMA OF THE SIGMOID FLEXURE.

BY E. B. RICE, M.D.

Mrs. M. C., forty-two years old, and the mother of twelve children, was seen on Sept. 6, 1901. She had had severe constipation about three months, and had not had a satisfactory movement during that time. For two weeks before I saw her she had had no movement of the bowels. Her abdomen was abnormally distended, but she was otherwise in good general condition. Vaginal and rectal examination negative. She was taken to the Boothby Hospital on Sept. 8. A median incision showed enormous distension of both large and small intestines. There was an annular carcinoma of the sigmoid flexure, which was brought outside the abdomen through the lower angle of the median laparotomy wound, the wound being sewed together above it and the intestine and mesentery sutured so as to form a spur. An incision was made in the intestine just above the stricture, and an enormous amount of feces allowed to escape. It was found on opening the abdomen that the sigmoid was twisted around itself, forming a volvulus, which accounted for the complete obstruction which had existed for two weeks previous. A large glass tube was tied in the opening in the large intestine and attached to a bottle at the side of the bed. There was a profuse discharge of feces through the tube, which was left in two days. Mrs. Connor made a good convalescence, but it was complicated by a phlebitis. Her pulse remained rather poor, and it was thought wiser to amputate the carcinoma and apply guarded clamps to cut through the partition between the adjacent loops of intestine rather than to do a formal intestinal resection. This operation was done about three weeks after the primary operation, under local anesthesia. The first application of the clamps did not make a large enough opening, and a second subsequent application had to be made. The patient left the hospital in about two weeks after the first operation, still having a free intestinal opening, although a large part of the feces came through the phlebotomy. When she was in the hospital she had two gastrostomies, as the tubes were clogged with feces, after separating the intestines from these adhesions to the abdominal wall. These attempts were successful.

In December, 1903, she reported that she was in good general condition; had gained in weight, strength and color; still had some swelling of the feet, and a good portion of the feces came through the fistula.

During the winter of 1903-04 the fistula closed. When seen by the writer in the fall of 1904 she had gained about forty pounds, was in excellent health and doing her housework.

During the summer of 1905 the fistula reopened, and the partition grew up so that all the feces came out upon the abdominal wall. There was also a recurrence of the tumor, in the skin of the abdominal wall so that the fistulous opening was surrounded by an area of thick, rough tumor tissue. She was in good general condition, and it was evidently necessary to get rid of the tumor and, at the same time, close the fistula; therefore, on Dec. 28, the fistula and the tumor were encircled by an elliptical incision, the peritoneal cavity opened, the sigmoid flexure with the tumor drawn out, and the mass resected. There was hardly any recurrence of the tumor in the intestine, but it was practically confined to the skin around the opening. The mesentery was quite thick and well provided with blood vessels. The intestine was united by end-to-end sutures after the method of Connell, and the abdomen closed without drainage. Mrs. Connors had made an excellent recovery, and now you can see that the skin of the abdominal wall is healthy, and the bowels are moving the right way without difficulty.

The case is of interest on account of the employment of the clamp method to restore the continuity of the intestinal canal at the time the patient was too weak to stand a formal resection. She was in good health and fairly comfortable for two years after the removal of the tumor and the application of the clamps; then, when recurrence having taken place, resection became imperative, she was in good condition to bear the operation. She is now in good health, and if we may judge by the way the tumor has acted previously, will probably be free from recurrence for a long time. Of interest also in this case is the fact that recurrence took place in the skin of the abdominal wall.

Adenocarcinoma is not to be compared in malignancy with the ordinary carcinoma of the intestine and it is fortunate that we occasionally meet these cases which are so much more encouraging than the everyday cases of intestinal carcinoma.

Dr. Lund also showed a specimen of SARCOMA OF THE FEMUR for which hip joint amputation had been performed, the iliac artery having been controlled by digital pressure through an abdominal incision. The tumor had resulted in a spontaneous fracture of the bone. In connection with this was shown a drawing of a specimen removed at autopsy from a case of spontaneous fracture of the femur in an old woman. The specimen showed a fracture resulting from an invasion of the femur by carcinoma secondary to carcinoma of the breast.

GOULT.

BY GEORGE B. SHATTUCK, M. D.

F. N., teamster, forty-nine years old; widower.

Family history: Maternal grandmother has had attacks of rheumatism distorting the hands. Mother

has had rheumatic attacks in one finger. Brother has had attacks similar to those of patient in hands. No tophi.

Past history: Gonorrhea in 1878; several attacks since. Chancroid in 1897. More or less steadily alcoholic, occasionally to excess. First attack of present complaint was twelve years ago, when metatarsophalangeal joint of great toe became affected, red, hot, swollen and tender. Had several attacks from 1894 until 1898, since which time there are fourteen records of entry in the hospital. Patient places number of attacks at from twenty-five to thirty-five. At first entry there is mention of "opaque, pin-head size swellings on both ears." No further record of tophi until 1903, when the diagnosis of gout was made.

Present illness: Has had two attacks in 1905, the first beginning Nov. 28, when the joints involved were the tarso-metatarsal of right foot and the right wrist and left ankle. The second attack began Dec. 25. Joints involved in the acute process were the terminal joints of left little and right forefinger. According to records, joints which have suffered most have been the second and third joints of all fingers except thumbs, the right wrist and the second joint of the left great toe. Practically all joints, except hips, have been affected at one time or another in a poly-articular process. Patient states that tophi on the ears grow to size of rice grains, the skin over them becomes abraded and he picks them off. He never has had any discharge from toes or fingers.

Physical examination: There is slight radial sclerosis. Heart is negative. Aortic second slightly accentuated. Small urethral fistula exists beneath the glans near the corona.

Fingers: Terminal joints of all fingers on both hands show limited motion with atrophy of tissue around joints: some swelling of joints (terminal) of third right and little fingers. Second joints of left hand show like process with fusiform swellings on second and third fingers. Thumbs exempt. Toes: Ankylosis of second joint of great toe over which the skin is smooth. Wrist: Right somewhat thickened. No crepitus in any finger made out.

X-ray plates show left hand second joints, middle, ring and little fingers, with loss of joint surface; loss of bone on proximal phalanges; second joint of thumb similar; right, fusion of bones of carpus.

Feet: Destruction of joint surface of terminal joints two great toes.

Urine: Volumetric analyses, Jan. 14, 1906, no symptoms.

Amount in twenty-four hours, 2,420 cc.; acid; specific gravity, 1.0085; indoxyl sedim.; albumin, S. P. T.; sugar, 0; bile, 0; total solids, 47.31 gr.; urea, 15%, 27.225 gr.; uric acid, 0.2134 g.; chlorine, 6.84 gr.; phosphates (as P_2O_5), 1.089 gr.

Jan. 15, 1906. Amount in twenty-four hours, 2,560 cc.; specific gravity, 1.009; alkaline; albumin, S. P. T.; Indoxyl, diminished; sugar, 0; bile, 0; total solids, 52.99 gr.; ureas, 13%, 28.8 gr.; uric acid, 0.0752 gr.; chlorine, 6.29; phosphates (as P_2O_5), 1.72 gr.

Treatment: Patient has responded to ordinary anti-rheumatic treatment. During 1903 was given wine of colchicum also with salicylates.

Up to 1897 there are only eleven cases of gout catalogued in the medical index of this hospital. The interest lies largely in the differential diagnosis, and especially from arthritis deformans.

Dr. E. A. Loeke showed some admirable x-ray photographs of gouty and rheumatic conditions borrowed from Dr. R. B. Osgood.

EXOSTOSES.

BY GEORGE B. BRATTICE, M.D.

J. C., thirty-five years old; single, laborer.

Negative family history. Past history: Rheumatic fever in 1895, which kept patient in bed three months. Gonorrhea ten or twelve years ago; no connection with rheumatic attack made out; no specific history; four loaves, two whiskies and six cups of coffee daily.

Present illness: Admitted with acute articular rheumatism affecting both knees, both ankles and right shoulder, which showed tenderness, but no heat or swelling. Responded readily to ordinary rheumatic treatment. Patient states that condition of what he calls "double joints" has always been present.

Physical examination: Shows bone peculiarities as follows: Large exostosis over left internal tuberosity of tibia; enlargement of head of left fibula; enlargement of both left malleoli; exostosis size of walnut on left antero-internal aspect of femur two inches above the knee; smaller exostosis on outer aspect at same level; right tibia, large exostosis of internal tuberosity; large exostosis in popliteal space; external condyle of femur shows small tuberosity; spur on the right humerus three quarters of an inch long on anterior surface at lower edge of pectoralis major; large exostosis of crest of ilium on the left; old fracture of the right ulna.

Diagnosis. Multiple osteo-chondromata of developmental origin, arising from epiphyseal line.

Medical Progress.

PROGRESS IN PATHOLOGY.

BY JOSEPH H. BRATTICE, M.D., BOSTON.

(Continued from p. 321, No. 12.)

RECENT ADVANCES IN THE BACTERIOLOGY OF TYPHOID FEVER.

As has been stated, Grunberg and Rodly found in 45% of their cases of undoubted typhoid fever a higher agglutination-titer with the paratyphoid bacillus than with the causative micro-organism, the typhoid bacillus. Korte and Steinberg² point out that the results obtained by Grunberg and Rodly are not in accord with those of many investigators. In Stern's clinic no case of typhoid fever has been observed in which paratyphoid bacilli were agglutinated with more highly diluted serum than the typhoid bacillus. They regard the results of Grunberg and Rodly as faulty, and the result of imperfect technique. They assert that for the differential diagnosis between typhoid and paratyphoid, the microscope and not the macroscopic method of performing the Widal test should be employed. With the microscopic method only can the upper limit of agglutinability be accurately determined.

BLOOD-CULTURES IN TYPHOID FEVER.

Coleman and Buxton³ collected 1041 cases of typhoid fever in which blood cultures had been made. The bacillus was isolated in 453, or 75% of the cases. During the first week cultures were made in 85 cases, with positive results in 79, or 93%. In one case reported by Raschger

the bacillus was isolated from the blood on the third day of the disease. Busquet isolated the bacillus in every one of the 83 cases he examined. His success is attributed to the fact that he placed in flasks, each containing 300 cc. of bouillon, only a few drops of blood.

Zupnik⁴ states that typhoid serum in some rare cases agglutinates paratyphoid bacilli A and B in the same or higher dilutions than it agglutinates the typhoid bacillus itself. He asserts that the two paratyphoids, on the other hand, never produce sera which have the power of agglutinating typhoid bacilli in as high dilution as it does the homologous race. Hence, a serum that agglutinates, in equal dilution, all three of the species under consideration or two of them must be a typhoid serum.

Duffy⁵ made cultures from the blood in 88 cases of typhoid fever. The blood of 71 cases was examined in the second week of the disease, and found to contain the typhoid bacillus in pure culture in every instance. In 18 cases the diagnosis was made by blood cultures before the Gruber-Widal test was positive. Bacillus fecalis alkaligenes was found in the cultures made late in the disease in a number of cases. The statement that staphylococcus albus was found in the blood must be viewed with suspicion, inasmuch as that organism is a normal inhabitant of the epidermis, as Dr. Welch showed many years ago.

PARATYPHOID INFECTIONS.

von Krehl⁶ recently reported a case of sausage poisoning due to Bacillus paratyphosus B. Several hours after eating the sausages, diarrhea with colic developed. Severe headache, fever and malaise followed. Moderately high remittent fever persisted for eighteen days. The abdomen was distended; the spleen enlarged and readily palpable. There was no leucocytosis. Rose spots did not appear. The urine contained in the beginning of the illness albumin, numerous granular casts and a large amount of indican. From the stools an abundant growth of paratyphoid bacilli of the type B was obtained. At first, the agglutination test of the blood was negative. On the eleventh day of the disease it agglutinated Bacillus paratyphosus B in the dilution of 1:1000. Professor von Krehl attributed the severe symptoms at onset to toxins contained in the sausages. It is possible that the toxins were produced by Bacillus paratyphosus B. This supposition is particularly interesting because it is opposed to the theory of some investigators who do not ascribe to the typhoid bacillus any toxogenic properties.

Calhoun⁷ records seven cases of paratyphus infection due to sausage poisoning, that occurred in the same family and at the same time as the single case studied by von Krehl. In all, the onset was sudden, the fever rapidly increased, there were diarrhea and vomiting, the pulse was

¹ *Med. and Surg.*, 1903, 16, p. 283.² *Proceedings of the New York Pathological Society*, 1904, p. 10.³ *Deutsche med. Woch.*, 1905, xxx, p. 1749.⁴ *Journal of the American Medical Association*, 1905, xiv, p. 1558.⁵ *Deutsche med. Woch.*, Feb. 22, 1906, p. 326.⁶ *Ibid.*, p. 327.

remarkably accelerated. The temperature fell to normal after three days. Twenty-four hours after the onset the spleen was plainly palpable in four cases. The most interesting clinical feature was the appearance of typical roseole in one of the cases. *Bacillus paratyphosus B* was isolated from the stools of every case.

Kayser¹⁵ made a bacteriological investigation of the same paratyphoid house epidemic. The agglutination test with *Bacillus paratyphosus B* was positive in a dilution of 1:1000 in all the cases. Blood cultures were negative. A bacteriological examination of the sausages was made but no paratyphoid bacilli were found.

Lembke¹⁶ observed in Sobernheim and vicinity four cases of paratyphoid fever. Further investigation revealed paratyphoid infection in nine individuals who felt slightly ill for only a few days. The clinical picture in most of the cases resembled influenza rather than typhoid fever. One patient died on the forty-sixth day of the disease from intestinal hemorrhage. The sanitary condition of the village was very bad. It was thought that the disease was spread through contamination of the water in the gutters of the streets, and that the bacilli were brought into the houses on the shoes of the inhabitants.

Schottelius¹⁷ studied an epidemic of paratyphoid B infection which occurred in Freiburg. In ten cases in which the causative organism was isolated from the patients he made agglutination experiments. The microscopic method was employed. In all the cases the maximum agglutination was obtained with the causative micro-organism. In several cases the sera agglutinated B typhosus in a dilution of 1:100 but in one instance in a dilution of 1:1000.

A young man, ill with fever and severe diarrhea, was given an infusion of salt solution in the thigh. At the site of the injection an abscess developed. From the pus Kraneuhl¹⁸ isolated a bacillus which belonged to the hog cholera group. Although it formed acid in milk it was agglutinated by *B. paratyphosus B* serum, dilution 1:38200. The patient's blood agglutinated the paratyphoid bacillus B, dilution 1:640.

Marchoux¹⁹ states that typhoid fever, as it exists in temperate countries, is very rare in Brazil. Paratyphoid infections are common and are usually mild.

A much smaller number of cases of infection with *Bacillus paratyphosus* has been reported than with the other variety of paratyphoid bacillus. So that the recording of an additional case by Kayser²⁰ is of interest: The organism was isolated from the blood and urine. A second case was observed in which the diagnosis could not be made with certainty as all attempts to isolate it were futile, and the diagnosis was

based on the agglutination test alone. The serum agglutinated *B. paratyphosus A* 1:100. The test with type B and the typhoid bacillus was negative.

In the fall of 1905, an epidemic of typhoid fever due to paratyphoid bacillus A occurred in France. The attention of French physicians was called to this by the investigation of Netter and Ribadeau-Dumas.²¹ The clinical picture suggested to Netter the possibility of paratyphoid fever and the diagnosis of paratyphoid infection was made by the agglutination test in 43 out of 58 typhoidal cases. The symptomatology in 18 of the cases differed from that of typhoid fever. Thirty-two of the cases were regarded as instances of infection with *B. paratyphosus A*. Tarehetti²² believes that Eberth's bacillus is simply the colon bacillus attenuated in the human body. By growing a typical colon bacillus in the peritoneal cavity of rabbits he claims to have converted it into a paratyphoid bacillus.

RELATION OF JAUNDICE TO THE AGGLUTINATION REACTION.

Blumenthal²³ does not believe there is any connection between the Widal reaction and icterus. If a serum in high dilution agglutinates Eberth's bacillus it is safe to conclude there is an infection either with *B. typhosus* or a closely related micro-organism. The frequent infection of the biliary passages with the typhoid bacillus explains the apparent association of jaundice and the agglutination test. The bile was examined at the time of operation in 17 cases of cholelithiasis. In 4 cases, no micro-organisms were found. The typhoid bacillus was isolated from 4 cases, and the paratyphoid bacillus type A from one. In 4 of the 5 cases a history of typhoid fever could not be obtained. The blood serum of the cases in which *B. typhosus* or *B. paratyphosus* was not found did not yield a positive agglutination test in a single instance.

Forster and Kayser²⁴ examined bacteriologically the contents of the gall bladder at 148 autopsies. Only 8 had died of typhoid fever. In 2 of the non-typhoidal cases micro-organisms of the typhoid group were found,—in one case *B. typhosus*, in the other *B. paratyphosus B*. The intestinal contents were examined bacteriologically at autopsy in seven cases of typhoid fever. Drigalski-Conradi and Endo agar plates were used. The number of typhoid bacilli was greatest in the upper part of the small intestine and diminished regularly from above downwards.

Netter et Ribadeau-Dumas²⁵ state that in 10 out of 32 cases of infection with the paratyphoid bacillus type A there was pronounced icterus. In 9 other cases the skin was slightly jaundiced.

TYPHOID BACTERIOLYSINS.

Friedberger and Moreschi²⁶ have studied the racial differences of the typhoid bacillus. A

race named Sprung was carefully compared with another strain Giessen. The former was unusually virulent. Even after cultivation for a year upon agar alone it had a constant virulence of 1:20 oese. Culturally and morphologically, it had the typical characteristics of the typhoid bacillus. It was not, however, agglutinated by some typhoid sera of high potency. The agglutinin-absorption experiment as employed by Wassermann was likewise negative, and it could not be identified as a typhoid strain by Pfeiffer's bacteriolytic test. The active immunization of rabbits yielded a positive result. The serum of the immunized animal acquired the property of agglutinating typical typhoid bacilli in high dilutions. It agglutinated the homologous strain Sprung and the heterologous strain Giessen in equally high dilution. The serum had a high bacteriolytic power for Giessen but contained practically no Sprung bacteriolysis. The writers concluded from their study that the conception of Ehrlich and Morgenroth in regard to the receptors must be modified. The observations of Friedberger and Moreschi show that bacteria have two separate groups of receptors. One group forms anti-bodies, the other unites with anti-bodies. By the injection into rabbits of either one of the two strains of typhoid bacilli agglutinins for both strains were produced. These agglutinins are not identical; they differ according to the nature of the race used in producing them. For example, the Sprung agglutinin produced by injecting Giessen is different from the Sprung agglutinin produced by injecting the strain Sprung. Corresponding to the different agglutinins the two bacterial strains have different uniting and forming groups, "*bindende und bildende Gruppen*." The race Giessen had forming and uniting groups for both Giessen and Sprung, while Sprung had forming and uniting groups for Sprung, but for Giessen only forming groups. Hence, although Sprung had no uniting groups for a Giessen lysin it formed in rabbits large amounts of a bacteriolysin for Giessen. The more marked the loss in uniting groups the more difficult is bacteriolysis, and the greater is the virulence. The maximum virulence would be reached in bacterial races that had lost entirely the uniting groups. Whether such a strain of the typhoid bacillus exists is not known. Its specificity could be shown, as it was with Sprung, by its power of producing active immunity against typhoid infection. This it would do by means of its uniting groups. The practical importance of this work is evident. The serum to be used in immunizing men against typhoid fever must be in a high degree active against "*serum test*" races such as type Sprung. Preventive inoculations carried out among soldiers in South Africa by the Pfeiffer-Kolle method were generally successful. They failed in some cases in spite of active immunization against typhoid fever. It is not improbable, as the authors suggest, that these individuals became infected with a strain similar to Sprung, which had few

uniting groups, and those only for the bacteriolysins of the homologous strain.

Besserer and Jaffé²⁷ have discovered strains of typhoid bacilli that are resistant to the action of a bactericidal serum. With these bacilli Pfeiffer's experiment was negative. Strains with this singular characteristic were isolated from the stools of "typhoid-bacillus bearers." This term is applied to individuals whose stools for months or years after recovery from typhoid fever contain the causative micro-organism.

The agglutination tests and cultural properties were those of the typhoid bacillus. It was possible to immunize animals with these organisms against typical strains of typhoid bacilli. The resistance of the races studied is explained by a change in their receptor-apparatus brought about by long residence in the intestines.

Hahn²⁸ under the direction of Stern studied the bactericidal action of human blood serum against the typhoid bacillus. The cases investigated included healthy individuals and those ill with diseases other than typhoid fever. The test tube bactericidal method devised by Stern and Korte was employed. For this test only a small amount of serum is necessary. The article contains a detailed description of the technique. One hundred individuals were examined. In 77% of the cases the bactericidal titer was below 100. In the remainder of the cases he was able to demonstrate some bactericidal power against the typhoid bacillus. The bactericidal action compared with that of typhoid serum was relatively slight. In the non-typhoid cases there was no relation between the height of the bactericidal titer and any definite disease.

Korte and Steinberg²⁹ in the same clinic and employing the same method as Hahn, investigated the bactericidal action of the blood serum of typhoid patients. In 58% of the cases the bactericidal titer was above 100,000, and in only 3% was it below 1,000. In some cases it was above 1,000,000, in two instances 4,000,000. The bactericidal power sinks during convalescence, and after recovery from the disease it is usually low. No relation could be shown between the height of the bactericidal titer and the severity of the infection. Relapses occurred in patients whose blood was strongly bactericidal. The agglutination reaction and the bactericidal reaction are wholly independent. The diagnostic value of the bactericidal reaction is analogous to that of the agglutination test. The higher the bactericidal titer the greater the probability that the infection is due to the typhoid bacillus. As the bactericidal reaction requires greater technical skill and an expenditure of more time than the agglutination test its use in diagnosis will be largely limited to those cases in which the Gruber-Widal test is either negative or doubtful.

Landshammer³⁰ demonstrated the bactericidal properties in 8 out of 12 cases of typhoid fever.

²⁷ *Deutsche med. Woch.*, 1904, No. 51, p. 2034.

²⁸ *Deutsche Arch. für klin. Med.*, 1905, xxxv, p. 293.

²⁹ *Ibid.*, p. 321.

³⁰ *Zeitsch. für klin. Med.*, 1905, lxxi, p. 170.

In 3 cases specific bacteriylins for paratyphoid bacillus B were present, and in each of these paratyphoid bacilli were cultivated from the stool. The serum of one patient from whose blood typhoid bacilli were cultivated was in a high degree bactericidal for paratyphoid bacillus A and only slightly bactericidal for the typhoid bacillus. The bactericidal test makes such demands upon material and time that its practical value, even in hospitals, will be very slight.

A NEW SERUM TEST IN TYPHOID FEVER.

Appiani³¹ has devised a new method of serodiagnosis in typhoid fever, which he regards as more reliable and simpler than the agglutination reaction. It is based upon the precipitating action of typhoid serum upon ground-typhoid bacilli. Several cubic cc. of serum from the suspected case are needed for the test.

THE TECHNIQUE OF THE AGGLUTINATION TEST.

Kapka³² has published from Příbram's clinic in Prague a comparative and critical study of the various methods of performing the agglutination test. The literature has been carefully studied. Most of the methods advocated by different investigators have been tested. The recently discovered fact that clinical typhoid fever may be due to a number of different micro-organisms has renewed interest in the quantitative Gruber-Widal test. In order to make a bacteriological diagnosis it is now necessary to determine the highest agglutination-titer of a whole group of organisms.

METHODS OF DIFFERENTIATING THE TYPHOID BACILLUS AND ALLIED MICRO-ORGANISMS.

Sacquépée and Chevreil³³ found that the salts of various metals added to media produced color reactions which serve to distinguish the typhoid and paratyphoid bacilli.

The Genoa Institute of Hygiene has been testing the v. Drigalski-Conradi method of isolating typhoid bacilli from stools. As a result of this investigation Monti³⁴ states that by this method, even when supplemented by the agglutination test other micro-organisms may be mistaken for typhoid bacilli. On the other hand, negative findings with the v. Drigalski-Conradi test do not positively indicate the absence of typhoid bacilli.

Trapani³⁵ found that after typhoid bacilli were kept for forty-eight hours in tubes containing glycerin, that they lost their power of proliferation, while the growth of the colon and pseudo-typhoid bacilli is not checked by this procedure. Based upon this action of glycerin he has devised a method of differentiating B. typhosus.

Endo³⁶ has introduced a new method for demonstrating typhoid bacilli in the feces. The preparation of the medium is less complicated than that of v. Drigalski-Conradi, and Endo claims it gives equally good results. The essential ingredients of the medium are lactose, fuchsin, and sodium sulphide. These are added to a 3% agar. The colonies of colon bacillus are red, while the typhoid colonies are colorless.

According to Ficker and Hoffmann³⁷ caffeine checks the development of the colon bacillus but does not interfere with the growth of the typhoid bacillus. For the examination of stools 105 cc. of 1.2% caffeine solution were mixed with 100 cc. of bouillon and 1.4 cc. of 0.1% crystal violet solution added. This solution was inoculated with 0.8-0.9 cc. of a suspension of the stool or the stool itself if of thin consistence. After thirteen hours in the incubator v. Drigalski-Conradi plates were inoculated.

Ruata³⁸ has tested Endo's method of differentiating Eberth's bacillus from the colon bacillus and finds that it is not trustworthy. Sometimes both micro-organisms colored the medium red and sometimes both failed to change the color.

Lentz and Tietz³⁹ found that malachite green in a concentration of 1:6000 added to an ordinary 2% agar prevented the development of colon bacilli, while the typhoid bacilli grew luxuriantly. The bacilli grown on this medium were not readily agglutinated. For this reason transplantations were made to v. Drigalski-Conradi plates. The advantage over other differentiating media lies in the fact that typhoid bacilli can be isolated when present in very small number. From a stool containing typhoid bacilli inoculations were made. Only four typhoid colonies developed on the v. Drigalski-Conradi plates, while on the malachite green medium a large number of typhoid colonies appeared.

Klinger⁴⁰ examined the stools of typhoid patients for the typhoid bacillus during the febrile period by three different methods. v. Drigalski-Conradi plates gave a positive result in 35%, Endo's fuchsin plates 55%; malachite green 68%.

Nowack⁴¹ recommends the use of a malachite green medium in cultivating typhoid bacilli from the stools. He found one part of malachite green No. 120 to 2,000 or 2,500 of medium the best for practical purposes. Endo's agar also proved to be a serviceable medium.

After years of experimentation Loeffler⁴² has devised a satisfactory medium for isolating typhoid bacilli from feces, soil and water. Comparative tests have shown its superiority over the v. Drigalski-Conradi agar. The essential ingredient of the new medium is malachite green which checks the growth of colon bacilli without interfering with the typhoid bacillus. Malachite green No. 120 is made by the Höchst Dye Works.

An infusion is prepared by placing four pounds of chopped beef in five liters of water; 750 gm. (15%) of gelatin, and 50 gm. (1%) of Witte's peptone, and 5 gm. (1%) of sodium chloride are added. The whole mixture is slowly heated until the gelatin is completely dissolved, and is then boiled for forty-five minutes. While hot, it is made neutral to litmus with sodium carbonate. After boiling again, it is filtered. A clear golden-yellow gelatin is thus obtained. To every hundred cc. of this medium add three cc. of a double normal phosphoric acid solution, and two cc. of a 2% malachite green solution. A drop of the material to be examined, for example, a typhoid stool, is placed in each of two tubes containing about 20 cc. of this medium. The gelatin should be melted before the inoculation is made. From one of the tubes plate cultures should be made; the second should be placed in the incubator for twelve hours. A series of tubes containing the green gelatin should be inoculated and poured into Petri plates, which should be kept at a temperature of 45° C. Other subcultures may be made from the original tube at the end of eighteen and twenty-four hours. The typhoid colonies appear on the green gelatin plates as bright gray, granular, round or oval colonies, the size of a pin's head. Frequently small projections appear on the surface, giving a characteristic appearance. The colonies are easy to identify.

ISOLATION OF TYPHOID BACILLI FROM DRINKING WATER.

In the spring of 1904, typhoid fever developed in Prague, and within a few days spread over the city. v. Jaksch and Ran² examined the city drinking water for typhoid bacilli, using the method of Hoffmann and Ficker. In three different places typical typhoid micro-organisms were isolated. Six tests were made and three (50%) yielded a positive result.

ISOLATION OF TYPHOID BACILLI FROM MILK.

It is generally known that water is the most frequent source of typhoid infection. Scheller³ has collected statistics from six hundred and thirty-eight typhoid epidemics. In 77% of the cases the infection was conveyed by water. Milk stands in the second place and is responsible for the disease in 17% of the cases. Konrad⁴ investigated the recent epidemic, and succeeded twice in isolating the typhoid bacillus from milk. This observation is of importance because in no previous epidemic has the presence of the typhoid bacillus in the milk been proved, although it is known that many typhoid epidemics originated from an infected milk supply.

Hoffmann⁵ found that typhoid bacilli would live two months in an aquarium. They survived four weeks in the water and eight weeks in the mud which covered the bottom of the bank.

Paladino-Blandini⁶ has isolated bacillus paratyphosus A from water. The action of the typhoid, paratyphoid and colon bacilli was tested on a number of sugars. Inulin was fermented by the paratyphoid bacillus B and the colon bacillus. It was not acted upon by paratyphoid bacillus A or the typhoid bacillus.

THE RELATION OF BACILLUS FAECALIS ALKALIGENES TO TYPHOID FEVER.

Doebert's⁷ investigation seems to show that there is a close relation existing between the typhoid bacillus and *Bacillus faecalis alkaligenes* of Petruschky. He obtained from Petruschky a culture of *Bacillus faecalis alkaligenes*. This organism rendered litmus milk blue in twenty-four hours. A pellicle formed on the surface of the milk. On potato, in twenty-four hours, it produced a yellowish brown growth. This micro-organism had an agglutination titer of 1:800 with typhoid serum. By passing the bacillus through three guinea pigs it acquired all the cultural properties of the true typhoid bacillus. Its growth on potato was now colorless and in twenty-four hours it produced slight reddening of litmus milk. The micro-organism cultivated from the third guinea pig was not agglutinated by the alkaligenes serum 1:100. Typhoid serum agglutinated it in the dilution of 1:15,000. Doebert studied another race of *Bacillus faecalis alkaligenes* which belonged evidently to another group. This bacillus could not be converted into *Bacillus typhosus* by passage through animals. It preserved its own cultural and agglutinative properties.

Altschuler⁸ studied a case with the clinical picture of typhoid fever and from the blood of which *B. typhosus* was isolated in pure culture. The agglutination tests with *B. typhosus* and with the paratyphoid bacillus, type A, were positive in dilutions of 1:250. At the autopsy the typical lesions of typhoid fever were found. Cultures from the spleen yielded a pure growth of *B. faecalis alkaligenes*. Apparently cultures were not made from other organs. A series of experiments convinced the writer that the so-called *B. faecalis alkaligenes* is really a typhoid bacillus that forms alkali in milk instead of the initial production of acid. Typical typhoid bacilli after growing six weeks on bits of human placenta lost their power of agglutination, formed alkali in milk, and produced a yellow growth on potato. In old cultures of *B. faecalis alkaligenes* the micro-organisms were found to have acquired the cultural properties of true typhoid bacilli. They now produced a slight amount of acid in milk, and the growth on potato was colorless. He frequently found *B. faecalis alkaligenes* in the stools of typhoid patients, and once isolated it from the blood. In the feces of seventy healthy persons it was present only once. Thirty strains of typhoid bacilli that had been isolated from the stools of typhoid patients were collected and their action on litmus milk noted. All

redness the milk during the first two days. Five formed alkali after the third day. The remainder were still acid at the end of three weeks. Agglutination tests and Pfeiffer's experiment proved that the alkali producing races were true typhoid bacilli.

The growth of the typhoid bacillus and *Bacillus faecalis alkaligenes* upon 3.3% urine-gelatin inclines Piorkowski⁴⁹ to the view that they are different organisms although closely related.

RELATION OF BACTERIUM FLAVO SEPTICUM TO TYPHOID FEVER.

Brion and Kayser⁵⁰ in a description of the nosological position of the symptom-complex typhoid fever show clearly that under this term are embraced a group of infections due to different organisms. These different diseases cannot be distinguished clinically. They report a case in which the clinical picture corresponded completely to that of a mild typhoid. There was moderate fever, apathy, palpable spleen, ictericuria, leucopenia. From the blood a bacillus was cultivated, which was agglutinated by the patient's serum in a dilution of 1:500. The organism differed markedly from the typhoid bacillus. It liquefied gelatine, and formed yellow colonies. *Bacterium flavo septicum* is the name given to this hitherto undescribed micro-organism.

THE VALUE OF FICKER'S DIAGNOSTIC.

Klemens⁵¹ compared Ficker's typhoid and paratyphoid suspensions with living cultures in testing the power of agglutination. If the time of observation was extended to eighteen hours the results with Ficker's diagnostic fluids was found to be as trustworthy as with living cultures.

THE NATURE OF THE AGGLUTINATION PHENOMENON.

At the time of the discovery of the agglutination reaction by Gruber and Durham it was thought that the clumping of the bacteria was due to the change in the bacterial membrane by which it became sticky so the bacteria adhered one to another. Dineur suggested that the flagella became entangled; Pfeiffer and Kolle held that there was a paralysis of the motile organisms. Recently Zangger and Pauli have studied the phenomena of suspension and their relation to agglutination. Porges⁵² in the Paltauf Sero-therapeutic Institute has made an experimental investigation which supports the theory that there is a relation between the agglutination reaction and the suspension of colloid. They held that the precipitation of a bacterial ingredient is the cause of the bacterial clumping.

Iverson⁵³ has studied the variations in the agglutination phenomenon during the course of typhoid fever in a large series of cases. Every few days he determined in each case the maxi-

mum dilution at which agglutination occurred. In mild infections the agglutination curve rises slowly. At the end of the febrile period or at the beginning of convalescence there is a sharp rise followed by a rapid fall. In the cases in which relapses occurred, the agglutination reaction frequently failed to develop until after the onset of the relapse. The agglutination titer was always higher during the relapse than during the original attack. In some individuals the blood loses its agglutinative power during convalescence; in others it is found to be present after many years. Iverson obtained in one instance a reaction in a dilution of 1:100, ten years after an attack of typhoid fever. Ambulatory cases exhibit chiefly a low atypical agglutination curve.

Reports of Societies.

BOSTON HOMEOPATHIC MEDICAL SOCIETY.

STATED MEETING, THURSDAY, MARCH 1, 1906.

DR. FREDERICK C. SHATTUCK and DR. FREDERICK B. PERCY read papers on

THE VALUE OF DRUGS IN THERAPEUTICS.¹

DISCUSSION.

DR. WALTER WESSELHOEFT: I can only say that I have listened with the greatest interest and closest attention to both the speakers, and I wish especially to thank the first speaker for coming here. I look upon it as a kindness. He comes here to instruct us, to offer us peace and harmony. He has hardly uttered a word with which I do not agree fully. There is but one point upon which I venture to differ, that he excludes from his consideration an infinite number of observations (I will not as yet call them facts), observations which have been placed together and seen to possess one uniting feature, in that a reaction takes place in certain pathological conditions and processes on the administration of certain remedies possessing the peculiar features of the disease itself. These, I say, are observations, observations that are countless to-day and at the same time are only recognized as correct by those who closely pursue them, those who attempt to bring them about and those who attempt to observe them. To those who have been in the habit of observing these reactions they have come to have the aspect of being governed by what we call a law, a law that has its distinct limitations, but is, nevertheless, a law.

The existence of such a law has been practically ignored on the one hand; on the other, it has been seized upon and extended, its phenomena reproduced, under countless varying circumstances, with results that have strengthened the conviction of the existence of these observations as scientific facts. As I said, on the one hand these have been rejected; on the other hand they have been applied in practice.

The lapse of time has tended more and more to separate these two views concerning the existence of what we may call the curative power of drugs, and notwithstanding that there is unquestionably an affiliation or an approach in general practice between these two divergent tendencies, there is yet this wide division of view that can never be reconciled so long as we do not deliberately set about testing these facts under the most rigid, the most scientific and equitable conditions. Otherwise there is no possibility of reaching

any conclusion. We may discuss these things late and early, we may hold to our convictions, and yet, at the same time, we shall never come to an agreement unless we positively abandon all the old facts and deliberately set about to create new ones, and those new ones under rules that shall be recognized as scientific by the entire profession, and that shall govern a method of observation open to every doubter, every believer. I hold that we on the believing side, that of homeopathy, should conduct these observations.

It rests with us to make good our beliefs. I trust the time is not far distant when such observations shall be undertaken and shall lead to positive results.

DR. PACKARD: Mr. President, you have certainly made a mistake in calling upon an obscure surgeon to discuss such a subject. What can I know about drug action? I deal with things more material. I want to say, however, that I would like to extend the right hand of fellowship to Dr. Shattuck. He has spoken words which have sunk very deep in my heart. I would like to move to make him an honorary member of this society.

I am sure that many members of this society would welcome most heartily the breaking down of the barrier that has so long existed preventing affiliation with our colleagues of what is called the "old school." We are all specialists; knowledge of our homeopathic materia medica and the practice of homeopathy is a specialty. We also include within our ranks all of the general specialties in medicine. I think I may safely say that all of our members who are specialists of the latter class would welcome the breaking down of the obnoxious barriers which have so long kept us apart.

Now, a word about Dr. Shattuck's subject, "Drugs and Their Action." Of course I cannot shut my eyes to the fact that sick people want to be treated. They do, and we must recognize that oftentimes the drug has a potent influence psychologically upon the patient, irrespective of what it may do otherwise. Still, now and then impressive things occur. I suppose I do not meet them to any such extent as my colleagues in general practice, but they come to my attention now and then, tributary to my surgical work. I do not know how any one can help marvelling at the influence of sulphide of calcium upon suppuration. I think that it is a remedy which has been somewhat widely adopted by the old school. Another impressive thing is the stimulating effect of fluorine acid upon wounds which have become, as we say, inactive, that is, granulations do not readily and rapidly spring up to effect repair.

I might give you fifty illustrations of this kind as examples of what drugs homeopathically prescribed will do for various complications following surgical operations.

DR. RICE: I wish first to express my personal thanks to Dr. Shattuck for coming here to-night. I wish also to call to the minds of some of you that twenty years ago, at a meeting, I think, of this society, Dr. H. C. Bowditch appeared and gave a talk on drug therapeutics. He was answered by Dr. Conrad Wesselschoff. I remember Dr. Bowditch said a great deal about drug compounds, about the increased efficacy of drugs when combined, and he mentioned a good many compounds consisting of three, four, five and six different drugs.

I noticed to-night that Dr. Shattuck has said little about the drug compounds, but has expressed his belief in the administration of the single remedy when possible. This, I presume, is an evidence of progress. We think so. I believe that the time is fast approaching when we shall be together, when our friends on the other side will believe that there is much in the

efficacy of drugs when given according to the law of similars, and when we shall more universally believe that there is a great deal in serum therapy and in the other remedies which Dr. Shattuck has mentioned here to-night. When this bond of union has been firmly established we can easily put aside the minor considerations and form one vast organization for the support of all that is true and enduring.

DR. J. HERBERT MOORE: Dr. Shattuck has certainly presented this subject of "The Value of Drugs in Therapeutics" in a very refreshing manner, from the physiological standpoint, considering the wave of skepticism and even nihilism, concerning the efficacy of drugs in the treatment of disease, which was spread over the older school of medicine during the past few years.

It seems to me that between the positions taken on the one side by Dr. Shattuck and on the other side by Dr. Percy, lies the line of demarcation or distinction as regards the value of drugs in disease, and differentiating the therapeutic practice characterizing the two schools of medicine. On the one side, that presented by Dr. Shattuck, is the physiological action (used for the want of a better term) of the drug, constituting the more palliative action; and on the other side, presented by Dr. Percy, the specific or curative action of the drug prescribed in accordance with the homeopathic principle of therapeutics.

Those of us who consider homeopathy in the light of an addendum to general medicine, and not a subtraction, acknowledge the efficacy of drugs in producing their physiological results when prescribed for this purpose, and advocate this use of physiological therapeutics whenever it is indicated. In order that you may not accept this statement merely as a personal opinion let us note the opinion of this phase of the question on the other side of the water. To this end I will quote a few extracts from the presidential address of Dr. Peter Procter, president of the Liverpool Branch of the British Homeopathic Society, entitled "The Province of Homeopathy in Medicine," and found in the January number of *The Journal of the British Homeopathic Society*.

DR. PROCTER says: "While homeopathy has its supreme place within its own province, it does not cover the whole domain of medicine, and that outside its special province it must yield to other laws." "We must frankly allow the law of contraries to exist and to be a true law, as is admitted by our late colleague, Dr. R. Hughes, and, indeed, by all liberal-minded men on our side. . . . In short, in any severe organic failure, where relief must be immediate, there is no alternative to the giving of the special physiological stimulant. This rule applies often in cases of aged patients in whom the vital reaction is feeble, and can hardly, at times, be eluded at all. We have in such cases to fall back upon stimuli whose entire physiological action is not absorbed in their therapeutical, but whose physiological action is very much wanted."

"The law of *similia similibus curantur* is perhaps the most comprehensive that has ever been proposed in the whole history of medicine, and it is amazing to see the extent of its usefulness, but that it covers the whole ground is obviously not true. We have for a long period been testing its capacities in every direction, and rightly so, but now I venture to submit some attempt should be made to define its limits."

In the second place, I would point out the obvious fact that the mere universality of any law, whether of physics or physics, affords no guaranty of its scientific sufficiency. Gravitation is probably a universal property of matter, but it is not the only force in the universe. So with homeopathy, true and universal as

it may be, it yet has its range of action, and it is for us to determine its province in the domain of medicine."

When the older school of medicine will recognize and acknowledge the curative action of drugs prescribed in accordance with the homeopathic principle of therapeutics, to the same extent that we acknowledge the more palliative effect of drugs from the physiological therapeutics of the older school, there will be no line dividing us as a profession; and Dr. Shattuck's kindly expressed desire of the necessity, on this ground, of but one state medical society in Massachusetts may be realized.

I know our guest will not consider it discourteous to him if I express disagreement with him concerning a few points which he brought out in his address.

Dr. Shattuck says there are very few specifics in medicine. This I grant to be the case in physiological therapeutics; but when we consider that homeopathic drug prescribing is the giving of a remedy which, by means of its selective or affinitive action which nature has given it, will select out and operate directly upon the same part as the disease and, in accordance with the homeopathic principle of therapeutics, will produce upon that part drug effects which enable and cause the part to throw off the disease, we can appreciate how this direct specific or curative action of drugs characteristic of homeopathy causes these curative remedies to become literal specifics for the various phases of disease against which they are prescribed.

Another point, and as an outcome of this action of remedies, drugs have not lost their pre-eminence in homeopathic therapeutics, which Dr. Shattuck states is the case in the therapeutics of the older school.

I am sincerely glad Dr. Shattuck has brought up the matter of suggestion; but I am sorry that he attributes the success of homeopathic therapeutics to this factor, for such is not the case. I am glad he brought it up, because too much emphasis cannot be placed upon the fact that mental suggestion furnishes the explanation of results obtained by those methods of practice properly belonging to the sphere of psycho-therapy, of which mental healing and Christian science are notable examples.

But when Dr. Shattuck accounts for the curative action of homeopathic remedies through suggestion, he does not recognize the fact that homeopathic remedies act as markedly upon the animal as upon the human; as Dr. Neidhard so convincingly demonstrated by the clinical results obtained with these remedies in the so-called epizo-otic which prostrated so many of the horses in Philadelphia during the early sixties that the fire and other public service, dependent upon them, was seriously crippled; nor does he recognize the curative effect of homeopathic remedies upon infants and the younger children; nor upon adults when circumstances attending their sickness make suggestion impossible of operation; in neither of which cases could such favorable action be properly ascribed to suggestion. On the other hand, and proving the place suggestion occupies in the results obtained by Christian science and all other psychopathic cults, their results are not forthcoming in any cases or under any circumstances where suggestion cannot operate.

I must again differ with Dr. Shattuck in his statement that homeopathy has outlived its usefulness. Those of us who, from our intimate connection with it, know that homeopathy furnishes the most successful therapeutic method of treating disease, and that, too, with specific remedies acting strictly curatively, know also that such a method will continue to live its life of usefulness; and further, we believe it will ultimately be acknowledged by the entire profession to consist essentially of a therapeutic specialty in medicine. As

such, there is no more reason why homeopathy or its practitioners should be discriminated against by the American Medical Association, or its allied state and county societies, than electro-therapeutics or any other specialty now recognized by this national association of the older school.

In closing, I desire to express my personal appreciation to Dr. Shattuck for addressing us this evening, and for extending to us the olive branch. We accept it in the spirit that it is the forerunner of that true affiliation between our two so-called schools of medicine, which can readily be brought about when full fellowship is extended to us, by the older school, which carries with it a recognition of us as physicians who have added to our knowledge and practice of medicine a special knowledge and practice of homeopathic therapeutics.

When Dr. Shattuck closes this discussion, will he kindly tell us whether or no he believes it possible for drugs to cure disease in accordance with the homeopathic principle of drug action; and if so, to what an extent does he believe this to be possible?

DR. RICHARD C. CABOT: I am delighted to add a word to this discussion. I have certainly been very much instructed. I wish a larger number of our school could have been present to see, in the first place, the admirable spirit in which you have received Dr. Shattuck, and to hear what we have heard from Dr. Wesselhoft, Dr. Moore and the others. We need to know more about each other. We need to know more about you; you need to know more about us. I do not believe we differ anywhere nearly as much as we have supposed. I feel sure that when we come together it cannot be by wholly giving up the spirit of either movement. No process of agreement can ever come about in that way. There always has to be maintained something of the spirit of that which was before.

The thing that surprises all of us, I think, who come in contact with homeopathic practitioners, is how little we differ. In the old days I have been told it was a rule that practitioners of our school were not supposed to consult with members of the other school. Following the practice of the illustrious professor of medicine from whom you have heard, I have taken every opportunity of consulting with members of your school. I have never been able to discover the difference between your practice and ours. I recently saw a patient in consultation with Dr. Rockwell, of Cambridge, a member of your school. We agreed entirely as to the diagnosis and treatment, and as a result of that treatment I hear lately that the patient is much improved.

I certainly have very little confidence in most of the electro-therapy of which Dr. Moore has spoken. If the American Medical Association can take in the electro-therapists I cannot imagine why it cannot take in the homeopaths, especially if homeopathy is to be an addition to and not a subtraction from medicine.

We want the truth; you want the truth; none of us wants anything else. On that basis, what can longer keep us from unity? I was delighted to hear what Dr. Wesselhoft said as to the prospect of tests in this matter. That is what we want; tests by representatives of your association and ours, by men of the highest standing, public tests; then we shall be getting evidence appealing to us all, commanding adherence from us all. I hope before many months are past such tests will be under way, and I am sure if any one on our side can help in these tests it will be with the greatest pleasure that we shall do it.

DR. SHATTUCK (in closing): Dr. Moore asked me a question. In that question he used a word which we of the old school do not often use, namely, "cure."

We very seldom cure our patients. Our patients get well — or they don't. The cases in which we can say that we cure are very small in number. Boerhaave's words are true to-day, "I cared for him, God cured him."

Some years ago in Lyons I was making a visit with a physician, and in his delightful French he said: "The physician rarely cures; he often ameliorates, he always consoles."

As far as remedies go I have had the pleasure of seeing several cases with Dr. Moore and he was giving the patients just about what I should have given them and in just about as big doses. He has not called me in in the cases in which a specific is needed.

Several of you have been good enough to speak of my kindness in coming here to-night. I do not look at it in that way. When your president invited me to come I accepted his invitation with alacrity. I thank you for the privilege.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

EIGHTEENTH ANNUAL MEETING HELD IN LOUISVILLE, KY., DEC. 12, 13 AND 14, 1905.

(Continued from No. 12 p. 325.)

GOITRE, WITH A REPORT OF 182 OPERATIONS UPON THE THYROID

DR. CHARLES H. MAYO, of Rochester, Minn., said that surgery of the thyroid was increasing. Operations were as satisfactory as any made, giving relief with brief disability. In fifty years the mortality had fallen from 10% to less than 3%. Kocher's being 2%. Accessory glands, like branchial cysts, were more often found in the lines of hypoblastic involution. The lymphatics served as ducts. Total extirpation was followed by cachexia in from 50% to 70% of cases. Graves' disease was probably due to an over or perverted secretion, the gland showing a general or local condition of cell activity.

The great majority of enlargements in young people responded to medication. Part of the benefit attained in the removal of the sympathetic was from cutting the lymph channels draining the thyroid. During the past seventeen years the Mayos had operated upon 182 thyroids, with 9 deaths. Of these, 57 were cases of well-marked Graves' disease, with seven deaths in all, and but one in the last twenty-three. Of these cases, 50% made an early recovery; 25% did so during several months. The remainder were improved, but had occasional relapses of a temporary nature. Among the remaining 125 operations representing cysts, colloid, parenchymatous and 5 malignant tumors, there were but 2 deaths, one from pneumonia, the other from tracheal collapse on the third day following extirpation of a carcinomatous goitre. Cocaine was used in 13 cases, but ether anesthesia preceded by morphia and atropine was the rule. The head was maintained in the high position. The incision was usually transverse. Parenchymatous enlargements, and some colloid were extirpated; cysts and encapsulated growths were enucleated. Saline solution was freely given after operation.

THE DIAGNOSIS OF RENAL CALCULI

DR. GEY EMMY HENNER, of Baltimore, Md., took up the subject from the general relationships, first considering the various other maladies of the kidney from which nephrolithiasis must be differentiated, and then discussing the diseases of other organs which might

mislead the diagnostician. The Roentgen ray and the wax-tipped bougie were considered invaluable aids in the diagnosis of renal calculus, but they both failed at times, and the importance of the urtic examination in all suspected kidney cases was emphasized. Several cases were reported to illustrate the difficulties of diagnosis.

REQUIREMENTS AND QUALIFICATIONS FOR A SUCCESSFUL CAREER IN SURGERY.

The President, DR. LEWIS C. BOSHER, of Richmond, Va., selected this subject for his address, and said, among other things, to the recent graduate in medicine no department of his chosen profession appealed with the same force as did surgery. While a student he had been impressed by the brilliancy of the results secured by his professors before his very eyes; at the meetings of the Alumni the clinics in surgery were crowded, while those in other branches were usually either simply attended or else attended as a complement to the individual holding them rather than from actual interest in the subject. In most medical colleges the prominence of the professors of surgery in all faculty affairs was well-known; while, considering the more material side of the question, he had little trouble in ascertaining that it was no unusual thing for a surgeon to secure for a single operation, occupying but an hour or two, or even less, a fee greater than the entire collections of the general practitioner for a week's steady work, with broken rest and with cares and responsibilities innumerable. On leaving college, if he entered into hospital service, these facts were impressed on him with even greater force, and later on, having himself entered the ranks of struggling practitioners, the same lessons were borne in upon him with increasing emphasis. Little wonder was it, then, that so many young medical men, bearing all these things in mind, decided that they, too, would enter this alluring field, where they believed they would effect such marvelous results in brilliant cures, in abundant pecuniary reward, in the homage of their fellowmen, and, it moved by even higher motives, in the eternal good they might do to suffering humanity.

Dr. Bosher called attention to the importance of an academic education. Many a man had attained success in surgery without this advantage, but we were dealing with the rule, not the exception. This academic education should be truly liberal, both in quantity and quality, and should include as much as possible of studies of a scientific nature, especially biology, physics and chemistry. Of these three branches, physics would prove of the greatest use to the surgeon, while biology and chemistry were branches of more practical value to the general practitioner.

It was incumbent on our teachers and practitioners of surgery to make it plain to the public that there was no material difference between the trained surgeon and the layman. The latter often would enable the public to discriminate as a whole as a matter and would ultimately have the effect of rendering it apparent to the candidate for surgical practice that he must properly equip himself before he could stand before the world as a representative of the great surgical art.

TRAUMATISM OF THE UTERUS AND PERITONEUM OF THE KIDNEY

DR. RUFUS B. HART, of Chicago, Ill., presented a paper on this subject, to which he reported two cases, and said that the ultimate results were most gratifying, and said that he hoped they might be of sufficient interest to warrant their record in detail. The exact nature of the injury was not determined in either case. The first patient was a girl, a year or less of age, who had

a male, seventeen years of age. In reviewing the history of the first case, he was inclined to believe that there was a free rent either in the pelvis of the kidney or in the ureter.

In the second, there was a narrow opening either in the ureter or the pelvis of the kidney, from which urine leaked very slowly at first. In this case rupture had taken place evidently on Sept. 10. It was more than ten days later before urine was extravasated to make a palpable tumor so that it could be outlined. On Nov. 1, the tumor appeared to be not larger than the boy's head. Both patients were relieved by operation, with drainage.

ANEURYSM TREATED BY SUTURE INSIDE THE SAC.

Dr. F. W. PARHAM, of New Orleans, La., read a paper on this subject in which he reported two cases treated after the method of Matas. One was an idiopathic aneurysm of the popliteal artery; the other, an aneurysm of the second and third portions of the left subclavian. The popliteal aneurysm was treated by suture inside the sac of proximal and distal openings separately, and continuous suture of the groove of the artery intervening. In the subclavian case only the proximal opening was sutured, the distal bleeding being controlled by ligatures. Both patients recovered.

The indications for this procedure were: (1) The practicability of laying open and inspecting the interior of the sac. (2) The possibility of applying a constrictor, clamp, or temporary ligature to the proximal side of the tumor.

In the second case reported, the suture was employed because the proximal ligature failed to stop the bleeding completely.

The operation of suture within the sac was to be preferred to ligature, because, first, every possible bit of artery was saved except that actually forming the sac of the aneurysm. Second, suture accomplished simple approximation of the intima, and did not cut through as might happen with ligature of an atheromatous artery. Third, all collateral bleeding in the sac was stopped by direct suture of the vessel mouths within the sac, and packing of the sac became unnecessary. Fourth, hence there was no disruption of the outside vascular (collateral) connections of the sac wall, already much relieved by the emptying of the sac.

The reconstruction of the artery was to be attempted only in certain cases, as in aortic aneurysm, where suture of the proximal opening would, like ligature, probably be fatal, and in other aneurysms where from swelling and lymphangitis, as in Morris's case, the danger of gangrene was too great to risk any interference with the nutrient stream. In such case reconstruction of the artery might be preferred for two reasons: (1) Because even a temporary continuance of the main stream would be a great advantage until the subsidence of edema consequent upon the evacuation of the sac shall have somewhat relieved the stress upon the collateral vessels; and, (2) because, as remarked by Matas, and shown in Dana's case, it was feasible at a secondary operation to again open the sac and close the arterial opening.

In abdominal aneurysms the method of Matas offered some hope of cure.

VARICOSITY OF THE SAPHENOUS VEINS WITH RESULTING VARICOSE ULCER.

Dr. ROBERT CAROTHERS, of Cincinnati, Ohio, mentioned the operations most commonly employed for the relief of this condition, and among them reference was made to the Schede operation, the Trendelenburg, but, he said, complete excision of the internal saphenous vein was undoubtedly the most satisfactory

operation to be employed; but until the ingenious invention, by Charles H. Mayo, of two instruments which subcutaneously strip the vein, it was an operation requiring a long incision, tedious dissection and considerable time for its performance. This operation, as advised by Dr. Mayo, was, that after making a small incision in the upper third of the thigh over the saphenous vein, the vein was located, tied in two places cut between the ligatures, and the distal end threaded into the enucleator, which was pushed under the skin along the course of the vein for about six to eight inches, where another small opening was made on to the instrument, the vein taken out, then the instrument drawn out from the first opening, rethreading the vein into the instrument, and again pushing it under the skin for another six or eight inches, another small incision on to the instrument allowing the vein to be drawn out, which was again ligated and removed. The lateral branches were torn off, and, as a rule, closed themselves. This operation was very quickly and easily performed, but was not without danger from hemorrhage or sepsis. He has twice done this operation and the immediate results were satisfactory. His cases were too new to say what would be the ultimate result. They were old cases with large troublesome ulcers treated by skin grafting. The patients were able to leave the hospital in less than three weeks, wearing an elastic porous bandage for support, and were now, at the end of about eight weeks, both at work as housewives. In one case in which there was a troublesome eczema, after an effort for one week to relieve the same, he again followed the advice of Dr. Mayo, sealing the eczematous area with compound tincture of benzoin, until the skin wound had healed.

THE DANGERS IN SCOPOLAMIN-MORPHIN ANESTHESIA.

Dr. HORACE J. WHITACRE, of Cincinnati, Ohio, read a paper with this title, in which he based his conclusions upon observations made in forty cases of anesthesia induced by this method, upon animal experimentation, and upon a review of all deaths that have been reported in the literature up to the present time: "(1) Scopolamin-morphin narcosis is not devoid of danger. (2) The use of scopolamin-morphin alone for surgical narcosis is not justifiable, and in my experience is not practicable. (3) A single dose two hours before operation lessens the discomfort attendant upon the operative procedure to a high degree, and may obtain a definite place in surgical practice. (4) Four deaths have occurred in a series of twenty-four hundred collected cases which have been so definitely related to the use of this method of narcosis that they are probably scopolamin deaths, this, however, in the absence of autopsy demonstration. (5) These deaths have been reported as occurring with a type picture of alkaloid poisoning, and heart failure has been given as the direct cause of death. (6) A fatty degeneration of the liver and kidney has been produced by repeated doses of scopolamin alone, and of the scopolamin-morphin combination, in animals. (7) This method of producing or assisting narcosis cannot yet be recommended for use in general practice in spite of the great advantage it seems to offer."

SCOPOLAMIN-MORPHIN-ETHYL CHLORIDE-ETHER ANESTHESIA.

Dr. H. A. ROYSTER, of Raleigh, N. C., said that of all the combinations suggested for aiding and abetting these agents, that which formed the subject of his paper commended itself to him, because he believed, first, that ether was our safest general anesthetic;

second, that ethyl chloride secured the pleasantest primary narcosis; third, that the preliminary use of scopolamin with morphin increased the patient's mental resisting power and lessened the quantity of ether. In his opinion there could be no question of the superiority of ethyl chloride over nitrous oxide gas as a preliminary to ether anesthesia. Its action was more certain and constant and equally agreeable, and he could not help feeling that it was safer. This experience in regard to the combination of morphin and scopolamin was confined solely to the use of those drugs prior to the administration of ether. Of those who had investigated scopolamin, some state that it was isomeric with hyoscin; others that the effect in the combination was due largely to morphin; still others that the drug was dangerous and uncertain in its action. Its most marked effects were in quieting the nerves and fears, the promotion of an easy courage in beginning the anesthetic, and a prolongation of the restful sleep afterwards. Clinical tests had led him to conclude that scopolamin was not identical with hyoscin, and that it did something more than morphin alone, and that it was safe in proper doses.

He sounded a note of warning in regard to the use of scopolamin, inasmuch as several deaths had followed its employment.

OVERLAPPING THE APONEUROSIS IN THE CLOSURE OF WOUNDS OF THE ABDOMINAL WALL.

DR. CHAS. P. NOBLE, of Philadelphia, recommended a method of overlapping the aponeuroses which he had used with the utmost satisfaction for nine years, in the closure of all wounds of the abdominal wall, including the Alexander operation, inguinal and umbilical hernia, diastasis of the recti muscles, appendectomy and nephrorrhaphy. In but a single case did he know of a post-operative hernia where the abdominal wound had been closed by this method. When drainage was employed through the abdominal wound, the method was not applicable. The technique of the operation was illustrated by several drawings which demonstrated the method clearly. He closed his article by describing the methods of overlapping the fasciae employed by Lucas-Championniere and B. Wyllis Andrews in the operation for inguinal hernia.

THE EARLY DIAGNOSIS AND RADICAL CURE OF CARCINOMA OF THE PROSTATE, WITH A REPORT OF FORTY CASES.

DR. HUGH H. YOUNG, of Baltimore, Md., presented these conclusions, which were drawn from this study of forty cases: Carcinoma of the prostate was more frequent than was usually supposed, occurring in about 10% of the cases of prostatic enlargement, as shown by Albarran. It might begin as an isolated nodule in an otherwise benign hypertrophy or a prostatic enlargement which had for many years furnished the symptoms, and signs of benign hypertrophy might suddenly become malignant. Marked induration, if only an intralobular nodule in one or both lobes of the prostate in men past fifty years of age, should be viewed with suspicion, especially if the cystoscope showed little intralobular prostatic outgrowth, and pain and tenderness were present. The posterior surface of the prostate should be exposed as for an ordinary prostatectomy, and if the operator was unable to make a positive diagnosis of malignancy, longitudinal incisions should be made on each side of the urethra, as in prostatectomy, and a piece of tissue excised for frozen sections, which could be prepared in about six minutes and examined by the operator at once. If the disease was malignant, the incisions might be cauterized and closed and the radical operation performed. Cancer of the prostate remained for a long time within the confines of

the lobes, the urethra, bladder and especially the posterior capsule of the prostate resting inviolate for a considerable period. Extraprostatic invasion nearly always occurred, first, along the ejaculatory ducts into the space immediately above the prostate, between the seminal vesicles and the bladder, and beneath the fascia of Denonvilliers. Thence the disease gradually invaded the inferior surface of the trigone and the lymphatics leading toward the lateral walls of the pelvis, but involvement of the pelvic glands occurred late and often with disease metastases into the osseous system without first invading the glands. Cure could be expected only by radical measures, and the routine removal of the seminal vesicles, vasa deferentia and most of the vesical trigone with the entire prostate, as carried out in four cases by the author and fully described by the illustrations, was shown to be necessary by the forty cases, including eight autopsies and ten operations.

The four cases in which the radical operation was done demonstrated its simplicity, effectiveness and the remarkably satisfactory functional results furnished.

(To be continued.)

Recent Literature.

Urinary Analysis and Diagnosis. By LOUIS HEITZMANN, M.D. Second revised and enlarged edition. New York: Wm. Wood & Co. 1906.

The author has evidently spent much time in the preparation of this work and in revising it. The methods given for the analysis of urine are mostly old-time methods and those which are not are without much value. Particular stress is laid upon diagnosis, what we may term "cellular diagnosis." The author makes claims which are far beyond those of any pathologist or other microscopist; for example, he is able to tell by the microscopic appearance of a cell in the urinary sediment whether or not it is a renal cell, and if a renal cell, from which uriniferous tubule of the kidney it comes—convoluted or straight tubule. It is safe to say that such ideas have not been generally accepted. The book has little if any practical value.

The Modern Mastoid Operation. By FREDERICK WHITING, A.M., M.D. Philadelphia, P. Blakiston's Son & Co. 1905.

The complete mastoid operation, as advocated by Whiting, consists mainly in the reflection of large flaps of skin over the process, and secondarily in the ablation of the mastoid, including the cells in the posterior root of the zygoma. The author deems this expedient in all cases, thinking that in this way all danger of recurrence of the disease is prevented.

The subject is treated exhaustively, a separate chapter being devoted to each step of the operation; in addition there are chapters mainly historical, while the pathology of the disease and the post-operative treatment are also considered.

The illustrations are really beautiful, and greatly add to the value of the work.

A Textbook of Physiological Chemistry. By JOHN H. LONG, M.S., Sc.D., Professor of Chemistry in Northwestern University Medical School, Chicago. Philadelphia: P. Blakiston's Son & Co. 1905.

This new contribution to Physiological Chemistry is comprehensive and is a book of 413 pages. The subject matter is divided into four sections as follows: 1. The nutritious and related substances; 2. Ferments and digestive processes; 3. The chemistry of the tissues and secretions of the body; and, 4. The end products of metabolism, excretions and energy balance. Under each section are chapters devoted to the individual subjects. Much attention is given to processes of digestion, to the ferments and to the chemistry of the blood, but comparatively little to the urine. An outline has been given of the chemical phases of the recent theories of immunity, and a short explanation of the important applications of the methods of cryoscopy and electrical conductivity and other physical processes in the field of chemistry related to medicine. A number of illustrative experiments are given in the text, but there are no references to the literature of the various subjects treated. The book is a credit to the author and a thorough, up-to-date textbook.

The Diagnosis of Tuberculosis of the Lung. With Special Reference to the Early Stages. By DR. K. TURBAN, Privy-Councillor of the Grand Duchy of Baden. Director of the Sanatorium at Davos. With an introduction by Sir Dyce-Duckworth, M.D., LL.D., F.R.C.P. Translated by Egbert C. Morland, M.D., B.Sc. (Lond.). pp. 135. New York: William Wood & Co. 1906.

The necessity for early diagnosis in pulmonary tuberculosis is appreciated by no one more than by the director of a sanatorium, for success in treatment is dependent largely upon the early recognition of the pathologic condition. Dr. Turban speaks with the authority born of large experience. He not only emphasizes the importance of early diagnosis, but also describes in minute detail the methods essential to that diagnosis. In this description of pathologic conditions and the physical signs produced by them, Dr. Turban goes far beyond the limits set by the ordinary textbooks. Herein lies the chief value of the book.

A Guide to Anesthetics. For the student and general practitioner. By THOMAS B. LUKE, M.B., F.R.C.S. (Ed.), Instructor in Anesthetics (University Surgical Classes), Royal Infirmary, Anesthetist to the Deaconess Hospital, and the Dental Hospital, Edinburgh. With 45 illustrations. Second edition. Edinburgh and London: William Green & Sons. 1905.

This book is a guide as to how to administer the various anesthetics rather than a statement of how the different anesthetics produce their

therapeutic effects. Ethyl-chloride is, in the author's opinion, the most valuable anesthetic. He believes that it bids fair within a few years to be the most frequently employed anesthetic that we possess. In the summary of the history of anesthetics, on page 6, the statement regarding the administration of ether should read "Dr. Warren operating" rather than "Dr. Collins operating." We are glad to see that Dr. J. Bapst Blake's ether inhaler is recommended by Dr. Luke as the best method of administering ether by the semi-open method. The book is thoroughly practical and is certainly one of the best guides to the use of anesthetics for the student or general practitioner.

Koplik on Diseases of Children. A Treatise on the Diseases of Infancy and Childhood. For Students and Physicians. By HENRY KOPLIK, M.D., Pediatricist to Mt. Sinai Hospital, Ex-President American Pediatric Society, etc., New York. New (2d) edition. Revised and enlarged in text and illustrations. Octavo, 868 pages, 184 engravings and 33 plates. Philadelphia and New York: Lea Brothers & Co. 1905.

This second edition of Koplik's well-known work has been thoroughly revised and enlarged, the text containing nearly 200 more pages. The number of the illustrations has been increased and their character improved. The author's personal views are more evident than in most textbooks. The references to current literature, so valuable in the first edition, have been retained. The work is in every way practical, especial attention being devoted to treatment, which is, on the whole, rational and satisfactory. We are surprised, however, at the low dosage of diphtheria antitoxin recommended. The section on the specific infectious diseases has been much enlarged and that on infant feeding entirely remodelled. This section which was, perhaps, the least satisfactory in the first edition, is now very good. We like very much the way in which the subject is approached, although we cannot agree with all of the author's ideas. This edition is a decided improvement on the first which was, however, itself very satisfactory.

Saunders' Question Compend. Essentials of Materia Medica, Therapeutics and Prescription Writing. By HENRY MORRIS, M.D., College of Physicians, Philadelphia. Seventh edition, thoroughly revised, by W. A. BASTEDO, Ph.G., M.D., Instructor in Materia Medica and Pharmacology at the Columbia University (College of Physicians and Surgeons), New York City. 12mo. 300 pages. Philadelphia and London: W. B. Saunders Co. 1905.

The book is well arranged, in the form of questions and answers, contains, as its name indicates, the essentials of materia medica and therapeutics, and will prove a useful book for student use. In this, its seventh revision, it is brought into accord with the last (1905) Pharmacopœia.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MARCH 29, 1906.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 706 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE, Incorporated,
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

MASSACHUSETTS GENERAL HOSPITAL HOUSE PUPILS' ALUMNI ASSOCIATION.

The first meeting of the Massachusetts General Hospital House Pupils' Alumni Association was held March 21 in Boston. The afternoon was taken up by various clinics and demonstrations at the Massachusetts General Hospital, where an opportunity was given previous house pupils to inspect the improvements, both in accommodations and in technique, which have taken place within the past few years. This meeting was well attended by many former house pupils of the hospital, not only from this neighborhood but also from cities at a distance. In the evening, final organization was effected at a dinner held at the Hotel Vendome at which between one hundred and fifty and two hundred former house pupils and members of the staff of the hospital were present. Dr. E. H. Bradford presided with grace and dignity, and a large number of speeches were made by men long associated with the hospital and conversant with its early history.

The first speaker was Dr. James C. White who was elected president of the Association. Dr. White spoke in a reminiscent vein of conditions at the hospital in the middle of the last century, and of the achievement of the past and the possibilities of the future. Dr. Henry P. Walcott, chairman of the Board of Trustees of the hospital, assured the assemblage that in spite of the great changes which had taken place within the last fifty years even more would occur during the succeeding half century. The means, he affirmed, are already in sight which will render the Massachusetts Hospital stronger than any

other, either old or new, in this community. Dr. Walcott made an appreciative reference to Drs. John C. Warren and James Jackson, founders of the hospital, and alluded to their far-sighted policy in insisting that the hospital was not only for the care of the sick, but also was to be regarded as an indispensable addition to the Medical School. In conclusion he said, "I congratulate you on your auspicious beginning and I know that the end will never come."

Following Dr. Walcott, Dr. L. C. Shattuck spoke for medicine at the hospital. He referred to the fact that the Massachusetts General Hospital was following the example of the Boston City Hospital in forming an alumni association, and put in a plea, tempered with much humor, for a more generous recognition of the claims of medicine as opposed to surgery. Dr. Arthur T. Cabot discussed surgery at the Massachusetts Hospital from the early days down to the present, and urged the members to build up the Treadwell Library at the hospital by sending their various reprints and publications. Dr. C. B. Porter also spoke in a reminiscent vein and described his early efforts toward a more general consideration of the staff in relation to the trustees. Dr. H. P. Howard, resident physician, spoke appreciatively of the conditions as he met them at the hospital when he undertook the superintendency, and expressed the hope that sometime a boulevard would be cut through in such a way that the Bulfinch front of the old hospital building might come again into public view.

Dr. W. S. Thayer of the Johns Hopkins Medical School, who was introduced as "one who had climbed the pinnacle of science," spoke of his perennial pleasure in returning to the Massachusetts Hospital and the inspiration he derived therefrom. Much of his speech was, however, in lighter vein, as was that of John B. Blake who followed him. Dr. George I. Walton, closed the literary portion of the evening with some verses, which added much to the increasing feeling of good humor which was by this time pervading the assemblage. The evening was further enlivened by many admirably rendered songs under the general direction of Dr. H. C. Baldwin.

The beginning of this new association, due largely to the efforts of certain of the younger men, among whom Dr. G. W. W. Brewster and Dr. L. A. Wadleigh, Jr., should be especially mentioned, was certainly as auspicious as Dr. Walcott said and there can be small doubt that it will increase in usefulness and prosperity as time goes

on. The advantages which may develop from such an organization of men who have had their training in one hospital, but who are practising in various localities, cannot be over-estimated.

THE ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION AT BOSTON.

THE next annual meeting of the American Medical Association, as our readers in general already know, is to be held in Boston, from June 4 to June 9 after an interval of forty-one years.

The General Committee of Arrangements with the five sub-committees, again many times subdivided, have already for many weeks been occupied with the preliminary preparations, and matters are now so far advanced that it is possible to give some outline of the probable provision for the entertainment and instruction of the visitors, outside of and apart from the usual routine professional work of the Association for which the various halls in the Back Bay District of the city have been engaged.

At the opening meeting prayer will be offered by the Rev. Edward Everett Hale, and there will be an address of welcome by President Eliot, in addition to short addresses by the president and president-elect of the Association, by the president of the Massachusetts Medical Society, the Governor of the Commonwealth, and it is hoped the Mayor of the city.

Harvard University has given permission to use the new Medical School buildings, and it is proposed to have three afternoon teas from 4 to 7 o'clock with music in the quadrangle and on the terraces of those buildings. These teas will be conducted by the ladies connected with and under the direction of the Committee on Entertainments. One evening will be devoted to a reception given to the president of the Association by the profession of New England. One evening there will be a special concert at Symphony Hall, and special facilities will be offered for the theatres. There will probably be a reception, with music, by the city in the fine building of the Public Library, and one by the trustees at the Art Museum. Harvard College and Cambridge are easily reached and will be at their best at that season.

It will be the aim of the appropriate committee to facilitate excursions to historic places, such as Plymouth, Lexington and Concord, to the attractive suburbs of Boston, and to points on the seashore. For those who desire that pleasant

experience, a Rhode Island elmbake may be made possible and, in combination with this or apart from it, a visit to Newport might be secured.

As relaxation for the serious laborers in the medical vineyard there will be the different hospitals and clinics, a scientific exhibit, clinical exhibits and a commercial exhibit. The commercial and educational exhibits will be held in Mechanic Building. The committee on the commercial exhibit states that it intends to have the exhibit excel in quality rather than in size. With this end in view such firms only will be invited to exhibit as have been passed upon by the committee, and any others asking for space will be subjected to a like inquiry. Drug firms showing their goods here will thereby be recognized by those in charge as reliable. There will also be a show of motor cars.

The following are the hotels selected for headquarters: The Vendome, for the general officers; the Brunswick, for the section of surgery; the Copley Square for the section of obstetrics and gynecology, and for the section of pathology and physiology; the Lenox, for the section of ophthalmology; the Nottingham, for the section of diseases of children, as well as for the section of cutaneous medicine and surgery; the Oxford, for the section of pharmacology; the Somerset, for the section of medicine; the Thorndike, for the section of hygiene and sanitary science, and for the section of laryngology and otology; the Touraine, for the section of nervous and mental diseases; the Westminster, for the section of stomatology.

The War Department has agreed to send on an army field-hospital, which will be conveniently placed for the study and inspection of visitors. The Navy Department will send some representative vessels ranging from the most modern battleship, down through the armored cruiser to the torpedo boat destroyer. These will lie at the Charlestown Navy Yard, where the visitor may see the great new dry dock, and then revert to an earlier period of our history by walking the deck of the "Constitution" (Old Ironsides) and climbing the monument on top of Bunker Hill. He will naturally have previously been to the Old South Church of Revolutionary tea-party fame, and to the Old State House where the Lion and the Unicorn are still rampant.

Perhaps after this our industrious visitor will feel inclined at the end of the week for a few quiet days off at the shores and lakes of Maine, or amid the hills of New Hampshire or Vermont. However this may be, it will be the aim of the

committee on transportation to make his arrival devoid of friction and to smooth his departure, if go he must, wherever possible.

A MEDICAL AND HISTORICAL GUIDE BOOK OF BOSTON.

THE Committee of Arrangements for the coming meeting of the American Medical Association, have had prepared a Medical and Historical Guide Book of Boston, which is to be presented to each visiting member of the Association. The work has been in the hands of one of the sub-committees who have given much time and thought to the undertaking.

Matters of past and present medical interest, and the various medical institutions are to be included, thus making the book appropriate for this gathering.

In addition to these special features, an adequate and satisfactory guide to the city of to-day will be furnished.

The maps are to be modern and the illustrations both copious and attractive.

ANATOMY IN AMERICA.

A RECENT copy of the *Bulletin* of the University of Wisconsin is devoted to a discussion of anatomy in America from the pen of Dr C. R. Bardeen, professor in the University. Dr Bardeen's effort has been to gather together in comparatively small compass a history of the development of the study of anatomy in this country with a list of the more important investigations and a description of the present status of this branch of medical science. The subject is regarded from the broad general standpoint which has been rather slow of growth in this country, and considers anatomy from the developmental and biological standpoints as well as on the purely descriptive side. It is, in fact, only within recent years that contributions of significance in the anatomical sciences have appeared in America. There is every evidence, however, that this period of unproductiveness is past and that anatomy hereafter will be cultivated with vigor and enthusiasm by men whose time is not distracted by the exigencies of medical practice. Following the general description of the subject, Dr Bardeen discusses at considerable length the position of anatomy in other countries, the work done at individual medical schools, care of anatomical material, endowments, salaries, and various other matters of interest primarily to the anatomist, and secondarily to the profession at

large. Dr. Bardeen has certainly rendered a definite service to the gradual growth of medical history in this country by adding this admirably prepared account of one of the fundamental branches of medicine.

MEDICAL NOTES

YELLOW FEVER ON THE Isthmus of PANAMA.

— It is reported that a case of yellow fever has appeared at Bocas del Toro on the Isthmus and that a conference will forthwith be held to provide for the most efficient means of eradicating the disease there.

THE BOSTON MEETING OF THE AMERICAN MEDICAL ASSOCIATION. — In its discussion of rates to Boston we notice the *California State Journal of Medicine* says: "The prospect of securing this concession seems good, but even if it cannot be arranged, the one-fare rate, plus the local fare from Boston to New Haven, will be very much less than the regular rates which heretofore we have been compelled to pay. It is to be hoped that a large number of our physicians will take advantage of this opportunity to attend what will undoubtedly be the biggest meeting the Association has ever held."

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. —

For the week ending at noon, March 28, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 31, scarlatina 31, typhoid fever 1, measles 102, tuberculosis 30, smallpox 0.

The death-rate of the reported deaths for the week ending March 28, 1906, was 21.12.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, March 24, 1906, was 268, against 209 the corresponding week of last year, showing an increase of 59 deaths and making the death-rate for the week 23.48. Of this number 145 were males and 123 were females, 265 were white and 3 colored, 159 were born in the United States, 102 in foreign countries and 7 unknown, 56 were of American parentage, 182 of foreign parentage and 30 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria 53 cases and 3 deaths, scarlatina 32 cases, no deaths, typhoid fever, 6 cases and no deaths, measles, 178 cases and 5 deaths, tuberculosis 39 cases and 30 deaths, smallpox, no cases and no deaths. The deaths from pneumonia were 44.

whooping cough 3, heart disease 28, bronchitis 13, and marasmus 6. There were 19 deaths from violent causes. The number of children who died under one year was 49; the number under five years, 77. The number of persons who died over sixty years of age was 64. The deaths in public institutions were 82.

There were 11 cases and 3 deaths of cerebro-spinal meningitis reported during the week.

LECTURE BEFORE MASSACHUSETTS VOLUNTEER MILITIA. — Col. Valery Havard, Assistant Surgeon General United States Army, will address the medical officers of the Massachusetts Volunteer Militia at 3 P.M., Wednesday, April 4, at the South Armory, Irvington Street, Boston. While this lecture is primarily for the medical officers of the militia, civilian physicians will be welcome.

LOWELL TUBERCULOSIS EXHIBITION. — A tuberculosis exhibition under the auspices of the Lowell Anti-Tuberculosis Association was held March 19 to 26 in that city. The exhibition was open daily from 10 A.M. to 10 P.M., and each evening an address was given by physicians and others regarding the general subject in the same manner as in the Boston exhibition which was attended with success. Among the speakers were Dr. W. T. Councilman, Dr. G. S. C. Badger, Prof. William T. Sedgwick and Mr. Alexander M. Wilson, secretary of the Boston Society for Prevention and Control of Tuberculosis.

NEW YORK.

BETH ISRAEL HOSPITAL. — The large Purim biall, given at the Madison Square Garden on March 14, netted nearly \$15,000 for the Beth Israel Hospital.

BEQUEST TO WOMAN'S HOSPITAL. — By the will of Mrs. Helen Ellis Cole, who died on February 2, the Woman's Hospital receives \$5,000 for the endowment of a bed in perpetuity.

SENTENCE OF A STREET CAR CONDUCTOR. — On March 23, Albert Orenan, conductor of a Lexington Avenue street car, was sentenced to ten years in Sing Sing prison by Judge Foster, in the Court of General Sessions, for causing the death of Bernard McDonald, driver of a United States mail wagon. In passing sentence Judge Foster said to the defendant: "I have been reliably informed that it costs the Metropolitan Street Railway Company nearly \$2,000,000 a year to settle the damage suits resulting from

such carelessness and neglect of duty as you have been adjudged guilty of. And of far greater moment is the loss of life and limb and the suffering inflicted by such men as you. I will punish you heavily, in the hope that it will serve as a deterrent to others of your kind." At the time of the collision, Orenan was running the car in the place of the motorman, and the driver of the wagon was thrown to the ground and instantly killed. The family of McDonald accepted \$20,000 in settlement of their case against the company.

Obituary.

ROBERT OGDEN DOREMUS, A.M., M.D., LL.D.

By the death of Prof. R. Ogden Doremus, which occurred on March 22, New York loses a picturesque figure, long prominent in the scientific, social, literary and artistic life of the city. He was born in 1824 in the family home, at Broadway and Cortlandt Street, and from early manhood he took a leading part in all the developments in his native town along the line of his special objects of interest, chemistry, scientific education and music. His father was one of the founders of the University of the City of New York, and from that institution he was graduated both in arts and medicine. He then became assistant to Prof. John W. Draper in the chemical laboratory of the University Medical School. He also spent a considerable time in Paris in the study of chemistry and electro-metallurgy. In 1848 he equipped, with Charles Townsend Harris, a laboratory in the New York College of Pharmacy, in which he had been appointed Professor of Chemistry. He was one of the founders of the New York Medical College, of the Long Island College Hospital, and of Bellevue Hospital Medical College. In all of these he filled the chair of chemistry, urging in each school the necessity of the provision of a laboratory, where the students could have the opportunity of thorough chemical training. In the Bellevue College where he retained his professorship for many years, he was associated with that brilliant corps of teachers composed of such men as the Austin Flints, senior and junior, Van Beuren, James R. Wood, Fordyce Barker, Lusk, Sayre and Alexander Mott. Of this famous old Bellevue Faculty, but one member survives, the younger Flint, now Professor of Physiology in Cornell University Medical College. From 1853 to 1861 Dr. Doremus was Professor of Natural History at the Free Academy, now the College of the City of New York, and afterward was appointed to the chair of chemistry and physics in the same institution.

He made the laboratory at 234 Street and Lexington Avenue a noted center for study;

particularly in connection with electricity. He was always a very popular lecturer, not only on account of his remarkable command of language but also of the brilliant experiments with which he illustrated his remarks. On one occasion at the Academy of Music, in 1855, he took daguerreotypes of all the persons in the boxes by an arc light, and exhibited a spark six inches long from an induction coil, an extraordinary achievement in those days. He was also a notable figure in municipal affairs. He was the first toxicological expert to be called in New York in a murder case, and his services at the trial of James Stephens for poisoning his wife with arsenic led to improvements in the conduct of autopsies for the courts. For many years after this he was a well-known expert in criminal cases, and he was one of the first presidents of the Medico-Legal Society. He was a member of the Medical Advisory Board of the city, and assisted in the organization of the municipal department of health and the establishment of the Bureau of Chemistry in connection with the latter. In 1871 he was appointed president of a board for the examination of druggists and drug-clerks for licenses to practise pharmacy. He introduced the disinfection of ships by the use of chlorine, and thus did away with the necessity for prolonged detentions at quarantine. One of his important inventions was granulated, compressed gun-powder, the powerfulness of which greatly exceeded that of ordinary gunpowder. It was used by the French in the Franco-Prussian War and for the excavation of the Mont Cenis tunnel.

Dr. Doremis was interested in every department of culture and was the friend and patron of writers and of workers in all branches of the fine arts. No mean musician himself, he was especially prominent in musical circles. He was one of the founders of the Philharmonic Society, and for some time was its president. For many years he and his beautiful and accomplished wife maintained a delightful *salon* where one was sure of meeting the celebrities of the day. The Professor was an imitable *raconteur*, and always had a fund of pleasant reminiscences and good stories for the entertainment of his friends. Among his intimates were Tommaso Salvini and Christine Nilsson, and both these great artists maintained a correspondence with him up to the time of his death. Two or three years ago he celebrated his golden wedding. Since then his wife has died, and he is survived by four children, the oldest of whom is Prof. Charles A. Doremis.

burgh Asylum for the Insane, held on Monday Dr. T. S. Clouston, the physician-superintendent in submitting his report for 1905, said one of the most striking things in regard to the admissions from a medical point of view was the large number of cases of that terrible disease, general paralysis, and more striking was the comparative increase of this disease in the female sex among the poorer classes. When he was at the asylum as an assistant physician in the early sixties it was so uncommon a thing to have a woman admitted suffering from general paralysis that the medical staff would all go to see such a case. Last year there were thirty-eight women suffering from the disease, all except one being of the rate-paid class. For the first time in the history of the asylum the number of women with that disease exceeded the number of men. That was a bad sign of the moral status and mode of life of the class from which those patients came. He had become a convert to the microbial theory recently discovered by Dr. Ford Robertson and made public in his Morrison lecture in the College of Physicians. An increase was also shown in the number of cases due to alcoholic excess. The latest researches into the subject of heredity tended to prove that its results did not end with the one generation, but produced physical and mental degeneracy in the descendants of those who destroyed their reason by excess in drink. This melancholy phase of mental disease greatly prevailed during the year. Dr. Clouston believed that the great epidemic of influenza in 1889 and the subsequent lesser epidemic caused a lowering of the mental tone, and melancholy had been more common than before.

JOSEPH LEADY MEMORIAL.

At a meeting held recently by a number of public spirited citizens it was resolved to present to the city of Philadelphia, for a place upon the City Hall Plaza, a statue of Dr. Joseph Leady, in recognition of his memorable contributions to the natural sciences. Dr. Leady was universally recognized as one of the most distinguished figures which American science produced in the last century. His reputation was not alone national but international in character. Nevertheless, America has failed to show, in any practical way, an appreciation of his varied labors in the field of original research.

An appropriate statue can be erected for the sum of ten thousand dollars, \$10,000. Over one-half of this amount has been subscribed. It is proposed to raise the balance as speedily as possible.

Believing that many of Professor Leady's friends and admirers outside of Philadelphia will be glad to share in erecting this memorial, the committee in charge cordially invite co-operation in their undertaking.

Subscriptions may be sent to Dr. H. S. G. O. (treasurer, 514 Chestnut Street, Philadelphia).

Miscellaneous.

GENERAL PARALYSIS AMONG WOMEN.

From the weekly issue of the London *Times*, March 2, we take the following: "At the annual meeting of the Corporation of the Royal Edin-

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING MARCH 24, 1906.

- W. J. ZALESKY, assistant surgeon. Detached from the "Yankee" and ordered to the "New York."
- F. E. CAMPBELL, assistant surgeon. Detached from the "Newport" and ordered home to wait orders.
- E. M. BROWN, passed assistant surgeon. Orders of March 5 revoked; detached from the Naval Medical School, Washington, D. C., and ordered home to wait orders.
- C. C. GRIEVE, assistant surgeon. Detached from the "Frolic" and ordered to the "Winnington."
- J. FLINT, assistant surgeon. Ordered to the "Franklin."
- I. F. COHN, assistant surgeon. Ordered to the Naval Hospital, Norfolk, Va.

RECENT DEATHS.

DR. CHARLES LOUIS FINCKE, of Brooklyn, N. Y., died on March 19, in the thirty-third year of his age. He was born in Brooklyn and was a son of the late Col. Charles L. Fincke of the Twenty-second Regiment of the National Guard. Dr. Fincke was graduated from Yale in 1896, and from the Long Island College Hospital in 1899.

DR. JOHN P. HENRY, of Jersey City, N. J., died on March 15. He was graduated from the College of Physicians and Surgeons, New York, in 1881.

JOSEPH BYRON KINGSBURY, M.D., M.M.S.S., died in Holbrook, March 24, 1906, aged seventy-one years.

BOOKS AND PAMPHLETS RECEIVED.

Modern Materia Medica and Therapeutics. By A. A. Stevens, A.M., M.D. Fourth edition, thoroughly revised in conformity with the eighth revision (1905) of the United States Pharmacopoeia. Philadelphia and London: W. B. Saunders & Co. 1905.

Gall-stones and their Surgical Treatment. By B. G. A. Moynihan, M.S. (Lond.), F.R.C.S. Second edition, revised and enlarged. Illustrated. Philadelphia and London: W. B. Saunders & Co. 1905.

Dose-Book and Manual of Prescription-Writing with a List of the Official Drugs and Preparations, and Many of the Newer Remedies with their Doses. By E. Q. Thornton, M.D., Ph.G. Third edition, revised and enlarged. And adapted to the eighth revision (1905) of the United States Pharmacopoeia. Illustrated. Philadelphia and London: W. B. Saunders & Co. 1905.

The Dissociation of a Personality. A Biographical Study in Abnormal Psychology. By Morton Prince, M.D. New York, London and Bombay: Longmans, Green & Co. 1906.

The Management of a Nerve Patient. By Alfred T. Schofield, M.D. Philadelphia: P. Blakiston's Son & Co. 1906.

Surgical Nursing and the Principles of Surgery for Nurses. By Russell Howard, M.B., M.S. (Lond.), F.R.C.S. (Eng.) Illustrated. London: Edward Arnold, 1905.

Quiz-Compend. A Compend of Diseases of the Skin. By Jay F. Schamberg, A.B., M.D. Fourth edition, revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1905.

Word-Blindness, with the Record of a Case Due to a Lesion in the Right Cerebral Hemisphere in a Right-handed Man; with Some Discussion of the Treatment of Visual Aphasia. By Charles K. Mills, M.D., and T. H. Welsenburg, M.D. Reprint.

Differential Diagnosis and Treatment of Disease. A Text Book for Practitioners and Advanced Students. By Augustus Caille, M.D. Illustrated. New York and London: D. Appleton & Co. 1906.

Trip to the "Land of the Midnight Sun." Summer of 1905. By Dr. Flavel B. Tiffany.

A Manual of Materia Medica and Pharmacology. Comprising all Organic and Inorganic Drugs which are or have been Official in the United States Pharmacopoeia, together with Important Allied Species and Useful Synthetics. Especially designed for Students of Pharmacy and Medicine, as well as for Druggists, Pharmacists and Physicians. By David M. R. Culbreth, Ph.G., M.D. Fourth edition, enlarged and thoroughly revised. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1906.

Urinary Analysis and Diagnosis by Microscopical and Chemical Examination. By Louis Heitzmann, M.D. Second revised and enlarged edition. Illustrated. New York: William Wood & Co. 1906.

Prostatitis without Enlargement of the Prostate. Its Diagnosis and Treatment. By Charles H. Chetwood, M.D. Reprint.

Recent Experiences in Kidney Surgery and the Utility of Diagnostic Aids. By Charles H. Chetwood, M.D. Reprint.

A Manual and Atlas of Orthopedic Surgery. Including the History, Etiology, Pathology, Diagnosis, Prognosis, Prophylaxis and Treatment of Deformities. By James K. Young, M.D. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1905.

Man and his Poisons. A Practical Exposition of the Causes, Symptoms and Treatment of Self-Poisoning. By Albert Abrams, A.M., M.D. (Heidelberg), F.R.M.S. Illustrated. New York: E. B. Treat & Co. 1906.

The Food Factor in Disease. By Francis Hare, M.D. Vols. I and II. New York, London and Bombay: Longmans, Green & Co. 1905.

Baumgarten's Jahresbericht. Neunzehnter Jahrgang. 1903.

A Textbook of Pharmacology and Therapeutics, or the Action of Drugs in Health and Disease. By Arthur R. Cushny, M.A., M.D. (Aberd.) Fourth edition, thoroughly revised. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1906.

Thirty-fifth Annual Report of the Secretary of State on the Registration of Births and Deaths, Marriages and Divorces, in Michigan for the Year 1901. Lansing, Mich. 1905.

Refraction, including Muscle Imbalance and the Adjustment of Glasses. By Royal S. Copeland, A.M., M.D., and Adolph E. Ibershoff, M.D. Illustrated. Philadelphia: Boericke & Tafel, 1906.

A Manual of Bacteriology. By Herbert U. Williams, M.D. Revised by B. Mende Bolton, M.D. Fourth edition, revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1905.

Massage and the Original Swedish Movements: their Application to Various Diseases of the Body. By Kurze W. Ostrom. Sixth edition, revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1905.

Department of the Interior. Bureau of Government Laboratories. Biological Laboratory. Intestinal Hemorrhage as a Fatal Complication in Amoebic Dysentery and its Association with Liver Abscess. By Richard P. Strong, M.D. The Action of Various Chemical Substances upon Cultures of Amoeba. By J. B. Thomas, M.D. Biological and Serum Laboratories. The Pathology of Intestinal Amoebiasis. By Paul G. Woolley, M.D., and W. E. Musgrave, M.D.

On the Nature, Causes, Variety and Treatment of Bodily Deformities: in a Series of Lectures delivered at the City Orthopedic Hospital in the year 1852 and subsequently. By the late E. J. Chance, F.R.C.S. (Eng.) Edited by John Poland, F.R.C.S. (Eng.) Second edition. Illustrated. In two volumes. Vol. I. London: Smith, Elder & Co. 1905.

Original Articles.

THE MENTAL SYMPTOMS OF CEREBRAL TUMOR.*

BY PHILIP COOMBS KNAPP, A.M., M.D.,

Clinical Instructor in Diseases of the Nervous System, Harvard Medical School; Physician for Diseases of the Nervous System, Boston City Hospital.

The older writers upon the mental symptoms of tumor of the brain made various estimates of their relative frequency. Andral¹ in 13 cases and Durand-Fardel² in 70 cases found that such symptoms were very rare and thought that they should be regarded as exceptional. Nasse,³ however, found mental symptoms in 19 out of 50 cases, Friedreich⁴ in 19 out of 44 and Lebert⁵ in 29 out of 90, while Ladame⁶ in 1865 noted them in 112 out of 331 collected cases—a proportion of from one third to two fifths. Calmeil⁷ made the curious observation that while mental disturbances occurred in over one half the cases of cancer of the brain, they were rare in tubercle, an hypothesis which subsequent investigations have not confirmed. Some years later Bernhardt⁸ found that in more than half of the tumors of the cortex and lobes there were mental symptoms.

In later years the frequency with which mental symptoms occur is regarded as somewhat greater. Giannelli⁹ found them in 323 out of 588 collected

In the last edition of his *Lehrbuch*¹⁰ Oppenheim says that we may consider it the rule that the sensorium is not unaffected at the height of the disease,—a somewhat more liberal estimate than is indicated in his monograph¹¹ in Nothnagel's system.

It is possible that some of the earlier estimates, like Andral's, were due to the failure to lay sufficient stress upon the minor mental disturbances. Attempts have actually been made to estimate the frequency of mental disturbances by an inquiry into the frequency with which tumors are found at the autopsies of the insane. Fischer¹² found a new growth only once in 318 autopsies, but Leubuscher¹³ found a growth four times in 350 autopsies, and Blackburn¹⁴ 29 times in 1642 autopsies, which is not quite as frequently as I have found tumors in autopsies of patients not insane (101 in 5069 autopsies at the Boston City Hospital).

I have made an attempt to estimate the frequency of mental symptoms in cases of tumor of the brain from a study of the clinical history of 104 cases in which a growth of some nature was found at the autopsy. All but two of these cases are taken from the records of the Boston City Hospital. Many of them came under my own observation, and 39 of them have already been reported in a monograph published some years ago.¹⁵ For the rest, I am indebted to the

TABLE I.

cases, but he reckoned all cases with speech disturbance among the mentally disturbed. Schuster¹⁶ estimated that 50 to 60% of all cases showed some such disturbance. Bramwell¹⁷ believes that the great majority of cases show mental symptoms, and Bruns¹⁸ holds that only rarely, when the growth is very small or has some special situation, is mental disturbance entirely absent.

kindness of my colleagues at the hospital for the privilege of citing them here.

In these 104 cases, mental disturbances sufficient to attract attention were noted in 79, a little over 75% of the cases. On further study, however, and on applying a rigorous criterion, a large number will have to be excluded. In less than 14 cases the tumor, although of considerable size, was but one manifestation of a widespread disease of the brain, and therefore mental symptoms coexisted. In 1 case there was marked

alcoholism; in other cases the new growth was congenital (chordoma) or insignificant, or there were complicating diseases,—Bright's disease, typhoid fever and the like,—or the patient was brought to the hospital unconscious, and no history of the previous condition could be obtained. Such cases, 40 in all, have been excluded, even though it seemed probable that the symptoms of tumor and the symptoms of intercurrent disease might fairly be differentiated.

In the 64 cases remaining, mental symptoms were noted 58 times, a trifle over 90%. In considering these figures, many things must be borne in mind. The patients were hospital cases, often ignorant and stupid, often of foreign birth, with no friends or relatives at hand to give an intelligent history of their previous condition. Under such circumstances it is by no means easy to determine whether there has been any change in the mental condition, especially when the mental level is normally low. Furthermore, we must admit regretfully that hospital records are often defective, and that the house officers sometimes fail to report, or even to note, important symptoms. The patients, moreover, came under the care of different physicians, and sometimes were seen only cursorily, if at all, by the neurologists of the hospital. Finally, we lack a definite and generally accepted method of examination of the mental condition of the average patient, such as we have for determining sensation, motion or reflex activity. It would therefore not be surprising if the slighter mental changes should sometimes escape observation. It is surprising to me, however, that under such adverse conditions mental disturbances should be so frequently recorded, and it goes far to strengthen the opinion I expressed some fourteen or fifteen years ago¹² which Oppenheim¹³ possibly regarded as extreme, "that in every case some change can be found by a competent observer who has known the patient intimately before; in other words that there can be no gross lesion in the brain without some disturbance, greater or less, in the psychical functions."

A case under my observation a few months ago will illustrate this point. The symptoms pointed very definitely to a tumor in the occipital lobe, but no autopsy could be obtained. The patient was a young man of unusual mental attainments, who had won high honors at two great universities. He was of a high-strung, intense, poetical nature. On many occasions it seemed as if there were no mental impairment whatever, but closer study revealed almost invariably a readily induced exhaustion of the brain, so great at times as to compel a cessation of inquiry, or even of ordinary conversation. With this was associated an exaggerated emotional instability and a good deal of mental depression. The latter, however, might be regarded as natural under the depressing conditions. He had a quadrant hemianopsia, but under ordinary conditions there was no sign of any psychical blindness. Under the excitement,

however, of an examination by a strange physician, he was temporarily unable to give the names of ordinary objects exposed to his view. Yet later, when free from excitement, he could do so normally.

Mental disturbance as the result of a cerebral lesion is what we might fairly expect *a priori* from our knowledge of the anatomy and functions of the brain. Anatomically we know that the brain is a mass of interconnected neurones, each one of which is in contiguity with many others and may be aroused through many different chains of neurones. If even a small group of neurones be obliterated by disease, there are some lines of nervous conduction in which a link is broken and the mental processes become just so far defective or slow in operation. If the single factor of its characteristic smell be eliminated from our concept of an orange, our mental patrimony becomes just so much the poorer. "Any destructive focal lesion of the brain," says Bianchi¹⁴ in his recent admirable treatise on psychiatry, "must also have as an effect a diminution of the mental patrimony and of the vigor of the personality in some direction." With small lesions, however, especially if located in certain regions of the brain, such disturbance might be insignificant and might not be detected by our present methods of clinical research.

We must also recognize the fact that there are certain growths which are apparently unattended with any cerebral symptoms whatsoever. The chordoma, one of which is included in my series, is a congenital growth and apparently gives rise to no symptoms in the few recorded cases where it has been found. Osteophytes in the skull and psammomata may sometimes attain considerable size without giving rise to any disturbance; the same is also true of the small cysts which develop in the choroid plexus. Furthermore, we occasionally meet with growths which are inclosed in a calcified capsule where no history of cerebral trouble can be elicited. Nine of the cases in the present series may be classed under one or the other of these various types and may fairly be excluded from consideration. They all entered the hospital for some other disease, the symptoms were not cerebral, and the tumor was discovered only at the autopsy. Various cases are on record where the presence of a large tumor was not suspected during life, and where the cerebral symptoms were absent or insignificant. In the present series of cases, however, there were no instances where a large growth existed without cerebral symptoms, although there was often a question whether those symptoms were due to the growth or to intercurrent disease. The statement which I have made above, therefore, needs a little modification to this effect, that in every case of brain tumor presenting any cerebral symptoms, some mental symptoms can probably be discovered, — at least by a competent observer who has known the patient intimately before.

The cases here under consideration, however,

¹² Кларк: *Op. cit.*, p. 41.

¹³ Oppenheim: *Die Geschwülste des Gehirns*, p. 52.

¹⁴ Bianchi: *Trattato di Psichiatria*. Naples, 1901-1904, p. 786.

were, of course, seen in the terminal stages of the disease, a few weeks, or sometimes a few days, before death. One of them, which only recently came to autopsy, came under my personal observation over two years before. At that time the mental symptoms were insignificant, but in the last year of his life, after he had been trephined, they developed to such an extent that he became suspicious, deluded and violent, developed hallucinations of sight and hearing, and had to be committed to an insane asylum. Later, he grew quieter, and for some months before death was dull and stupid, gradually becoming comatose in the weeks preceding death. In this case the optic nerve presented analogous conditions. So long as he was under my observation, no neuritis could be discovered, but after he had been trephined, I learned that he became almost totally blind. The mental symptoms were observed comparatively early in the progress of the disease in 28 of the 64 cases. The importance of the early onset of such symptoms with reference to the location of the growth, can be more advantageously discussed later, when we consider the relation between the symptoms and the seat of the growth.

In regard to the nature of the mental symptoms occasioned by a new growth within the skull the prevalent opinion has been that expressed by Oppenheim and Bruns, that there is a steadily progressing stupidity, beginning as somnolence and mental torpor, and eventually going on to stupor and coma. They both recognize the occasional occurrence of other mental conditions, such as melancholia, hallucinatory excitement, simple dementia, delirium, etc., as well as the peculiar form of mental weakness associated with a childish propensity to jest (Witzelsucht, moria puerilis), but Oppenheim regards them as rare, and Bruns believes that when specific psychoses occur they are to be regarded as due to pre-disposition, and not caused by the new growth. Dupré¹⁰ describes the characteristic mental condition as one of dullness of the intellect, affective torpor and inertia of the will, with occasionally ambulatory automatism. He lays especial stress upon a state of puerilism manifested by an infantile character of the psychical reactions, with various modifications of the affective tone—depression or excitement, often associated with the childish joviality above mentioned. Giannelli, however, has pointed out clearly that the mental symptoms of tumor of the brain may be varied and manifold, and this opinion has been confirmed by the exhaustive study of Schuster.

Schuster, as a result of a study of 775 collected cases, found that the conditions of simple mental weakness, dullness, sopor and dementia were present in 124 cases, while 352 cases presented some active symptoms which were classified as follows:

| | |
|---|----|
| Symptoms similar to those of general paralysis, | 20 |
| Symptoms similar to those of chronic paranoia, | 19 |
| Symptoms similar to those of melancholia and depressive states, | 57 |

| | |
|---|----|
| Lachrymose with mental weakness, | 3 |
| Depression with great irritability, | 1 |
| Mental symptoms as in neurasthenia and hysteria, | 15 |
| Mental symptoms as in mania, | 13 |
| Euphoria, Witzelsucht, moria, hypomania, | 23 |
| Irritability, "epileptic character," maniacal and similar states, | 95 |
| Unrest, anxiety, | 1 |
| States with confusion and hallucinatory delirium, | 52 |
| States similar to Korsakow's psychosis, | 2 |
| States similar to moral insanity, | 7 |
| States with impulsive acts, | 3 |
| Circular states, | 5 |
| "Mental weakness with states of excitement," | 10 |
| State as in senile dementia, | 1 |
| Unclassified, | 16 |

His investigations prove, therefore, that the conditions of stupor and mental torpor, although they are present in a greater proportion of cases, are not in such an overwhelming majority as the statements of Bruns, Oppenheim and Dupré would imply, and that specific psychoses are sufficiently common to cast some doubt upon Bruns's statements.

My own investigations would agree in the main with those of Schuster, although I have found a lesser proportion of certain states than he has given. The largest number of cases, thirty-one in all, presented the recognized type of mental failure and dullness. The patients exhibited various degrees of languor, somnolence, dullness, apathy, mental torpor, failure of memory, and a general failure of all the mental functions, ending usually in complete stupor and coma. In the earlier stages it was sometimes noticeable, as has been observed by so many other writers, that when aroused by sufficiently powerful stimuli, the mental processes could be performed clearly and correctly, but with unusual slowness.

Seven cases showed noticeable mental confusion and disorientation, with mental failure, failure of memory, irrelevancy in speech, mild mental wandering, somnolence, stupidity and a dazed mental condition.

In fifteen cases the mental impairment went on to actual states of delirium, which became wildly maniacal in three patients and which demanded restraint in several others. Actual hallucinations were occasionally noted. In these delirious states there was also mental failure, confusion, disorientation, failure of memory and often more or less stupor, mental slowness, incoherence and vague and unsystematized delusions.

Neurasthenic and hysterical states were occasionally noted in the earlier stages of the disease, but, with a single exception, there eventually developed more marked mental disturbances, so that the cases were eventually classified under one or another of the divisions given above. The diagnosis of hysteria or neurasthenia was indeed occasionally made at first by other physicians, although not quite as frequently as I have known it to be made in private practice. One or two patients who afterward became much deteriorated at first showed the scrupulousness and quiet feelings so common in the neurasthenic condition, while others showed the emotional instability of hysteria.

¹⁰ Dupré, *Psychopathes organiques*. Bailet Traité de pathologie mentale, Paris, 1903.

Vague and unsystematized delusions were occasionally noted in the confusional and delirious states, but in only two cases were there definite delusions of persecution of a somewhat systematic character. One of these had also well marked hallucinations of sight and hearing. Only one case presented symptoms of marked mental depression unattended by any mental failure or confusion. The normal depression, natural upon the appreciation of the disease, must of course be omitted from category. One patient also, whose case I reported some years ago,¹⁶ presented a fairly typical picture of general paralysis. The condition of childishness, *puerilisme*, emphasized by Dupré, was noted exceptionally, but true Witzelsucht was not observed. I have seen it in one or two cases of probable tumor in private practice, but in my experience it is a rare phenomenon in cases of brain tumor. It is, however, not uncommon in cases of incipient general paralysis.

I found no very striking differences as to the period of the disease at which the different types of mental disturbance developed. The mental symptoms were of early onset in about half of all the cases, 28 in 58, and they were also of early onset in about half of each of the three main groups, stupor (13 in 31), confusion (4 in 7) and delirium (8 in 16). One distinction, however, must be made. Although some mental symptoms appeared early in the course of the cases which became delirious, the delirium was usually a later feature. Confusion, mental dullness, somnolence and the like characterized the earlier stages; delirium, violence and profound stupor, the later stages.

Turning now to the question of the relation between the seat of the tumor and the mental symptoms, it may be well first to deal with two general questions in regard to the relative position and size of the growth before we consider in detail the exact localization.

Schuster has found that in the collected cases of tumor with mental symptoms, the growth was located in a much larger proportion of the cases on the left-hand side of the brain, excepting with tumors of the temporal lobe, where the proportions were about equal. In the frontal and occipital regions there were about four tumors on the left to three on the right, while in the central and parietal regions the left-sided tumors were about twice as numerous. This agrees with Phelps's¹⁷ study of brain injuries, in which mental symptoms were much more frequent in injuries of the left frontal lobe than of the right. My own cases do not support these conclusions. Of the cases involving the cerebral lobes, only 11 were on the right and 9 on the left side, and the only one of these 20 cases where no mental symptoms were recorded was on the left side. Taking all the 64 cases, 28 were on the right side and 29 on the left, and of those without recorded mental symptoms, 3 were on the left side and none on the right.

¹⁶ Knapp: *Op. cit.*, p. 71, case xiv.

¹⁷ Phelps: *Traumatic injuries of the brain and its membranes*. New York, 1897.

In regard to the size of the tumors it is obvious that a large growth is likely to give rise to more mental, as well as other symptoms, than a small one, and the resultant symptoms are, of course, apt to be more pronounced. I have arbitrarily divided my cases into three classes, — large, where the growth was over two centimeters in diameter, medium, from one to two centimeters, and small, below a centimeter. Following this classification, the cases may be arranged as follows:

| | |
|--------------------------------|------------------------------|
| Cases with mental symptoms, | 31 large, 21 medium, 5 small |
| Cases without mental symptoms, | 2 " 3 " 1 " |
| Cases rejected, | 7 " 13 " 20 " |
| Total, | 40 " 37 " 26 " |

In one instance the size of the growth was not stated. In other respects the table gives us no very definite date, and gives no special support to our *a priori* conclusions.

Coming now to the special problem of the relation of the mental symptoms to the special regions of the brain, it may be well first to reproduce the three following tables from Schuster. In the first he gives the scale of frequency with which the different regions are affected by tumors in general, as follows:

| | |
|------------------------------------|------|
| Cerebellum, | 21.6 |
| Multiple, | 14.7 |
| Frontal, | 12.1 |
| Central, | 12.0 |
| Brain stem and crura, | 9.9 |
| Basal ganglia and ventricles, | 7.0 |
| Occipital, | 4.3 |
| Temporal, | 3.9 |
| Hypophysis, | 3.8 |
| Medulla oblongata, | 3.4 |
| Parietal, | 3.3 |
| Corpora quadrigemina and parietal, | 3.1 |
| Corpus callosum, | 2.5 |

In the second he gives the relative percentage with which the different regions are affected in cases with mental symptoms.

| | |
|-------------------------------|------|
| Frontal, | 18.8 |
| Multiple, | 18.6 |
| Cerebellar, | 10.6 |
| Hypophysis, | 7.0 |
| Basal ganglia, ventricle, | 6.9 |
| Brain stem, crura, | 5.9 |
| Temporal, | 5.8 |
| Central, | 5.2 |
| Corpora quadrigemina, pineal, | 5.0 |
| Occipital, | 4.3 |
| Corpus callosum, | 4.0 |
| Parietal, | 2.4 |
| Medulla oblongata, | 2.3 |

In the last he shows the percentage of mental disturbances in 100 cases in any given region.

| | |
|-------------------------------|-------|
| Corpus callosum, | 100.0 |
| Frontal, | 79.3 |
| Temporal, | 66.6 |
| Hypophysis, | 65.3 |
| Occipital, | 60.0 |
| Multiple, | 59.6 |
| Corpora quadrigemina, pineal, | 53.8 |
| Parietal, | 52.1 |
| Basal ganglia, ventricle, | 50.0 |
| Cerebellum, | 35.5 |
| Central, | 28.8 |
| Brain stem, crura, | 25.0 |

Schuster moreover is inclined to the belief that the type of mental disturbance is dependent to some degree, at any rate, upon the location of

the growth. The more active mental disturbances are more frequent in tumors of the frontal, temporal and occipital lobes; the forms of simple mental failure in callosal and parietal tumors. Cases presenting the symptoms of moral insanity and general paralysis are commoner with frontal tumors, cases of the neurasthenic, hysterical or hypochondriacal type with frontal or parietal tumors, while cases of the type of paranoia and mania are rare in frontal tumors; and cases of confusion and delirium occur less often in frontal tumors than elsewhere, and are especially common in occipital growths. He agrees with other recent authors in the opinion that Witzelsucht occurs in tumors of any region, not exclusively in frontal tumors, and believes it is dependent somewhat upon the size of the growth.

Giannelli, drawing conclusions very probably from many of the same cases as those collected by Schuster, agrees with him in assigning special importance to tumors of the frontal lobe and corpus callosum in the production of mental symptoms. His conclusions are as follows: (1) Hallucination, when it exists, indicates an irritation of the corresponding cortical sensory center, although we cannot affirm with absolute certainty that the neoplasm is in the immediate vicinity of that center. (2) The more the mental disorders — torpor, intellectual arrest, weakness of memory — are manifested at the beginning of the morbid process, the more likelihood there is that the neoplasm is in the frontal lobe and especially the prefrontal region. (3) Tumors of other lobes or in other parts of the encephalon exhibit the mental disorders above mentioned later in the course of the disease; but, when the mental disorders do appear, they do not differ materially from those manifested by tumors of the frontal lobe, excepting that tumors in the speech area may produce the form of dementia characteristic of aphasic disturbances. (4) These mental disorders indicate a more or less intense and more or less diffuse alteration of the cortical morphological elements. (5) Tumors of the corpus callosum are always (2) accompanied by mental disturbances. (6) The modifications of sentiment, which may develop in the course of a cerebral tumor, have no localizing value. (7) When a cerebral tumor presents the syndrome of general paralysis it is very probably in the frontal lobe. (8) When ideas of grandeur develop in the course of a cerebral tumor, the tumor is probably in the frontal lobe. (9) Witzelsucht is indicative of a tumor in the frontal lobe, probably on the right side. (10) Marked alterations of character, with irritability, violence, insolence, obscenity, threats, indicate a frontal growth. (11) When, in the course of a cerebral tumor, there are exhibited disordered actions of a higher order (forced actions with consciousness) the growth is most probably near the psycho-motor zone, and preferably in the frontal lobe.

In spite of the importance ascribed to tumors of the frontal lobe in the production of mental symptoms, by both Giannelli and Schuster, and

in spite of the corroborative evidence both on the clinical side and from animal experimentation, Müller¹⁹ has contested the generally accepted opinion that the frontal lobes are associated with the higher psychical functions. Although Müller's arguments are somewhat plausible, I do not think that he has succeeded in controverting the great mass of evidence that has been collected which ascribes to the frontal lobes an important part in the mental processes, although they are in no sense to be regarded as the sole psychical centers. The integrity of the mind must depend upon the harmonious functioning of many regions of the cerebral cortex, and the analysis of even a simple concept will almost invariably show that it is the result of the combination of many sensory processes which demand unbroken links of succession between several widely separated sensory regions. The occipito-temporal region, and especially the zone of language, must play an extremely important part in our ideational processes, and the probability that the corpus callosum is a huge mass of association fibres renders its integrity also important. It is readily conceivable, assuming that a given association tract with a definite function runs from the occipital lobe through the corpus callosum to the opposite frontal lobe, that a lesion in any one of the three regions might break the conduction and give rise to the same phenomena of deficit, just as a lesion anywhere from the cuneus to the chiasma may give rise to the same symptom of deficit, hemianopsia. It is not unlikely that disturbances in the higher visual centers in the occipital region in Flechsig's posterior association center, may be responsible for much of the disorientation of confusional states, for example, and that the special phenomena of attention and many of the ideas of personality are dependent upon associated processes in the frontal lobes, but this is still undetermined, and the cases at present under consideration unfortunately give no definite information upon the subject.

Coming now to the cases that I have collected and considering them in detail, five of the six cases of tumor of the frontal lobe, or, to speak more accurately, of the prefrontal portion thereof, exhibited signs of mental disturbance. In all cases this disturbance was simple mental failure with marked dullness, but in only three of the cases was it noted as being among the early symptoms. The only case where no mental symptoms were noted was a sarcoma the size of an English walnut at the foot of the left second frontal convolution near the precentral sulcus and has already been reported.²⁰ It is curious that this is the only case of tumor of the pre- or paracentral or hemispherical in which no mental symptoms were recorded, but mental dullness may readily have been overlooked, as the patient was in bed for a number of weeks, complaining constantly of intense headache and therefore being averse to any attempts at conversation.

¹⁹ Müller, *Die Lokalisation der Seelenkräfte nach der neueren Lehre*, 1901, Verlag von J. Neumann, Neudamm. *Deutsche Zeitschrift für Neurologie*, vol. 17, 1902.

²⁰ Knapp, *Op. cit.*, 47, case III.

Of four tumors in the Rolandie region, two presented symptoms of mental dullness early in their course, a third, later in the disease, was noisy and delirious, and the fourth, to which I have already referred, finally developed hallucinations and delusions of persecution.

One of the two parietal cases presented neurasthenic symptoms early in the disease. The other became dull and stupid toward the close.

There were six temporal tumors. Two of these were mentally dull, two confused, one delirious, and one presented a typical picture of general paralysis. One of the dull cases did not show much mental change until late in the disease. In all the rest, the mental symptoms were of early occurrence.

The only case of tumor of the pons was mentally dull.

Five out of seven cerebellar tumors were mentally dull, but only one showed this mental failure early. The sixth was delirious. In the seventh case no mental symptoms were noted, but she had headaches with intense vertigo, aggravated by any effort, so that mental symptoms may well have been overlooked.

One tumor of the hypophysis showed mental confusion early in the disease. The second was delirious toward the close.

Of the seven tumors at the base of the brain, five were in the anterior fossa. Of these, one became dull early, three showed mental confusion later in the disease, and a fifth was delirious, show-

* Cases with early mental symptoms in Roman numerals.

Every one of the three callosal tumors showed mental symptoms early in the disease, and all became confused, delirious, violent and demented. One case had had hallucinations.

Seven out of nine cases of a growth in the optico-striate region were mentally dull, but only two showed this symptom early. Two other cases showed early mental symptoms, and both became delirious, requiring restraint, one being wildly maniacal.

Two cases of tumor of the corpora quadrigemina became dull early, and the third also showed early mental impairment, with delusions of persecution. One of them manifested early various neurasthenic symptoms, scrupulosity and a sense of unworthiness, later growing demented.

ing mental disturbances early. One tumor in the middle fossa became delirious later in the disease. In only one case of a tumor in the posterior fossa, a growth of the cerebello-pontine angle, not involving the brain deeply, there were no noteworthy mental symptoms.

Eleven tumors were classed as multiple, but two other cases might fairly be regarded as in this class, one a multiple growth in the optico-striate region, the other a multiple growth in the pons. They have, however, already been considered under the other headings as the growths were close together. Three of these eleven cases showed mental failure late in the disease. One was confused early, and three were delirious. One of them showed mental disturbances early.

One was mentally depressed. Of the three cases where no mental symptoms were recorded, two were under observation a very short time, one dying suddenly with cysticerci in the brain, the other dying suddenly of surgical shock. A third case, with multiple gliomata in the basal ganglia has already been reported.²⁰

In one other case with mental failure the autopsy record of the findings in the brain was lost, the only note being "glioma of brain."

Since mental symptoms were so frequent, no matter in what part of the brain the tumor was located, and since the failure to note such symptoms in a few cases is susceptible, for the most part, of explanation on other grounds than by the assumption that mental symptoms did not exist, the series of cases here presented can hardly give much support to any theory which seeks to establish one special psychical center in the brain. If, however, we study the cases according to the period of development of the mental symptoms, it may, perhaps, be of greater advantage.

If we note the early development of the mental symptoms as shown in the final column of table I, the relative importance of the different regions of the brain in regard to psychical functions becomes more pronounced. In every case of tumor of the corpus callosum or tumor of the corpora quadrigemina the mental symptoms were of early development. This is in accordance with the other data which indicate that callosal tumors are most frequently attended with mental symptoms on account of the important part played by the corpus callosum in the processes of association. Growth involving the region of the corpora quadrigemina and pineal gland are usually attended with marked dilatation of the lateral ventricles on account of the blocking of the *iter a tertio ad quartum ventriculum*. They thus give rise early to a marked increase of intracranial pressure which might favor the early onset of mental disturbances. Next in importance to these regions in favoring the early onset of mental symptoms come the temporal and frontal lobes. A study of these cases, in fact, has led me to believe that the temporal lobe, apart from its association with the function of speech, has perhaps as important a share in the psychical functions of the brain as the frontal lobe. The other regions of the prosencephalon, with the optic-atriate region and the hypophysis, come next and the brain stem plays a less important part.

The pathogenesis of the mental symptoms in cases of cerebral tumor is susceptible of various explanations. The mental disturbance may be regarded as a focal symptom, either of defect or irritation, due to the destruction or irritation of certain centers which have especial psychical functions; or it may be a general symptom, due either to the increased intracranial pressure or to the formation of certain toxins in the brain either from the new growth itself or by the disturbance in circulation caused by the growth.

From a study of these cases we have found that the most common psychical states are those of

confusion, delirium and mental stupor or dementia. These states often co-exist, or at least are often present in successive stages of the same case, in mental diseases due to causes other than tumor. This is especially true of the toxic and infectious psychoses, or of the various mental affections which Bianchi has brought under the one comprehensive heading of sensory phrenosis. Persistent hallucinations, obsessions, phobias and limited systematized delusions with a clear sensorium and fairly active intellectual processes were notably rare. It is fair to assume that these later syndromes are dependent upon some derangement in a definite group of association neurones, limited, it may be, in number, but possibly having connections with one another over a wide cortical area. A new growth may disturb some of these groups in its initial stage, but as it increases in size, especially in the case of a growth so large as to involve several cortical regions and the basal ganglia as well, so that its regional classification becomes a problem, the mental symptoms will become more general and widespread. While it seems probable that the functions of certain areas, notably the frontal and temporal lobes, are especially of a complex psychical nature, and that those areas are especially to be considered as psychical association centers, and that the corpus callosum is to be regarded as a vast association tract connecting various association centers, it is not strange if a good-sized lesion in one of those centers should disturb many groups of associated neurones and lead to more diffuse psychical disturbances. In studying the early development of mental symptoms I have already indicated the relative importance of certain areas in the possible production of such symptoms, but the fact that mental symptoms may arise from a growth anywhere within the cranium forces upon us the conclusion that other factors beside the location are of importance in their production.

Vigouroux²¹ has maintained that there is no special region of the brain which elaborates intelligence, but that the intellectual function requires the co-operation of all parts. He thinks that a diffuse alteration of the cortex is requisite to produce obtundation, confusion and dementia, and that when these symptoms occur they are due not to the growth alone, but to compression, chronic meningitis, and the formation of toxins. Gannelli, indeed, has demonstrated the existence of these diffuse changes in a number of cases of tumor, finding changes in the cells and disappearance of tangential fibres in all parts of the brain.

The factor of pressure is undoubtedly of great importance. We know that pressure will inevitably lead to a dilution of all the cerebral functions. Levasseur²² has tried to show that the habitual mental symptoms of tumor are obtundation, confusion and weakening of the intellect, and that these are due to compression of

²⁰ Vigouroux, "Psychiatrie des tumeurs cérébrales," *Revue de Psychiatrie*, 1896, 1, 100.

²¹ Levasseur, "Fonction intellective psychique dans les tumeurs cérébrales," *Thèse de Paris*, 1901.

²² Knapp: *Op. cit.*, p. 115, case xxxvii.

the brain. Outbursts of delirium with hallucinations are exceptional, and are due to toxic influences. Systematized delusions are due to coexisting degeneracy and not to the tumor at all. This seems somewhat strained. Increased pressure existed in many of my cases and was an important factor, but not the only factor. I have already referred to a case with hallucinations of sight and hearing and delusions of persecution. When he first came under observation he had typical Jacksonian epilepsy with slight paresis of the right hand due to an endothelioma growing from the dura in the left mid-Rolandic region. At that time he had no optic neuritis, no noticeable mental disturbances and very little headache. He passed from my observation, but nine months later he was trephined. It was reported that the growth could not be removed on account of hemorrhage. A hole four cm. in diameter was left in the skull, and hernia developed. A year later he became blind, the mental symptoms above mentioned developed and he was sent to an asylum. Later he became extremely dull and

wandering and delirium; in the third there was simple mental failure.

I have already shown the resemblance between the mental symptoms usually met with in cases of cerebral tumor to those occurring in toxic psychoses. Dupré, an ardent advocate of the toxic origin of these symptoms, has emphasized this point. He believes that the mental disturbances are due to the impregnation of the brain by products of disassimilation, cellular toxins coming from the new growth. He shows that many of the symptoms of tumor of the brain, such as headache, mental disturbance and neuritis, may also arise in toxic conditions such as uremia, diabetes and lead poisoning. He believes that the new growth secretes toxic substances growing at the expense of the brain, and that the gray matter of the brain is peculiarly sensitive to such poisons. He has found, furthermore, lesions throughout the brain, in cases of tumor, similar to those found in toxic-infectious troubles, and calls attention once more to the importance of toxins in the production of optic neuritis.

TABLE III.

| Nature of growth. | Total cases. | Total considered. | With mental symptoms. | TYPE OF MENTAL DISTURBANCES. | | | | | |

stupid, dying in coma. The mental symptoms and blindness developed after the pressure had been relieved by trephining.

In considering the possibility of toxic influences I have tried to see whether the nature of the growth had any influence on the development of mental symptoms. That a rapidly growing tumor will more speedily cause mental symptoms than one of slow growth is obvious, but beyond that I have been unable to find any special relation between the nature of the growth and the form of mental disturbance, except that delirious conditions were more apt to occur in cases of sarcoma, as the accompanying table will show.

The cases of diffuse multiple sarcomatosis of the brain, four in number, deserve special mention. One of them entered on account of a huge sarcoma of the neck, which was cured, the patient dying of shock the same day. No note was made of his mental condition by the surgeons. In two of the others there was marked mental confusion,

Pressure alone is hardly capable of producing optic neuritis, but when pressure is combined with the influence of some toxin, neuritis is speedily produced. The cases under consideration reveal nothing as to the nature, or even the existence, of these toxins, but it seems probable that while the situation of the growth is often of influence in producing mental symptoms, especially in the early stages of the disease, and possibly has an influence upon the nature of the symptoms, a combination of increased cranial pressure and the action of toxins is of greater importance, and in some cases may be the only factor to be considered in the production of such symptoms.

SMALLPOX IN VIRGINIA.—According to the *New York Medical Journal*, on account of the prevalence of smallpox in Richmond and in Petersburg, the secretary of the Manchester Board of Health has, by direction of the board, notified all manufacturing firms and employers of labor to see that all of their employees are promptly vaccinated.

THE OPERATION FOR CATARACT.*

BY FREDERICK E. CHENEY, M.D., BOSTON.

Ophthalmic Surgeon, Massachusetts Charitable Eye and Ear Infirmary, Ophthalmic Surgeon, Massachusetts General Hospital.

At the beginning of my work in ophthalmology what most impressed me in connection with the operation for cataract was the ease of its accomplishment. This is to be accounted for in a measure by the fact that I was fortunate in seeing a number of exceptionally skilled operators, and an operation, like many other things, appears simpler and easier the nearer it approaches perfection. After nearly twenty years of operating, the view point is naturally a different one and my attitude is probably that of most men who have performed a number of hundred extractions. I now realize that it is not as easy and simple as it at first appeared and I am continually on the outlook for new points and suggestions. Most of us appreciate the advantage of seeing other surgeons operate and it is a matter of regret that a busy life gives so little opportunity for this adding to our knowledge. There is, however, something to be gained by an exchange of individual opinions on the various points of technique, etc., and in presenting this paper to the Society, I shall hope for a very general discussion.

In operating it is safe to say that all men prefer a thoroughly mature cataract, a chamber of good depth, a pupil that dilates well under a mydriatic, a quick light perception and good projection. While the absence of one or more of these favorable conditions does not of necessity contraindicate operation there is often a marked difference of opinion expressed in advising the patient. The complete maturity of the lens is not so much insisted upon as it was fifteen or twenty years ago. If the vision of the second eye is so defective that the patient is unable to read, get about satisfactorily or carry on his usual occupations, I do not object to operating on a lens that is swollen and the chamber narrowed, nor do I hesitate, under these conditions, if a certain amount of the lens is still transparent. There is one class of immature cataract where operation is, it seems to me, needlessly delayed. I refer to an extremely slowly developing nuclear variety that I have seen more often in the later part of middle life and not infrequently in myopic eyes. The anterior chamber is of good depth, sometimes deeper than normal. The central opacity is usually dense and well defined, with a number of striations extending towards the periphery while the larger proportion of the lens substance is transparent. The location of the opacity, however, and the resulting irregular astigmatism, give rise to a very defective vision that is little if at all benefited by glasses or mydriatics.

As both eyes are apt to be involved to about the same degree, and the waiting for maturity is a question of years, the condition is naturally a discouraging one for the patient. In two or three of these cases I have attempted ripening by making a free desiccation of the cortex, but there was no

swelling of the lens substance and the opacity produced extended little beyond the area directly involved in the needling. I have ended by doing an extraction and think in the future I shall not attempt a desiccation but extract in the beginning. The eyes have been unusually free from infection and have made good recoveries.

It is perhaps unnecessary to say that visual statistics should never be considered in deciding for or against operation. The fact that an iris is discolored or tremulous, that there are numerous posterior synechiae, opacities of the cornea or even faulty projection should not prevent one from operating if the patient is blind and there is a chance of improving his condition. To a man blind the ability to count fingers even at a distance of two or three feet will be of inestimable value and if he is properly constituted as to temperament it will be duly appreciated. Temperament is a factor that must always be reckoned with in considering the results of a cataract operation. The patient with 20/2000 vision is often the contented, grateful patient, and the one with 20/200 as often the chronic grumbler. While the absence of light perception of course forbids operation, except for the cosmetic effect, it is to be remembered that an occasional patient will be met with who absolutely refuses to see light, even after repeated trials, in spite of the fact that the pupil reacts satisfactorily. Such cases are probably naturally stupid and having been told that they must be blind before they can be operated upon, insist on being absolutely blind. It is unusual nowadays for a man to advise against extraction because of extreme old age, and the results are often surprisingly good even when the patient's general condition is far from satisfactory. I wish in this connection to report briefly a private case I operated on in 1901 as the exceptional acuteness of vision in a woman eighty-five years of age is worth recording. The sight had been failing gradually in both eyes for seven or eight years. One eye had been operated on the year before I saw her and the result had not been fortunate. An ophthalmist who had examined the eyes two or three years earlier wrote me that the opacity was so far back that he had located it in the anterior part of the vitreous so that it evidently began near the posterior capsule of the lens. In the fall of 1901, as the lens was entirely opaque, operation was advised and accepted. The extraction was with iridectomy and the recovery perfectly normal. She reported in November, 1905, and the visual result was as follows: At a distance of twenty feet with a C 11 = 4/3, cylinder axis 0. She read the 20/15 line without hesitation including the last letter a B, which two-thirds of my refraction cases fail to name at this distance. She then read correctly with the exception of three letters the 20/12 line. There had not been a secondary, and the clearness of the media and healthy condition of the fundus as indicated by this vision is certainly unusual in so old a patient.

In a case of mature cataract in one eye and good vision in the other is operation advisable.

* Read before the New England Ophthalmological Society, Dec. 13, 1906.

or is it better to delay until there is a marked failure of vision in the second eye? There is naturally a difference of opinion on this point although it is probably safe to say that the majority of men advise waiting. Personally, while I do not urge operation, if the patient lives in the city or other thickly settled community, there is much to be said in its favor and I regard it as perfectly justifiable. It is not, of course, often practicable to wear a cataract glass but nevertheless the ability to see even dimly large objects approaching from the side, — electric cars, automobiles, etc., without having to turn the head as one must continually with but one eye, — is a decided gain and will be an additional protection against accidents. Especially is this so if the patient is more or less deaf and, in consequence, unable to accurately locate approaching objects by sound.

In considering the question of antiseptics it must be admitted that the ophthalmic surgeon labors under decided disadvantages. The thorough scrubbing with soap and water, alcohol, ether, etc., which is so valuable to the general surgeon in preparing his field of operation is, of course, not applicable to the conjunctival sac, and we have most of us learned by experience that unless we can make use of germicides that are practically non-irritating it is better to use nothing at all aside from irrigation with the normal salt or other mild solution. It seems impossible with our present knowledge to have a conjunctival sac free from micro-organisms, and all that we can hope to accomplish is to reduce their number or lessen their activity. During my last Infirmary service, I made use of a 25% argyol solution, using it as a collyrium (t.i.d.) for three days preceding the operation and at the daily dressings following. It does not render the conjunctival sac sterile, as shown by the bacteriological examinations kindly made for me by Dr. Vierhoff. Nevertheless, the eyes have been exceptionally free from infection and conjunctival discharge and as far as can be judged from so short an experience it is of a decided practical value. When we consider the micro-organisms found in the normal conjunctival sac, that the lids are closed and the eyes bandaged for a number of days after the operation and everything thus made favorable for their multiplication and development, it certainly seems remarkable that infections are so infrequent. The most reasonable way to account for this is, it seems to me, that the constant flow of aqueous from the anterior chamber effectually irrigates the corneal wound until union has taken place. I believe that most infections are made at the time of the operation and that the instruments which enter the interior eye are the means of infection. If this is so, it is important not only to thoroughly sterilize our instruments but to use the greatest care when passing them into the anterior chamber that they come as little as possible in contact with the outer surface of the globe. For the same reason, the fewer instruments that enter the anterior chamber the less chance of infection, and

to remove and re-enter an instrument is always to be avoided unless absolutely necessary. The cleansing of the lids and integument adjacent to the eye, the thorough scrubbing of the hands, the sterilization of instruments, bandages, etc., has, of course, become a routine practice with every operator although there is naturally some variation in their individual methods. In my private operations the instrument case, dressings, cotton, towels, bowls, droppers, bottles of collyria, in fact, everything that I am to use about the eye is placed in Shearings' Formalin Sterilizer and sterilized. My instruments, after being boiled for ten minutes, are then placed in the case, the case left open, the lamp again lighted, the sterilizer closed and not opened again until the following morning at the time of the operation. My cataract knives are an exception to the ten minutes boiling, but I dip them in boiling water for thirty to forty seconds before placing them in my sterilizer. Gowns are worn by myself, assistant and nurse; also caps with pucker-string, which cover the hair much better than any other form I have seen, and gauze masks covering the mouth and nose. These are, of course, sterilized either by steam or formalin. The mask seems to me of special importance not only for the protection of the wound but of the sterilized instruments which are to enter the anterior chamber. In this connection the experiments of Dr. A. H. Levings of Milwaukee ("Surgical Bacteriology of the Mouth," *The Journal of the American Medical Association*, Aug. 12, 1905) are interesting, and the following which I quote especially so:

"Examinations were made to determine the number of bacteria thrown from the mouth in ordinary conversation, forced, explosive expiration and in coughing.

"A plate exposed for two minutes just in front of the mouth during ordinary conversation showed 235 colonies. A plate exposed for one minute at the distance of five feet during forced expiration showed 105 colonies. A plate exposed for one-half minute at the distance of five feet during explosive expiration showed 192 colonies. A plate exposed at a distance of ten feet showed 35 colonies after five forcible coughs. A plate exposed at a distance of 20 feet showed a development of 23 colonies after ten forcible coughs. These examinations were made in a bathroom which had no ventilation and was practically free from germs, so that a plate exposed for five minutes in quiet showed the development of but three colonies. In other experiments plates were exposed at the distance of five feet and coughed at five times forcibly with one, two and three thicknesses of gauze in front of the mouth. The plate exposed with one thickness of gauze in front of the mouth showed a development of 156 colonies. The plate exposed with two thicknesses in front of the mouth showed a development of 35 colonies, and the plate exposed with three thicknesses in front of the mouth showed a development of 8 colonies."

Gowns, caps and masks are worn at my dress-

ings until the wound is well closed. An assistant or nurse removes bandages, with the exception of the pad or cotton directly in contact with lids which I remove myself. I wear rubber gloves in my Infirmary dressings as it is easier to cleanse them in going from case to case than it is the hands. The chance of infection from currents of air, open windows and doors in the operating room must not be lost sight of, though the natural protection of the eye, and short duration of the operation makes this perhaps a less important consideration than in general surgery.

To manage one's patients satisfactorily is an important factor in the success of the operation and in the making of a good operator. The personality of the operator, of course, counts for much and methods that may prove successful in one man's hands may be entirely unsuccessful in another's. In my experience, the less fuss and talk made about the operation the better. It is advisable to explain to the patient, in as few words as possible, the amount of pain to be expected, the importance of not moving the eye except when told to, of not talking, etc.; but to impress them too much with the gravity and seriousness of the undertaking is certainly a mistake. That it is "all in a day's work," an every-day occurrence with the operator and that success is the rule, is the better attitude to adopt. The management of the case should, so far as possible, be entirely in the hands of the operator. If the assistant tells the patient how to look, the nurse holds up the finger as a point of fixation or someone else offers a suggestion, it will lead to confusion. After the speculum is introduced, it is a good rule that no one but the operator should speak or in anyway interfere with the patient unless asked to. During the operation, it is well to talk quietly and encouragingly. To speak firmly or even scold an unruly patient is sometimes necessary. To lose one's temper, however, is, of course, a mistake, though the provocation that a stupid, pig-headed patient will sometimes give is almost irresistible.

As a local anesthetic, for the last few years, I have used a 1% solution of holocaine in the place of cocaine. As the effects of the latter (cocaine) pass off, there is usually more or less smarting and a general feeling of irritation that it seems to me is absent with the holocaine. As a consequence there is one less cause of annoyance at a time when the patient is naturally nervous, and so less tendency to squeeze the lids and disturb the bandage.

Being ambidextrous, I always stand behind my patient. The want of ambidextrousness certainly in no way interferes with a good operation if a man is in other respects capable, but its possession is a distinct advantage and should, if possible, be acquired.

The introduction of the speculum is a simple thing, but if the globe is pressed upon unnecessarily or the lids stretched too widely open, the patient may be frightened at the beginning and as a result restless and hard to manage during the entire operation. A most important thing

to avoid is the stretching of the outer canthus which adds so much to the discomfort caused by the speculum. After it is introduced, therefore, the arms of the speculum should be brought near enough together so that this is avoided, even if in some nervous cases it means a considerable narrowing of the palpebral aperture.

In fixing the eye, I grasp the conjunctiva a little below the cornea, which is probably the position preferred by most men. I have noticed, however, that some operators apply the forceps just beyond the inner corneal border. It has seemed to me that the conjunctiva in this region, perhaps for the reason that it is often more or less thickened in elderly people, did not yield readily to local anesthetics and that its consequent sensitiveness made it especially undesirable as a point of fixation in any operation.

In making my corneal cut, I try to confine it to the limbus from start to finish. If it is completed too far forward there is a greater liability to anterior synechia, and if it is carried backward involving the conjunctiva at any point, there may be bleeding into the anterior chamber which will often interfere greatly with the smoothness of the operation. The position of the incision is of little consequence, however, in comparison with its size, for a corneal cut that is too small is accountable for more bad results to my mind, than any other fault in technique. It is impossible to say just how much of the corneal circumference should be included, as the size of the lens may be out of all proportion to the size of the cornea. The mistake is oftenest made when the cornea is small, and if a good sized lens happens to be well sclerosed, trouble will be sure to follow.

A corneal cut is rarely too large, and it is a good rule in every case to make it a little larger than seems absolutely necessary.

In regard to the question of extraction with or without iridectomy, while I am not opposed to the simple extraction and do this operation when the conditions are favorable, I find that I incline more and more to iridectomy, as I continue to operate. A small, well made iridectomy is not a blemish and to my mind in no way detracts from the acuteness of vision. Statistics on this point are of doubtful value, as so many other factors must be considered besides the presence or absence of a coloboma. The question of prolapse of the iris is an important one in connection with simple extraction and I will here refer briefly to the condition that most strongly indicates to me the probability of this unfortunate result taking place. I think it is generally conceded that the mechanism of prolapse in the majority of cases is as follows: The corneal wound having united and the anterior chamber re-established, the lips of the wound suddenly separate from some cause and the iris is carried outward by the escaping aqueous. The point I wish to make is that in certain cases a greater tendency to prolapse exists than in others for the reason that there is a greater tendency to a separation of the corneal wound and extrusion of the anterior chamber. Also that this tendency can

usually be recognized at the time of the operation and when recognized is an indication for an iridectomy. If, after a simple extraction is completed the patient is instructed to look downward as far as possible, it will be found in the majority of cases that there is little if any tendency to a separation of the edges of the wound. In a certain number, however, a very marked separation will be noticed and it is in these cases that a prolapse is most liable to occur. For it can be readily understood that with so marked a predisposition of the edge of the wound to separate, a movement of the eye downward after the anterior chamber is re-established, but before firm union has taken place, is much more liable to result in a sudden evacuation of the aqueous and prolapse of the iris than in cases where no such tendency exists. In giving prominence to this condition as a cause of prolapse, I do not wish to be understood as believing that it is the only cause or that its general recognition will do away entirely with prolapses. I simply present it as an important causative factor that has not, so far as I am aware, received the general recognition which I am confident that it deserves.

It is perhaps hardly necessary to mention the importance of entering and withdrawing the cystotome heel first and thus avoiding any entanglement of the iris. I usually enter the anterior chamber near the right angle of my corneal wound carrying the cystotome obliquely to a point below the center of the pupil and after making the usual T-shaped opening in my capsule withdraw it obliquely to the left. Two years ago in a number of cases I divided my capsule with the point of the knife after making my puncture. It is not a difficult thing to do and in no way interferes with the proper completion of the corneal incision, if the pupil is of good size and the anterior chamber of moderate depth. My reason for giving it up was that the T-shaped cut in the capsule could not be made and there was consequently more difficulty in removing the lens. This method is, I believe, satisfactorily practiced by some surgeons, and the lessening by one of the number of instruments entering the eye is certainly a point in its favor.

In doing an iridectomy I aim to make a small one and so include as little as possible of the iris tissue in the forceps points, and cut with my scissors from below upward, that is, from the pupillary border toward the periphery.

With a good sized corneal incision, there is rarely any trouble in removing the lens, but most of us are occasionally caught with too small a wound. When the lens is a third or more delivered, the well-known method of having an assistant rotate it laterally with the iris forceps or some other instrument will often help one out of the difficulty. If it does not, a prompt enlargement of the cut or even the use of the scoop is preferable, I believe, to a prolonged manipulation of the eye. Neither does it seem to me necessary or desirable to spend much time in trying to remove small amounts of cortical. It absorbs quickly, as a rule, and much of the trouble

that it was formerly held accountable for is now more reasonably attributed to infection. If the nucleus is entirely removed a very large amount of remaining cortical causes me no anxiety, though I, of course, prefer to have it out, as absorption is not always rapid and a secondary is more often necessary. The various instruments devised for irrigating the anterior chamber have never appealed to me; first, because as I have just said, I believe the presence of cortical rarely interferes seriously with a good recovery and, second, because it means the introduction of one more instrument into the wound which I regard as a serious objection unless it contributes very materially to the success of the operation.

A source of infection in certain cases is probably the fluids — aqueous, lachrymal secretions, etc., — collected in the lower cul de sac after it has washed the conjunctiva pretty thoroughly, and is likely to be well laden with bacteria. Unless this is removed by occasional sponging the ends of the corneal wound are sometimes well bathed in it when the eye is rotated downward. Especially is it important to see that this space is well dried before removing the speculum, as the closing of the lids may force this collection over the entire length of the incision. In removing the speculum, it is also well to remember that some patients seem to take a solid satisfaction in giving the lids a good squeeze as soon as it is out or even half way out and it is therefore best to tell them when you are to do it and to caution them against closing the lids until they are told to and then to close them gently. I have always used atropine after my operations. It has never seemed to me to increase the danger of prolapse, and it is certainly an advantage to get mydriasis as early as possible.

I have used various bandages and have returned to the one I began with, the old Berlin knit bandage, as being on the whole the most satisfactory. As to after treatment, my patients are kept in bed for two to three days, the dressings changed daily, and the bandage removed permanently on the seventh or eighth day. Atropine is instilled, and, as I have already said, a 25% solution of argyrol, at each dressing. I have tried getting my patients up on the first day, of not disturbing the eye until the second or third day, of removing the bandage permanently earlier than the seventh day and various modifications suggested by other operators, but the more conservative after-care that I was taught as a house-officer, I have found to give the best results, and I think the same opinion is held by most of my Infirmary colleagues.

MOSQUITOES IN NEW JERSEY. — The bill appropriating \$350,000 for the purpose of mosquito extermination in New Jersey passed the Senate last week. The cost of draining with the processes devised by the Mosquito Department is about \$1.40 an acre. Newark last year drained 3,500 acres at an expense of \$5,000. The appropriation about to be made will dry up all the 200,000 acres of marsh land still remaining. The work, it is calculated, will take five years. — *Medical Record*.

THE EARLY DIAGNOSIS AND THE AGGRESSIVE TREATMENT OF PULMONARY TUBERCULOSIS IN A LARGE OUT-PATIENT CLINIC.

BY JOHN R. HAWES, 20, M.D., BOSTON.

THE HARM DONE TO CASES OF PHTHISIS BY THE TREATMENT ORDINARILY GIVEN IN OUT-PATIENT CLINICS.

To every out-patient clinic many cases of pulmonary tuberculosis—a great majority, indeed—come in an advanced stage when the diagnosis is far too evident, and when a single glance at the sputum suffices to confirm it. Others, however, are first seen in the early period, the closed stage of pulmonary tuberculosis, seeking relief and treatment for a troublesome dry cough or for vague general disturbances,—debility, anemia, stomach trouble, loss of weight, etc. Often there is no sputum; sometimes there can be obtained a small amount of mucoid material mixed with saliva, in which, on repeated examinations, no tubercle bacilli can be found. The signs in the lungs are slight or even apparently absent altogether. Of this class of cases some are of tuberculous stock and their general appearance suggests that they themselves have the disease. In the past, and to a large extent now, the routine treatment of these cases has been more or less as follows:

A woman comes in suspected of having phthisis but with no positive signs. She is carefully examined by the physician in charge, given potassium iodide if the sputum is scanty, and told to collect her sputum and return in three days. This is generally done. If the sputum is positive she is at once started on whatever line of treatment is thought best; if not, as is often the case, the patient is given careful directions by the house-officer about the need of fresh air, general hygiene, etc., she is supplied with iron if anemic, malt or cod-liver oil, and told to return again in a short time. This is sometimes done. Too often, however, she goes home, improves temporarily under treatment, but, making no radical changes in her method of living and gradually forgetting the warning given by the doctor at the hospital that she must return and be examined again, she soon goes back to her old ways, and when she returns to the hospital, months later if she ever does, is in an advanced stage of consumption.

It is the diagnosis of this class of cases that is difficult. In this country physicians are far too prone to delay treatment for tuberculosis until the bacilli are found in the sputum. Patients are seen and examined and then told to return again with their sputum without having the reason for this procedure explained or the difficulty of the diagnosis made clear. This is continued until the patient wears of what is to her a useless task and does not return. Admitted that an absolute diagnosis of pulmonary tuberculosis is not possible until bacilli are found, yet a diagnosis so very probable as to justify immediate energetic treatment is possible while the disease is still in the closed stage. The unfortunate re-

sults of waiting for localizing signs and for bacilli to appear in the sputum is shown by the following case:

Grace T., a young woman of thirty, first came to the hospital in April, 1898, complaining of a slight cough and a pain in her chest. She felt weak and tired. One sister had died of consumption in 1895, but until recently she herself had been well. Her hemoglobin was 65%, her temperature 99°. The heart and lungs are recorded as negative. She was given Bland's pills. She did not return until five years later in September, 1904. In the meantime, one brother had died of tuberculosis in 1903, as well as the sister in 1895. The patient said that for nine months she had been troubled with a pain in her chest and a bad cough which she had had off and on since her last visit. She was weak and tired. As before, her hemoglobin was 65%, and her temperature 99°. Over the left upper lobe there was prolonged expiration and an occasional fine rale. She was given potassium iodide and told to come back with her sputum. She did this, and on four separate examinations over a period of four months no tubercle bacilli were found. The same dry troublesome cough continued. In January, 1905, she was treated for a slight erosion of the cervix. July 7, 1905, she came again complaining of the same cough that she had had for the two years before. Bacilli were at last found in her sputum and signs of a small consolidation at her left apex.

In this case no active measures to combat the tuberculous process were taken until July, 1905, when the sputum was positive for the first time, although in view of the family history and the physical signs the diagnosis must have been more than probable nearly one year previous and suspected at her first visit five years before.

This case is a similar instance.

John W., thirty, single, came to the Out-patient Department Dec. 14, 1903, with a simple sprain of his back. He said he had been treated there for a cough five years before. He weighed 143 pounds. The lungs showed an occasional rale in the posterior portion. The sprain was soon relieved by strapping. Ten months later, in September, 1904, he returned, complaining of a pain in his chest and a cough with bloody sputum which he had had for four days. Except for this he felt perfectly well. His weight was 147 pounds, six pounds under that of a year before. His temperature was 99.2°. The lungs are recorded as negative. He was given a cone and told to return with his sputum. He did not come again until five months later in February, 1905. His cough and the pain in his chest were worse and he had lost seven pounds in the last two months. There were a few rales at both apices. He was given advice, a cough mixture and told to return with his sputum. This he did not do. Five months later, July, 1905, he returned with a very bad cough, having had repeated hemorrhages, very weak and emaciated. His entire chest was dull except at both axillae and there were moist rales all over. No tubercle bacilli were found in his sputum but chest films were present in large numbers. He was sent to the Free Hospital Consumption, where a few months later he died.

In this case the unwisdom of waiting for a positive diagnosis of phthisis and to treat the patient as a consumptive until the disease had appeared in the sputum is demonstrated in his life. In addition to this the mistake was made,

which the writer considers a grave one, of giving medicine, a cough mixture or a tonic, when the patient was told to bring back his sputum. He got the medicine for which he came and was unwilling to bother about his sputum.

THE NECESSITY OF EDUCATING THE PATIENT.

The grave difficulty of handling this problem is not that there is any lack of willingness on the part of the physicians—they are glad and eager to do all in their power—but that the patients will not co-operate with the doctor in his efforts to get at the trouble. They come for medicine which will cure them; when they get it they go away satisfied.

During the past summer in the service of Dr. J. H. Pratt in the Medical Out-Patient Department of the Massachusetts General Hospital, the writer was placed in charge of all the tuberculous or suspected tuberculous patients who entered the clinic. There was a large corps of assistants, intelligent and conscientious fourth year students, to each of whom every morning was assigned one or more new cases. The student made a careful physical examination of his case, taking pulse, temperature and respiration, examining urine and, when necessary, blood and sputum. Complete notes were written and the case demonstrated to the physician in charge or to his graduate assistant; after this, if the patient were suspected of having phthisis, he was handed over to the writer placed in charge of this department. Here, by means of a most detailed examination, by the use of tuberculin, x-ray, and chest measurements, and, most important of all, by trying to educate and to interest the patients so that they might realize the true state of affairs, work with the doctor and appreciate what he was trying to do, more encouraging results have been obtained; more early diagnoses have been made, and patients have returned for repeated examinations more often than before. Of the many cases in which tubercle bacilli were found in the sputum at once or after a few examinations no mention will be made. These were immediately started on whatever line of treatment that was best suited to them,—sent to Rutland, Tewksbury, or Long Island, or given hygienic open air home treatment as carried on by the Emmanuel Church Tuberculosis Class. The diagnosis once decided upon, no prolonged attempt was made to treat these cases of consumption in the Out-Patient Department itself. The methods used in other cases where there was no sputum, or, if present, no bacilli to be found in it, will be given more in detail.

Fever.—The temperature of most of these early cases is normal when it is taken at the hospital in the morning. In order to find out whether there was any fever, however little, at night, each patient was told to provide himself with a thermometer and was shown how to use it. He was then told to take his temperature night and morning for a few days and to return for further examination. In this way much valuable information was obtained and the way made

easy for giving tuberculin if this was deemed advisable. Some cases were not willing to get thermometers and others were not able to read them; they were in the minority, however.

Tuberculin.—As it was impossible to get beds in the hospital for this purpose, the test had to be carried on in the Out-Patient Department and the very obvious difficulties combated as best they could. The preparation used was Koch's old tuberculin made under the supervision of the German government and recently imported to this country. This was made into the proper dilution at the hospital, before each injection, by Dr. Pratt and the writer. Each patient had previously bought a thermometer or had been provided with one and he was shown how to use it; he was instructed to put it in his mouth for five minutes every two hours, not to shake it or disturb it in any way, and, after remaining quietly at home for twenty-four hours, to return to the hospital. A few patients, especially among the women, could read and record their temperatures; these brought in carefully written reports. The temperature in all cases had been normal previous to injection. In only a few cases was the result a positive one, but these few justified its use. In no case could it be seen that the slightest harm was done.

The following rather striking case in which the diagnosis was made after the use of tuberculin is of interest:

John H., twenty-two, single, came to the hospital July 5, 1905, with his mother who said that he had coughed for three months and at times had raised bloody sputum. The young man himself said that he was perfectly well and he certainly looked so. His temperature was 98° and his pulse 75. There was an occasional dry squeak in his right upper chest. The sputum was very scanty; no tubercle bacilli could be found in it after repeated examinations on different days. He was given 1 mg. of tuberculin and instructed how to take his temperature. The next morning he returned having a temperature of 99.5° six hours after the injection. On listening to the suspected right apex, instead of a rare, dry squeak, numerous fine, moist râles were heard, in other words a definite *local reaction* had taken place. While breathing deeply he raised a single homogeneous mass of muco-purulent sputum, one preparation of which showed eighteen tubercle bacilli. He joined the Tuberculosis Class, sleeps in a tent on his roof, has gained twenty-five pounds and is now ready to work.

Out of the 17 cases in which tuberculin was used, a definite positive result was obtained in four.

X-ray.—The x-ray was used whenever possible. In a few cases distinct help was obtained from it, especially as regards the movements of the diaphragm; it was found in practically all cases, however, that the limits of diaphragmatic excursion could be as accurately localized by careful percussion at the end of deep inspiration and expiration as by the use of the fluoroscope. The writer is therefore convinced that, except in the hands of experts, the x-ray is of very little value as an aid to the early diagnosis of tuberculosis.

Mensuration.—The chest of each patient was measured according to the methods used by Lawraon Brown and others. The circumference at the fourth rib on expiration and inspiration and also of each half separately was taken; the excursion of the diaphragm at the base of each Litten's sign was noted. One series of measurements of the chest contour was of special interest. The apparatus used for this purpose was the pectorimeter invented by Zander of Sweden, a complex but extremely beautiful and accurate piece of mechanism, by means of which the exact shape and size of the chest on both inspiration and expiration can be graphically shown on charts. One of these machines is now in the Department of Mechano-therapy at the hospital and with it the measurements were taken under the supervision of the director, Dr. Max Boehm.

Spirometry.—Late in the season by means of the spirometer, the vital capacity of each patient was measured. The small lung capacity of these early cases as recorded by this machine agreed with the other measurements which were taken, showing a restriction of the respiratory movements, in contrast to cases of cough not due to tuberculosis in which the lung capacity was very much greater in proportion. As with tuberculin and x-ray, while it was not often that mensuration, in the writer's hands at least, was a very large factor in making a diagnosis, yet in almost every case it formed one link in a chain of evidence, the sum total of which was enough either to make a negative diagnosis or a positive one of phthisis sufficiently probable to warrant immediate energetic treatment.

THE PERSONAL ELEMENT IN EFFECTIVE TREATMENT.

The object of this paper is not to throw any new light on the early diagnosis of tuberculosis as a whole, but to show the way that last summer's work has convinced the writer that these cases in the closed stages should be handled in a large clinic. In addition to the use of detailed methods of examination, and in his opinion of far more importance under the circumstances, is the fact that all of these cases were in the hands of one man who did nothing else at the clinic and who had plenty of time to go into every detail of the patient's past life and present surroundings. He was able to examine their chests and vital functions in every way; he could take the patients aside and carefully explain the difficulties of telling by one or two visits exactly whether he or she had or had not tuberculosis and he could show the importance of an early diagnosis. After the first visit the patient knew to whom they were to report and had a personal interest in their doctor. They did not have the long hours of waiting nor were they examined each time by a different man with new methods and ideas. The objection may be raised that this is taking the most important group of lung cases out of the clinic and forming a separate department. This is not so. Every new patient was first examined by a student assistant who

then, if necessary, handed the suspected case over to the doctor in charge of that group and he in turn, as he followed it along, demonstrated it to all the workers in the clinic.

The early diagnosis of pulmonary tuberculosis requires a careful and painstaking examination with the weighing of one detail against another. A correct diagnosis can only be made from the accumulative evidence of slight and apparently insignificant variations from the normal. Mensuration, spirometry and the use of tuberculin are all of value toward this end. Early diagnosis, however, in a large out-patient clinic where forty to seventy patients are seen every morning requires more than this. In addition to detailed methods of examination the *personal element* must be brought in. The physician must get acquainted with his patients, tell them what tuberculosis is and explain what he is trying to do; in other words, he must educate them. This is the real secret of a successful solution of the problem.

SUMMARY AND CONCLUSION.

1. By waiting until the diagnosis of tuberculosis is proved by the demonstration of tubercle bacilli, those in charge of out-patient clinics are sometimes responsible for the death of the patient.
2. Careful temperature records by the patients themselves, the use of tuberculin, mensuration and spirometry assist us to recognize the disease in the closed stage, i. e., before bacilli appear in the sputum.
3. Of supreme importance both for the early diagnosis and efficient treatment of these cases is an aggressive personal interest on the part of the physician in charge; he must himself take the initiative, educate and encourage the patient and hustle for his future good even when the patient himself is listless and indifferent.

New Instrument.

A NEW NEEDLE HOLDER.

BY J. FLETCHER BARNES, M.D., BOSTON.

THE chief objections to the needle holders in common use are two: (1) They do not hold curved needles firmly enough to prevent their turning when the tissue to be punctured is tough or thick. (2) If sufficient pressure is applied to prevent the needle from turning they usually break the needle.

It is with the idea of overcoming these objections that I have devised a new needle holder. Its principles are quite different from those of the ordinary ones and after being given a thorough test by several different surgeons, the claims made for it seem to have been fulfilled.

Its advantages are: (1) Curved needles are gripped too securely to turn over. (2) Needles are not broken. Combined with the simplicity of construction and durability

The accompanying illustrations show the mechanism of this holder. The handles and lock are like those of an ordinary hemostat. One shank is continued into a jaw, which is on the same side of the instrument as its handle, a feature in which it differs from the common clamp. This may be called the stationary shank. The other shank ends about three fourths of the way from the handles, is secured to its fellow by a screw,

FIG. 1.

and is tapered down to a point, its slopes being concave. This point bears on the convex slopes of a corresponding notch in the continuation of the shank. This continuation is pivoted at about its middle by a screw, and then continues on to form the other jaw of the instrument.

It is by this system of levers, alternating long and short from the handle, that the tremendous grip of the jaws is obtained. This leverage can be ascertained experimentally by a simple algebraic

FIG. 2.

equation. Let us consider the measurements of the levers to be as follows, said measurements being taken from center to center of each length.

From point A (center of ring) in the cut to the point B (center of screw) is 4 inches.

From the point B to the point C (point of contact in notch) is half an inch.

From the point C to the point D (center of screw) is three quarters of an inch.

From the point D to the point E (where needle is commonly held) is half an inch.

Let the pressure exerted on the handles be ten ounces. Then

$$4 \times 10 = \frac{1}{2} \times x$$

$$40 = x = 80 \text{ oz.} = \text{pressure at C}$$

$$\frac{1}{2} \times 80 = \frac{1}{2} \times x$$

$$40 = x = 120 \text{ oz.} = \text{pressure at E}$$

It will thus be seen that a very small amount of pressure exerted on the handle is multiplied many times at the jaws. In this way the powerful grip of the instrument is obtained, a grip sufficient to hold fast any curved needle.

Now with the corrugated steel jaws of the common needle holder and this magnified grip, curved,

and probably straight needles as well, would be broken every time. To obviate this I have had the approximating surfaces of the jaws faced with soft metal, the one on the single straight shank with brass; the one on the divided shank with copper.

These pieces of metal approximate the steel jaws on three surfaces and are soldered to them, thus giving added strength. This provides a comparatively soft bed for the needle of which the shape and curve is accommodated by the jaws.

For holding the larger needles I have had two notches cut in one jaw at some distance back from its point. Experimentally I found that if both jaws were lined with copper they were not as durable, and that it was sufficient to have only one of copper. The brass is soft enough to be slightly impressed by the needle and makes a much more durable bed. These pieces of soft metal have been found to wear a very long time, and when worn down too much can be replaced in a few minutes by any instrument maker, and at trifling cost. In using the needle holder it will be found more convenient to keep the divided shank uppermost, but it really makes no great difference which is on top.

In cleaning the holder the handles have only to widely separate thus throwing the pointed shank out of its notch, when all the parts can be manipulated as desired.

Clinical Department.

A CASE OF CEREBRAL ABSCESS.*

BY BENJAMIN T. BURLEY, M.D., WORCESTER, Neurologist to the Worcester City Hospital and Visiting Physician to the Neurological Dept., Memorial Hospital, Worcester, Mass.

THE following case seems worth recording on account of the extent of the abscess, its accompanying symptoms and the question of its etiology.

On April 7, 1905, I was asked to see E—D—, a boy seven years old, of whom the family physician, Dr. C. B. Stevens, gave me the following history:

The child, like its mother, had always looked pale and rather delicate but, aside from mild attacks of scarlatina and tonsillitis, had not been ill. There was no history of tuberculosis in the family. Though the boy had been in a street car accident six months previous he had escaped with no apparent injuries. Before March, 1905, he had at rare intervals complained of mild headaches and feeling tired. He had never had convulsions.

March 14, 1905, the boy in playing was thrown from a child's express wagon, striking his head on a brick sidewalk. He was a little dazed but not unconscious and a day later showed no signs of the accident except a hematoma one and one-half inches above the right eye. One week later he had a sudden attack of vomiting and was temporarily in an epileptiform convulsion with unconsciousness. A few days later he began to complain of pain in the head, especially

* Presented before the New England Psychological Society, Oct. 24, 1905.

across the forehead. This came on suddenly, sometimes making him cry out when at play, and it might leave us suddenly.

March 30. He is said to have vomited at school and came home with a headache. For the next three days he visited his grandmother. He was not active, did not eat well and had headaches. From this time until my visit the frontal headaches became more constant and the child was kept in bed, the pain being more severe with the head raised.

On examination I found a fairly well nourished boy with a pale skin. He was apparently of nervous temperament, bright and somewhat precocious. He was not complaining when under observation. The temperature was 99.2, the pulse 60. The head showed no evidence of injury, unless by slight blueness of the veins over the right forehead. The pupils were round, equal and reacted to light and distance. There was slight photophobia. The heart sounds were distinct and normal. The lungs and abdomen were normal. There was no marked disturbance of either superficial or deep reflexes. No Babinski. Sensation was normal, there being no hyperesthesia. No paralysis. No "tache cerebrale." Kernig's sign present.

On the evidence at hand I thought lumbar puncture hardly justifiable, but took some blood for a white count. Small doses of a bromide were advised to help eliminate the nervous element. For a day or two under this treatment the child made little complaint, then the headache again became severe. Having found a leucocytosis of 13,000 I again examined the boy April 11. On this date there was a leucocytosis of 18,000. The boy complained of a stiff neck and the post-cervical glands were found to be enlarged. The head was not retracted. Other than the glandular enlargement there was nowhere any local evidence of an inflammatory process. The temperature had ranged from 99.1 to 99.5. The pulse from 48 to 60. In fact the low pulse had been remarked even by the family. Though the examination was practically unchanged from before I began to take a grave view of the case and suggested a fundus examination.

On April 13, Dr. Estabrook reported that the nose and ears were normal. The optic disks, especially the right, showed a slight degree of hyperemia and had a "woolly outline," suggesting increased intracranial pressure. The next morning the child was sent to the Worcester City Hospital to have lumbar puncture performed and to be under constant observation by the surgeons. By spinal puncture 10 cc. of spinal fluid was withdrawn. It was clear, showed no cells or organisms and gave rise to no bacterial growth. For three days afterward the headache was practically absent, the appetite improved and the child seemed better. At this time there was a leucocytosis of 15,000. At times the heart beat rather hard against the chest and there was a systolic murmur at the apex, not well transmitted. Following this brief relief from pain the cerebral pressure symptoms returned worse than before. The temperature again rose, headache and restlessness increased and there were short intervals of delirium. April 21, a second fundus examination showed a noticeable increase of the hyperemia, especially of the right disk. The next morning, at their own request, the parents took the child home.

When seen two days later, the child showed rapid emaciation in spite of taking a fair amount of nourishment and was losing strength. Complete paralysis of the right third nerve appeared, producing ptosis of the lid, dilatation of the pupil and divergent strab-

ismus. The vision had already become somewhat clouded. Babinski reflex was found present on the right. April 30, it was noticed that the right arm and leg were not moved though the face was not then paralyzed.

From this time on the pulse became more rapid and irregular. Blindness rapidly became total. Tonic convulsions occasionally occurred, especially affecting the left side, with opisthotonos. The temperature was not now elevated. The child was conscious and fairly rational much of the time. Early in the morning of May 11, after a series of severe convulsions, the boy died.

AUTOPSY.

Five hours post-mortem. Body emaciated. No sign of injury about head. Cranium opened by the angular method. Dura not adherent and not abnormal in appearance. Cortex exposed by removal of dura. Venous engorgement is marked, especially over the left parietal region, and toward the Sylvian fissures slight cloudiness of the pia can be made out. The right hemisphere feels rather tense but fluctuant. No lesion of the cortex visible. Brain removal carried out from before backward and, while being manipulated, the cortex burst in right occipital region releasing about three ounces of foul pus. Base of brain showed some thickening of pia near blood vessels as well as some cloudiness. The basilar artery is hard and thrombosed. There was no crack or fracture of the skull visible. In the right middle fossa of the skull, 2 cm. from the sella turcica, is an irregular erosion 1 cm. across and involving both tables of the skull but not admitting a probe in any direction.

Spinal cord not removed.

During the autopsy cultures were taken from the cortex and base of brain and smears from the thick, viscid pus from the abscess cavity.

The bacteriological report by Dr. Hunt showed that the cultures from the meninges were sterile but the smears from the abscess cavity showed numerous streptococci in the necrotic brain tissue.

After having been hardened in S^4 formalin the brain was prepared for examination by a series of frontal sections. The abscess was found to extend from the level of the mid-frontal lobe horizontally through the central and upper portions of the right hemisphere to within 2 cm. of the tip of the occipital lobe. It reached nearest the cortex at the point where rupture occurred at the intraparietal fissure. While the main body of the right internal capsule was not actually invaded by the abscess the capsule was depressed and practically roofed by the abscess. The abscess was 7 cm. in diameter in its central portion. Aside from some compensatory distortion the left hemisphere was apparently normal.

This case has several interesting features. Here we have a boy who, following a concussion, develops symptoms of an intracranial lesion which two months later at autopsy proves to be a large focal abscess without accompanying meningitis. The point of entrance of the bacteria is not determined. Unfortunately, a general autopsy was not done, but clinically there was no evidence of a septic condition in any other part of the body. It might be hard for even a medico-legal expert to detect the part which the injury played contributory to this lesion or present.

During the last week of his life the child had a right hemiplegia, the same side as the abscess.

Though becoming early convinced that we were dealing with a purulent cerebral lesion, the difficulties of localization peculiar to this case prevented us from getting to the point of operation before the parents decided they would prefer to have the child at home. As it turned out, either an operation through the frontal bruised area, or, later, an opening over the motor area opposite the hemiplegia could not have led to the lesion.

thought the x-ray could be used with perfect assurance of safety providing caution and patience were employed in its manipulation. He was in favor of using a minimum quantity and making repeated applications, so that the effects of the ray were secured slowly and carefully. The speaker said the strength of the rays could be judged accurately by the character of the glow in the tube. Personally, he preferred a glow that was of a pale, apple-green color.

DR. THOMAS C. GILCHRIST, of Baltimore, Md., said that as the x-rays possessed no bactericidal powers, we had to depend upon their destructive action for a cure of the disease to which they were applied. In acne his results had been good, although some relapses had occurred. In lichen plants he had seen cures effected very much quicker by this method than by any other with which he was acquainted. In dealing with rodent ulcer and various other forms of malignant tumors, he was in favor of doing a preliminary curettage, as the x-ray did not have much effect upon the growth until the hard edge was broken down.

DR. S. POLLITZER, of New York City, said sufficient evidence had been adduced to prove that the x-ray was a valuable addition to our therapeutical resources, and the discussion regarding it was in general harmonious as to its indications and advantages. The speaker briefly reported two cases of epitheliomatous growths of the mucous membrane, both of which did very badly under the x-ray treatment.

DR. FRANK H. MONTGOMERY, of Chicago, Ill., said that after a considerable experience with the x-ray, he had never had any bad results from it in the way of troublesome dermatitis or burns.

DR. STELWAGON, in closing, said that in his x-ray work he always tried to employ the lowest current that would answer the purpose.

A CASE OF TROPICAL ULCERATION INVOLVING THE NOSE, PHARYNX AND LARYNX, WITH HISTOLOGICAL FINDINGS.

DR. JOHN A. FORDYCE, of New York City, and DR. W. F. ARNOLD, Surgeon, United States Navy (Retired), reported this case. The lesion was a granuloma, the nature of which could not be determined by the methods employed. It could be differentiated from others of this class, like blastomycosis, actinomycosis, rhinoscleroma and lepra by the absence of their specific micro-organisms; from mycosis fungoides by the character of the infiltrate and the absence of fragmentation. The histological picture could readily have been mistaken for tuberculosis, as the giant cells were numerous, with nuclei arranged peripherally, and many independent foci containing three or four cells were encountered deep in the corium. The existence of tuberculosis, however, seemed to be conclusively disproven by the failure of inoculations and tuberculin tests, as well as by the absence of bacilli in the secretions and sections. It was also probable that the affection was distinct from yaws. It was difficult to exclude syphilis microscopically, but the fact that the condition was influenced in no manner by large doses of iodide of potassium or of mercury, given internally, hypodermically and by inunction favored some other diagnosis.

A CASE OF MERALGIA PARESTHETICA.

DR. JAMES C. WHITE, of Boston, Mass.: The patient was a man, fifty-five years old, who became aware in July, 1905, of abnormal sensations in the skin of the outer, lower two thirds of the right thigh after an ordinary walk of four or five miles. The feelings were of a tingling nature. From that date, on standing or walking, this region became the seat

Reports of Societies.

AMERICAN DERMATOLOGICAL ASSOCIATION.

TWENTY-NINTH ANNUAL MEETING, HELD AT THE ACADEMY OF MEDICINE, NEW YORK CITY, DEC. 28, 29 AND 30, 1905.

THE PRESIDENT, DR. WILLIAM T. CORLETT, OF CLEVELAND, OHIO, IN THE CHAIR.

ADDRESS BY THE PRESIDENT.

DR. CORLETT, in his opening address, said that while the study of dermatology in this country was awakening keener interest, and was better taught than ever before, yet the character of the teaching in many schools left much to be desired. The almost general recognition of dermatology in the curriculum was an epoch in the evolution of American medical education.

ADDITIONAL OBSERVATIONS ON THE ROENTGEN RAYS IN DERMATOLOGY.

DR. HENRY W. STELWAGON, of Philadelphia, Pa., said that at the meeting of the Association two years ago he gave a résumé of his experience with the Roentgen ray treatment of various cutaneous diseases. Practically repeating, to some extent, his former conclusions, he could say now, in the light of wider experience, that we had in the x-rays a valuable addition to our therapeutic resources, but it was by no means a measure that should be used indiscriminately, or be permitted to supplant other methods equally useful but without possible deleterious effects; that its application should be extremely cautious and conservative in non-malignant dermatoses, and, excepting in extremely obstinate cases, it should be used more as an adjunct than as the sole remedy; that in malignant diseases it could be used somewhat boldly and often with the prospect of cure, or at least distinct amelioration; but that even in such diseases it might often be more advantageously employed as a helpful and supplementary measure than as the sole method of treatment.

DR. A. RAYOGGI, of Cincinnati, Ohio, said he had formerly felt very enthusiastic in regard to the value of the x-rays in dermatology, but the more he used them, the less he liked them. In psoriasis he had seen the lesions rapidly disappear under the use of the rays, only to reappear in the course of a couple of months. The same was true of its use in other skin diseases.

DR. M. B. HARTZELL, of Philadelphia, Pa., said he had seen numerous cases of acne and other skin diseases where a cure was effected with the x-ray without the production of a dermatitis, but in view of the absence of any reliable method of measuring the dose, he did not see how it was possible to avoid untoward effects occasionally.

DR. WILLIAM A. PUSEY, of Chicago, Ill., said he

of a variety of perverted sensations, described as tingling, tenseness and tearing, and formication. Sometimes there were darting sensations, like the bursting of a bubble; sometimes a dull, deep pain or ache when the leg was tired. They often began as a glowing sensation in the part. They generally ceased on sitting or lying down, but might recur in such attitudes on over-stretching or violently twisting the leg. Deep pressure with the hand over the part might bring them on, and the patient was always aware of something wrong there on standing or walking. The sensations were felt every day, and interfered with his habits of exercise. They were somewhat on the increase. There was no pruritus nor feeling of constriction in the affected surface.

On inspection, it was apparent that the area complained of corresponded strictly to the distribution of the cutaneous filaments of the external cutaneous femoral nerve. The skin presented to the eye no marked differences from the corresponding region of the opposite thigh. The patient was of good habits, and had shown no indications of a faulty nervous system previously, and there had been no manifestations of organic or functional disorder, with the exception of a feeble digestion.

Meralgia paresthetica, Dr. White said, was a condition always confined to the position occupied in this case. It was first described some ten years ago by Bernhardt and Roth, and now found a recognized place in the works on nervous affections, although, apparently, of rare occurrence. We had little definite knowledge of the causation of this well-defined affection. The morbid conditions with which it was said to be often associated, namely, neuritis, tabes, rheumatism, gout and alcoholism, were absent in the case reported by the speaker. The condition seemed to be outside the control of remedies, although massage had given partial and temporary relief in some cases.

THE INCUBATION PERIOD OF SYPHILIS.

Dr. ARNOLD POST, of Boston, Mass., read this paper. He stated that our knowledge of the incubation period of syphilis depended upon clinical observation, and the results of experimental and accidental inoculation. Clinical observation in this matter had the peculiarity that it was based not upon what the observer saw, but entirely upon the statement of the patient. Very few patients were at all reliable as observers. They forgot exact dates, and were influenced by their own preconceived ideas. After reviewing the sources of our knowledge on this subject from accidental and experimental inoculations, Dr. Post said that the recent inoculation of the anthropoid apes with syphilitic virus had opened up a new field of study. Melschinkoff and Roux had reported twelve successful inoculations, seven from human syphilis, upon chimpanzees. In these cases, the incubation period was reported in six as twenty-two, twenty-two, twenty-six, thirty-three, thirty-five and thirty-seven days, an average of between twenty-nine and thirty days, and none below twenty-two days. These inoculations of the human virus on chimpanzees were recognized as successful by Fournier and other competent authorities. So far as experimental inoculations were concerned, we were justified in believing that the true chancre always had a period of incubation; that this period varied within rather wide limits; that it never fell below fifteen, or possibly thirteen days, and that forty-two days was the widest limit.

Dr. J. NEVINS HYDE, of Chicago, Ill., said that with the aid of his colleague he had recorded more than two hundred cases of physicians and nurses who had been the victims of extra-genital chancres, and

the period of incubation in those cases coincided very closely with the conclusions reached by Dr. Post.

Dr. RAYCOTT said that the incubation period probably depended to some extent upon the quantity of the virus or germ with which the patient became inoculated.

Dr. ROBERT W. TAYLOR, of New York City, said that the cases on record in which the incubation period of syphilis was given as ten days or less were perhaps based upon the presence of broken-down herpetic vesicles, which were mistaken for beginning chancres. At all events the question would probably soon be definitely settled by the results of the experiments that were now being carried on with the anthropoid apes.

NOTES ON THE TREATMENT OF EPITHELIOMA BY MEANS OF CAUSTIC POTASH.

Dr. ARTHUR VAN HARBURG, of Philadelphia, Pa.: The author's conclusions on the subject were as follows:

(1) A certain number of cases of epitheliomata of the skin were best treated by means of caustic potash. (2) These cases comprised the small, well-defined, pearly lesions, from 3 to 1 or even 2 cm. in diameter, chiefly found upon the face and adjacent parts. (3) Larger lesions were best treated by the x-rays, but here caustic potash might be used to soften and dissolve the horny epithelium, and perhaps in some cases as an adjuvant. (4) In cases treated by caustic potash, the use of the x-rays did not appear to hasten the process of reparation, or to modify the cicatrix resulting from cauterization.

THE LIFE HISTORY OF A CASE OF MYCOSIS FUNGOIDES.

Dr. GEORGE T. JACKSON, of New York City, said that through the courtesy of Dr. F. S. Hope, of Portsmouth, Va., he had had the privilege of noting the clinical course of a case of mycosis fungoides from its beginning to its lethal ending. The patient was an unmarried woman, thirty-three years old, a native of the United States, and a person in easy circumstances. Her father had an epithelioma of the face, and many of his family were rheumatic. When Dr. Jackson first saw the patient, on Nov. 27, 1901, she was spare of flesh but in general good health. The only organic disease of which she complained was an irritability of the bladder. The duration of the mycosis was exactly five years. The disease first showed itself in August, 1900, and the patient died in August, 1905. The eruption was macular and scaly, with but slight tendency to tumor formation. Pruritus was a marked feature of the case. The application of the x-rays controlled the pruritus and caused a disappearance of the lesions, but produced excessive hyper-pigmentation of the skin, and possibly an exfoliative dermatitis. A chronic enteritis caused death by exhaustion.

To be continued.

SECTION ON GENERAL MEDICINE OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

STATED MEETING, JANUARY 8, 1906.

THE PRESIDENT, Dr. SAMUEL McC. HAMILL, IS THE CHAIR.

CLINICAL EXPERIENCES WITH ENDOCRINE GLANDS.

Dr. GEORGE DOCK, of Ann Arbor, referred to the frequency of simple goitre in Michigan, and its milder grades, and said that exophthalmic goitre also seemed to be unusually prevalent. Out of about

4,000 medical patients, 32 had exophthalmic goitre. Cretinism and myxedema are rare in that section. Twenty-nine of the cases were women, three men. All had distinct cases of Graves' disease, though some had been incomplete part of the time under observation. The youngest was nineteen, the oldest fifty-five. The histories gave comparatively little proof of the relation of shock, worry, care, etc. In twelve cases there was a goitre long before the other symptoms came on, from three to thirty-seven years. Goitre was present in all cases, but small in three, and not known to the patients in some others. The conditions of the heart, great vessels, eyes, skin, nervous system, etc., showed no great departure from the well-known type. Blood pressure observations showed a great difference in systolic pressure. In many cases it was high, up to 160 to 180, and others as low as 100. There was no great change of blood pressure under treatment. The blood showing anemia in comparatively few cases, the most striking feature being relatively few leucocytes. Observations on gastric juice showed hypochlorhydria in a number of cases, with good motility but low peptic power. One patient died from the disease; one died from pelvic suppuration. Of 14 still under observation or heard from the disease showed considerable variation in duration. Several patients are well enough to do their usual work, but none are entirely free from signs. Dr. Dock spoke of the importance of careful diagnosis in mild cases; many that can be readily detected are treated for anemia, nervous prostration, palpitation, etc. Dr. Dock spoke briefly of the pathology and pathological anatomy and of the prognosis. Under treatment he called especial attention to the importance of rest, diet, rational mode of life and systematic treatment as indicated. Some experiments with thyroidectomy and other organic products were described, showing that none of these substances are as yet satisfactory. X-ray treatment was used in two cases, with very little effect on the goitres and none on the other symptoms.

DR. JAMES TYSON discussed the

MEDICAL TREATMENT OF EXOPHTHALMIC GOITRE

which he said was, at best, unsatisfactory, because there could be no scientific treatment so long as there was a limited definite knowledge of its pathology. If, as seemed probable, the disease was due to a deranged secretion of the thyroid gland, experience with analogous diseases suggested the possibility of the discovery of an antitoxin which would counteract the symptoms. This idea was strengthened by the results of the studies of Drs. Rogers and Torrey, of New York City. On the other hand, it was well known that cases of exophthalmic goitre recover without the aid of such specific agent. In his experience he had known of but one fatal case. Many cases had passed from under his observation either totally or partially unrelieved. In the treatment he stated that patients should have rest, and protection from excitement. In mild cases of short duration this alone might effect a cure. Alcoholic stimulants and stimulating indigestible foods are contra-indicated. Food, however, should be nourishing. Prohibition might sometimes extend to tea and coffee. Sexual indulgence should be disjoined. The bromides and digitalis should be given in moderate doses at first; indeed, massive doses are contra-indicated, and if the tachycardia does not subside under moderate doses of digitalis or strophanthus, they should be discontinued. Ten or fifteen mm. of the new tincture three or, at most, four, times a day should not be exceeded. Of the bromides 15 gr. four times a day

was considered the maximum dose. He has found veratrum viride in lieu of digitalis to act well in conjunction with bromide; in like manner aconite may be expected to be of service where there is strong cardiac action. He has had no experience with ergot. Belladonna is useful in certain cardiac cases and he especially advocates the use of a fresh belladonna plaster over the region of the heart.

He quoted Prof. William H. Thomson as ascribing Graves' disease to gastro-intestinal ptomaine poisoning, due to excessive meat ingestion, and, accordingly, insisting upon the absolute restriction to a milk diet for two years.

The undoubted relief afforded by operative treatment in certain instances, on the other hand, would seem to show that if the symptoms were due to a toxin, that toxin is developed in the thyroid gland itself. Among other special treatments was mentioned that by suprarenal extract recommended by Dr. James C. Wilson, in the tablet form, 5 gr. at a dose. Treatment by thyroid extract, theoretically, should make the disease worse, and experience tends to confirm this, though such result has not been invariable. On the other hand, reference was made to some evidence that thymus extract has seemed to be beneficial in 10 to 15 gr. doses. Reference was made to the efficacy of nuxvomica in a case under the care of Dr. Hunsberger, of Skippack, Pa. Dr. Tyson would expect codeine to be superior to opium. Iodides were mentioned as of doubtful value, but iron and arsenic should be beneficial. He has been rather skeptical of the results claimed for electricity and he has had no experience with it. Brine and Naheim baths he would expect to be helpful, and probably, too, massage, although the latter should be gentle at first and discontinued if not well borne. The rationale of all measures recommended other than antitoxic must be that they are such as maintain the healthful functions of the organism, while it is its excretory organs casting out the toxic agencies which are responsible for the disease. The operative treatment and the antitoxic treatment when discovered does this more promptly, but some 14th, it is said, perish of the operation.

DR. W. G. MACCALLUM, of Baltimore, discussed the

PATHOGENESIS OF EXOPHTHALMIC GOITRE

and said that the weight of evidence is in favor of the view that the thyroid plays a predominant rôle in Graves' disease. The changes in the thyroid, however, are due to another primary cause. Several recent authors have claimed that there is no specific histological alteration of the thyroid in this disease (Reinbach, Kocher), but in the series under Dr. MacCallum's observation the well-known changes have been constant, but not always in the same intensity. In some early cases or in mild cases the change is focal, small patches of tissue showing the irregular alveoli, high epithelium and loss of colloid, while the surrounding tissue is practically normal. Such changes might be overlooked, especially if the patient had also a colloid goitre, as so often occurs in Switzerland. He thought it difficult to prove that the thyroid secreted more actively than normal, but the histological appearance is that of thyroid tissue which is hypertrophied in response to the operative removal of a large portion of the gland. Further, the blood supply, he said, was excessively rich, and further administration of thyroid extract to these patients causes an exacerbation of the symptoms, while excision of part of the gland relieves them.

He stated that no conclusions could be drawn

relative to the amount of colloid secreted by observing coagulated material in the lymphatics, for that is probably lymph plasma. Breuer, he said, claims that the symptoms of exophthalmic goitre may be simulated by chronic iodine poisoning and that even the whole clinical picture may be so produced. The solution of the problem of the function of the thyroid, he believes, probably depends upon the elucidation of the relations of iodine in the body. The primary cause of Graves' disease, he thought, seems to be some injurious agent or irritant which by causing destruction of part of the thyroid cell will cause the remainder to hypertrophy. The acute thyroiditis occurring in the course of infectious diseases might produce this effect and such infections are found to have occurred in a considerable proportion of the cases before the onset of the symptoms. Insufficiency of the parathyroid glands plays no part in the production of the disease.

Dr. JOSEPH C. BLOODGOOD, of Baltimore, discussed the

OPERATIVE TREATMENT OF EXOPHTHALMIC GOITRE.

A paper upon this aspect of the subject is shortly to be published in full by Professor Halsted.

Dr. WILLIAM OSER expressed his pleasure in meeting his "old chum," Dr. Dock, and his friends in the college. Regarding exophthalmic goitre he expressed his belief that medical treatment was not instituted sufficiently early. Since the disease was a serious one, not often cured and a distressing one to the patient, he thought it worth while, just as soon as the symptoms were manifest, to subject the patient to a rigid, thorough, systematic treatment of not less than three months' duration, in bed at rest, in the open air, ice bag on the chest and "drugs" — according to your taste. These he considered to be the essential features in the medical treatment of the disease, and this treatment yielded results, in a remarkable number of patients changed to fairly robust health. In the extreme cases, however, he believes that the surgical treatment offers by far the best hope of permanent cure. Personally he had been much gratified at the results obtained by his surgical colleagues in the cases which he had turned over to him, and thought it, probably, one of the most remarkable things in life to see within twenty-four hours after operation a patient transformed from a quivering bundle of nerves with a high degree of feline restlessness and a heart at 160, to a composed, quiet, rational individual, such as Dr. Bloodgood would remember in one of two remarkable cases of extreme Graves' disease of the most advanced type. He regarded the operation as a very critical, prolonged and dangerous one, and said that "when we physicians are handing over our very precious and increasingly diminishing number of patients to the surgeon," it was a very important question that the surgeon operating in exophthalmic goitre should know his business. He pointed out the extreme danger of operation under general anesthesia. It should be remembered that the fatal results following operation were not always due to the operation or to the surgeon, for in a certain limited number of cases there might be acute toxemia.

Dr. Dock, in closing the discussion, expressed his thanks for the kindly reception of his paper, his pleasure in hearing Dr. Bloodgood's description of the surgical treatment, and in having heard Dr. Oser who had put the matter in his own inimitable way.

He referred briefly to the subject of iodism, which he said was an extremely important symptom in the middle of the last century because of the use of iodine

for all sorts of diseases. An enormous literature had been developed in which might be seen pictures of acute exophthalmic goitre. By one authority this had been attributed not to the iodine but to a poison derived from the thyroid.

He emphasized Dr. Oser's caution for care in the selection of the surgeon who should operate in exophthalmic goitre. While heartily in favor of surgical treatment in certain cases he felt that the disease was one in which in certain other cases much could be gained by medical treatment.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

EIGHTEENTH ANNUAL MEETING HELD IN LOUISVILLE, KY., DEC. 12, 13 AND 14, 1905.

(Concluded from No. 13, p. 353.)

THE SURGICAL TREATMENT OF FLOATING KIDNEY; POST-OPERATIVE RESULTS.

Dr. FLOYD W. McRAE, of Atlanta, Ga., argued for surgical intervention rather than attempted support by bandages or corsets, but urged careful selection of cases for operation and the recognition of correction of associated pathological conditions. Especial attention was called to the frequent coincidence of floating kidney and chronic or recurring appendicitis.

The author described a new muscle-splitting operation, delivery of the kidney, partial decapsulation, the making of a broad quadrilateral suspensory ligament, by dissecting forward the fibrous capsule from near the hilum to beyond the convex border of the kidney. A mattress suture was put in each angle of the capsule, near the hilum, from which the suspensory ligament had been dissected, and including the reflected flap from either pole of the kidney. These sutures were passed deeply into muscles of the back, high up, so as to bring the kidney well into the hollow of the loin and close up to the twelfth rib. The quadrilateral suspensory ligament was next brought up between the separated muscles and held there by two silkworm gut sutures passed through all the structures from within out. A cigarette drain was placed between these sutures and the remainder of the wound closed in layers with interrupted catgut sutures. Care was taken to avoid injury to diaphragmatic and iliohypogastric and ilioinguinal nerves. The operation was illustrated by drawings. Twenty-two cases were reported.

CHRONIC ENDOCERVICITIS, A NEW METHOD OF TREATMENT WITH NEW INSTRUMENTS.

Dr. DANIEL H. CRAIG, of Boston, Mass., said that the diagnosis was made to depend upon the condition of contraction or relaxation of the internal os. If with an ordinary Simpson or Sims uterine sound, distinct resistance was encountered at the internal os, in the absence of flexions, the inflammation was confined to the tissues external to the internal os. If, on the other hand, the internal os was distinguished with difficulty or not at all, because of its relaxation and wide caliber, the inflammation was above the internal os, which was thus widely dilated to favor free drainage and to guard against back pressure. Treatment by Craig's method should be strictly confined to those cases in which the internal os was distinctly contracted.

The author's treatment, or operation, consisted in inserting the cervical canal up to, but not beyond the internal os with a specially designed dilator, and dilatation of the external os with a conical dilator, also specially designed for this purpose. The opera-

tion was quickly and easily performed at the office of the gynecologist without the use of anesthesia, except occasionally a few crystals of cocaine at the external os, and without confinement to bed. The pain, when done without cocaine, was about the same as that due to the filling of teeth.

Inasmuch as the most rigid asepsis was requisite to render such ambulatory treatment safe, the author did not offer this little operation for the use of those not thoroughly familiar with surgical and gynecological manipulations, but for those who were able to establish and maintain a rigid asepsis.

The preparatory and after treatment consisted of three 1-5,000 formalin douches daily for three days before and for ten days after the operation, with avoidance of unusual exertion and abstinence from sexual relations. The cure was prompt and complete, only a relatively very few severe cases having required more than the original curettement.

Tubo-ovariitis or other concomitant disease, which might be aggravated or lead to a recurrence, constituted a contra-indication to treatment, except as an immediate preliminary to radical operation.

The treatment was not intended as a substitute for tracheloplasty, nor for uterine curettement in cases in which the disease had invaded the corporeal endometrium. The use of the author's method should not be attempted until the original paper had been read in detail.

FRACTURE-DISLOCATION OF CONDYLES OF THE FEMUR WITH BACKWARD LUXATION OF LEG.

DR. GEORGE S. BROWN, of Birmingham, Ala., reported a case in which he did an open operation seven months after the receipt of the injury. He resorted to subperiosteal resection of the fragments with reduction in wiring, which resulted in the cure of a bad deformity, and the limb of the patient was now normal except for half an inch of shortening.

The patient, aged fourteen, was injured in a football game at a small college, and was treated for three months for sprained knee. A skiagraph revealed fracture, dislocation of condyles. He walked for four months after this, with bad valgus and flexion of the leg on the thigh, before submitting to an operation. The limb and knee joint were restored to normal. There was bony union of the fragments in their dislocated position. Through a four-inch incision down the inner aspect of the femur, the lower end of which stopped short of the level of the knee joint, the periosteum was cut through and pushed downward, the union chiseled through, the broken surfaces resected and the leg brought forward on the thigh without opening the joint. The fragments were wired and the internal lateral ligament closed with kangaroo tendon. The skin was closed with a subcuticular suture of silk-worm gut. Owing to the first dressing being left too long, there was a superficial infection which did not interfere with the final good result.

THE TECHNIQUE OF APPENDICITIS.

DR. W. P. CARR, of Washington, D. C., said that no disease presented more varieties and more grades of severity than appendicitis. There were all shades between a mild catarrhal attack and a severe gangrenous case with diffuse peritonitis. It was apparent that no one method of operating would suit all cases. Surgeons must modify the technique to suit the case and the strength of the patient. In his first 100 cases he had 8 deaths. In his last 72 cases he had had but 2 deaths, and he believed the improvement in mortality was due to a fuller knowledge of the condition of the

patients and a suitable adjustment of the technique to those conditions.

For practical purposes he divided all cases of appendicitis into four classes: (1) Unruptured, uncomplicated. (2) Unruptured, complicated by other serious disease, such as nephritis, tuberculosis or myocarditis. (3) Perforated or ruptured—first thirty-six hours; patient in good general condition. (4) Perforated or ruptured—after thirty-six hours; complicated by diffuse peritonitis or by asthenia from long illness, or by other serious disease; patient in bad general condition.

Each class was discussed at considerable length.

As to the incision, it should always be either the gridiron or through the rectus muscle; otherwise, hernia was very liable to follow. There was but one objection to the gridiron incision; namely, it could not be greatly enlarged without cutting across the fibers of the internal oblique and transversalis muscles. This, he thought, should never be done. It was better to close the wound and open again through the rectus muscle if a very large opening became necessary. However, if this incision was well placed, it might be stretched with the fingers and a fairly large opening made through which any uncomplicated operation might be done. The stretching should never be excessive, as paralysis of the stretched muscle fibers might result, and hernia follow.

NEGLECTED APPENDICITIS.

DR. CHARLES M. ROSSER, of Dallas, Tex., conceded the safety of an acutely inflamed appendix while the pathology was limited to the structures of that viscus; but the serious mortality following cases not so treated justified a classification of those passing the initial stage as being neglected, whether the delay was due to indifference, ignorance or cowardice, and whether the responsibility was upon the family, patient or medical adviser. The safe time limit would vary with the character of the attack of inflammation, the skill of the operator and the resistance of the individual.

The author considered the question of whether to operate settled affirmatively; that when to operate was agreed to, if early, but he proposed the question of who shall operate and what operation shall be done.

While appendectomies were occasionally simple in performance, yet they were prospectively delicate, and the patient was entitled to the most skillful service available in each instance, and he thought the geographical distribution of competent surgeons was sufficiently general that there was hardly an excuse for an emergency operation by the attending physician if he were not so equipped.

He advised incision in all cases at all stages except those already moribund, and in which added insult to vitality would be immediately hazardous, and a class having reached complete adhesive protection, in which a relaxed rectal orifice indicated early rupture and discharge by that route. After incision the surgeon must decide whether to remove the appendix alone, removal and drainage, or whether drainage alone should be the operation of election. But as exploration could best determine an otherwise indefinite pathological progress, the patient should be given the benefit of the doubt.

LATE RESULTS IN THE TREATMENT OF INOPERABLE SARCOMA WITH THE MIXED TOXINS OF Erysipelas AND BACILLUS PRODIGIOSUS.

DR. W. B. COLEY, of New York City, gave a brief history of the development of the method, stating that he had used the mixed toxins of erysipelas and bacillus prodigiosus since 1892.

Up to the present time he had advocated the treatment practically only in cases of inoperable sarcoma, but in view of the experience thus far gained from his own cases as well as the successful cases in the hands of other surgeons, he believed it wise to use the injections in all cases after primary operation for sarcoma as a prophylactic against recurrence. In these cases, however, the dose should be much smaller, just sufficient to produce a very slight reaction, and the treatment should be continued for two to three months. He also believed it wise, in practically all cases of sarcoma of the extremities, to give the patient the benefit of a trial with the mixed toxins before sacrificing the limb by amputation. This opinion was based upon 12 cases of sarcoma of the extremities in which the treatment had been so tried, with the result that the tumor disappeared, and in 8 of the 12 cases the patients were alive and well from three to six years afterwards; two were well at the time of the last observation, at the end of one year; the other two were recent cases. Three of these 12 cases were personal cases. Eight of them were of the round-celled variety; 2, spindle-celled, and in 2 no microscopic examination was made, although amputation had been advised by prominent surgeons; 5 were sarcoma of the tibia; 1 of the fibula; 2 of the femur; 1 of the forearm; 1 of the humerus; 1 of the thigh, involving the periosteum; 1 of the calf of the leg. In all of these cases amputation had been seriously considered, but it seemed justifiable to give the toxins a trial before resorting to operation.

As to the final results of personal cases, of 34 cases which may be fairly classed as successful, in that the tumor disappeared under the injections with the mixed toxins, the type of the neoplasm was as follows: 12, round-celled, 16, spindle-celled, 2, mixed-celled, 1, epithelioma, 3, no microscopic examination made, but the clinical appearance, together with a history of recurrence, left practically no room for doubt as to the diagnosis.

The results in these cases thus far have been as follows: Four were well less than a year; 3 were well from one to two years; 3 were well from two to three years; 3 were well from three to five years; 23 were well from five to thirteen years.

In five cases a recurrence took place and finally proved fatal. In one of these recurrent cases the patient had remained well for eight years; in one three and a quarter years; in one two and a half years; in one, seven months; in one, six months.

These five cases of recurrence, the author argued, were important in that they furnished absolute proof of the correctness of the diagnosis and refuted the statements formerly often made in regard to the successful cases, namely, that there must have been an error in the diagnosis.

The writer stated that he had been able to collect 56 cases of complete or partial success obtained by other men, of which 17 were round-celled sarcoma, 11, spindle-celled, 2, mixed-celled, 3, endothelioma, 2, epithelioma, and in 18 no microscopic examination was made, or it was not recorded, but in all of these cases the clinical diagnosis was confirmed by a number of surgeons, and the patients were considered hopeless from an operative standpoint. The results in these cases were as follows: Thirteen were observed less than one year, in 6 the tumor disappeared and the patient remained well from one to two years, in 9 the tumor disappeared and the patient remained well from two to three years, in 12 the tumor disappeared and the patient remained well from three to five years, in 9 the tumor disappeared and the patient remained well from five to eleven years; in 5 cases recurrence took

place six months to two years later; 2 died during the treatment, one of pyemia due to staphylococcus infection; the other of septic absorption, the tumor being a large intra-abdominal sarcoma which had completely degenerated.

Dr. R. E. FORT followed with a paper on

LAMINECTOMY

in which he reported a case that he had successfully operated upon, with recovery of the patient.

The following papers were read by title: "End Results in Appendicitis Work," by Dr. Edward E. Balloch, of Washington, D. C.; "Two Cases of Vaginal Cesarean Section for Eclampsia," by Dr. John E. Moran, of Washington, D. C.; "Cesarean Section Necessitated by Obstruction of Pelvis by Right Half of Bicornate Uterus," by Dr. George S. Brown, of Birmingham, Ala.; "Penetrating Wounds of the Abdomen, with Report of Cases, including a Case of Traumatic Rupture of Congenital Cystic Kidney," by Dr. C. E. Caldwell, of Cincinnati, Ohio; "The Vicious Circle after Gastro-enterostomy," by Dr. John B. Deaver, of Philadelphia, Pa.; "Some of the Uses of Pelvic Massage," by Dr. Joseph Taber Johnson, of Washington, D. C.; "Recent Progress in the Surgery of the Vascular System," by Dr. Rudolph Matas, of New Orleans, La.

OFFICERS.

The following officers were elected for the ensuing year: President, Dr. George H. Noble, of Atlanta, Ga.; Vice-Presidents, Dr. Stuart McGuire, of Richmond, Va., and Dr. E. Denegre Martin, of New Orleans, La.; Secretary, Dr. W. D. Haggard, of Nashville, Tenn., re-elected; Treasurer, Dr. Chas. M. Rosser, of Dallas, Tex., re-elected.

Baltimore, Md., was selected as the place for holding the next annual meeting.

Recent Literature.

1. *Syllabus of Materia Medica*. Compiled by WALTER COLEMAN, M.D., Professor of Clinical Medicine and Instructor in Materia Medica and Therapeutics in Cornell University Medical College; Assistant Visiting Physician to Bellevue Hospital. Second edition. New York: William Wood & Co., 1905.

This small book of one hundred and eighty-nine pages is designed by its author to offer to students an outline of the essential facts concerning the more important drugs. The brief statements of the names, dosage and uses of various drugs are such as a student might compile for himself from a textbook of *Materia Medica*, and may prove useful for pocket reference. The grouping of drugs likely to lead to an exanthem, to reduce Lehling's Solution those affecting the color of the feces or the urine and those excreted in the milk may lessen the labor of the student in the compilation of such facts for himself. An addition to the previous edition consists of two new sections on Minor Toxin Actions and Toxicology. It does not conform to the new *Drugs Pharmacopoeia*.

Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition. By PROF. DR. CARL VON NOORDEN, Physician-in-Chief to the City Hospital, Frankfurt a. M. Part VII. Diabetes Mellitus. Its Pathological Chemistry and Treatment. New York: E. B. Treat & Co. 1905.

This book constitutes the lectures delivered in the University of Bellevue Medical College, New York, under the Herter Lectureship Foundation. It is the best book of the series already published. Von Noorden's book on Diabetes in German has already gone through three editions, and these lectures now published in English represent not only the most recent work on this disease, but von Noorden's experience. The book will be found by all practising physicians a most helpful addition to their working library.

Dose-Book and Manual of Prescription-Writing: with a List of the Official Drugs and Preparations and the more important Newer Remedies. By E. Q. THORNTON, M.D., Assistant Professor of Materia Medica, Jefferson Medical College, Philadelphia. Third edition, revised and enlarged. 12mo. 392 pages, illustrated. Philadelphia and London: W. B. Saunders Co. 1905.

The book is designed by the author both for the student and the practising physician. It contains the usual statements concerning the composition and strength of official as well as the more important unofficial preparations. Separate sections are devoted to weights and measures, prescription writing, dosage, etc. The appendix contains a table showing the change in strength of important preparations, with a list of average doses for adults, in accordance with the new Pharmacopœia.

A Textbook of Pharmacology and Therapeutics or the Action of Drugs in Health and Disease. By ARTHUR R. CUSHNY, M.A., M.D., Aberd., Professor of Pharmacology in the University College, London, England; formerly Professor of Materia Medica and Therapeutics in the University of Michigan; Thompson Fellow in the University of Aberdeen and Assistant in the Pharmacological Institute of the University of Strassburg. Fourth edition, thoroughly revised. Illustrated with fifty-two engravings. Philadelphia and New York: Lea Brothers & Co. 1906.

This well-known textbook, so justly held in high esteem, hardly needs an extensive review. The author's conservative attitude and his reliance upon laboratory experiment rather than on empiricism for statements made concerning the action and uses of drugs makes the book equal if not superior to any other on pharmacology and therapeutics. The present edition is brought into accord with the new (1905) United States Pharmacopœia, and includes many references to the newer literature.

THE BOSTON Medical and Surgical Journal.

THURSDAY, APRIL 5, 1906.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 and 29 BROMFIELD STREET, BOSTON, MASS.

THE QUESTION OF HOMEOPATHY.

IN our issue of last week we published two papers, one by Dr. F. C. Shattuck, of the Harvard Medical School, on the "Value of Drugs in Therapeutics," and the other by Dr. Frederick B. Percy, of the Homeopathic Medical School, on "The Homeopathic Principle." These papers were read at a meeting of the Homeopathic Medical Society, and brought forth a discussion which should do something toward breaking down barriers and removing misconceptions. It is perfectly clear that medicine, both on its practical and theoretical sides should offer a solid front against the encroachments of manifest quackery. It is also evident that so long as a body of well-trained and conscientious men stand out on the basis of a single therapeutic principle, which they claim is of fundamental importance, such a consummation cannot be attained.

The present attitude of the great majority of thinking men toward the question of homeopathy is that its law of cure has not been proved, and that even if it were proved, this would in no sense justify a so-called separate school of practice. The fundamental difficulty is not a simple difference of opinion, but rather the use put to such a difference of opinion by our homeopathic brethren in maintaining a separate school of practice, with separate medical foundations and hospitals and all the appurtenances which go therewith. Judging from the discussion, to which we have alluded, and from the practice of many of its members it seems to be the opinion of the representative men of the homeopathic school, that the law of similars has merely a

limited application, and that, after all, it is still awaiting final demonstration, by modern scientific methods.

Dr. Wesselhoef's suggestion, therefore, that tests should be made under the most equitable conditions, might, from one point of view, meet with the approval of many interested in the best development of medicine. However such tests might result, we should remain of the opinion that in the present state of medical knowledge the whole field so far transcends the application of any single therapeutic principle whatever, that the name "homeopathy," with its false connotation in the popular mind, should be given up as standing in the way of medical progress. It is, after all has been said, somewhat absurd to add the adjective homeopathic to the honored name of surgery, ophthalmology, or in fact to any other field of medical practice, which at most in minor degree makes use of the homeopathic principle of treatment. It would be fairer, and it would certainly conduce to better feeling as well as to progress, if a name were dropped which implies far more than its significance warrants, as applied to a distinctive school of practice.

The false emphasis which homeopathy places on the superficial aspects of disease as distinguished from its fundamental character is a further misfortune. However useful symptoms may be as guides to treatment, we imagine few homeopaths would maintain at this time that the symptoms are the disease, and that we have fulfilled our duty as scientific physicians in limiting our inquiries to these superficial manifestations of underlying processes. We need now, as never before, to look at the great problems of disease from a broad standpoint and not with the inevitable prejudice which a special so-called "law" of treatment necessitates. Even if we admit the contention that the homeopathic idea expresses a fact and not a fancy, we see no justification for exalting it to a position which no other legitimate method of treatment has ever demanded.

We commend to our readers' attention the following statement of Dr. Wesselhoef: "We may discuss these things late and early, we may hold to our convictions, and yet, at the same time, we shall never come to an agreement unless we positively abandon all the old facts, and deliberately set about to create new ones, and these new ones under rules that shall be recognized as scientific by the entire profession, or at least that shall govern a method of observation open

to every doubter, every believer." Could such a method of procedure be carried out in good faith, without prejudice and on a sufficiently extended scale it might remove differences. Practically we do not feel very sanguine about its results.

But at the same meeting, Dr. Perry, one of the chief speakers, quotes with approval from Dr. E. C. Price as follows: "And finally, do not forget that nothing ever yet has modified in the slightest the truth of that eternal verity, the law of similars, and, to judge from the sublime verdict of the ages, nothing ever will. Its roots dip deep beneath the dust of remotest antiquity, and its branches reach out into the empyrean of coming time, bearing its leaves to all the ends of the earth for the healing of all the unborn nations of all futurity." This jars upon our modern prosaic sensibilities. It certainly does not savor of scientific method; it illustrates the spirit to which the profession at large objects and we think with reason; it does not ring true.

BOSTON TUBERCULOSIS HOSPITAL.

A VERY definite responsibility rests upon the recently appointed board of trustees of the proposed tuberculosis hospital to be established in this city. It is definitely settled that a certain amount of money is to be expended for the further relief of the tuberculosis situation; it is as yet not definitely determined what class of patients shall be admitted for treatment; and this is the crucial point which the trustees are forthwith called upon to meet. To those who have followed the matter during the past few years of agitation, the question permits of but one answer, and that is, that a hospital must be established for chronic cases. The early cases are amply provided for, whereas the so-called incurable cases have been absolutely neglected. They have gradually been excluded from our large general hospitals where formerly they were given a grudging consideration, so that now, apart from wholly inadequate accommodations at the Long Island Hospital, and a very few beds in the city proper, they are forced to spend their last months of life in their own homes, a menace to their families and neighbors. So far as public provision is concerned, the chronic and hopeless cases have been mercifully neglected in our enthusiasm to restore the moribund case to a measure of health. This has naturally resulted in a decreasing provision for the advanced cases, a state of affairs which should not be allowed to continue, if the city is to maintain

her position as a pioneer in the intelligent fight against the disease.

The present needs are, first of all, a hospital for the hopelessly advanced cases, and, secondly, for cases too sick to be received at the Rutland Sanatorium. There is absolutely no present necessity for further provision for early cases, which can be and are admitted to Rutland. With Rutland so near at hand there is no apparent reason why Boston should have a sanatorium for early cases of its own. If only cases favorable for "cure" were sent to Rutland there would be ample room there to meet the demand. As a matter of fact many others, probably about two thirds of the hospital population, are not, properly speaking, incipient, and should be cared for elsewhere. Both because there is room at Rutland and also because it would not be economical, but the reverse, it is undesirable and unnecessary to equip a Boston sanatorium for incipient cases, and it should not, therefore, at least for the present, be considered.

If, on the other hand, we turn to the needs of the advanced and hopelessly cases, a very different situation presents itself. There is no place for them, at all equal to the demand, and these unfortunates are the very cases which are most liable to spread the disease. The late case is too sick to dispose of his sputum; the family is crowded into one or two rooms; the rooms are almost inevitably infected, and naturally the disease is spread. Such persons are apt to become city charges, and must ultimately receive city aid, thereby bringing to the treasury an unnecessary expense. These are the cases which, from every point of view, need hospital care. Quite apart from the humanitarian aspect of the question, they are virulent sources of contagion and they are often so sick that they demand the attention of those who should be wage-earners, and thereby the tendency to pauperism is increased.

Experience has taught much with relation to the care of the tuberculous classes. It has, in the first place, through Dr. V. Y. Bowditch's early work, shown that certain very early cases may be cured, and that others may be materially benefited in this climate. It has also shown the need of checking the spread of the disease by removing the sources of infection, and it is to this last task that much of the work of the future must be directed. The first step is unquestionably to provide means of isolation for the advanced cases, and this opportunity now

offers itself as never before in this community. The trustees of the new hospital should have the power of transference of patients from Rutland to a new hospital for the advanced cases, when they can no longer be benefited at the state sanatorium, and also be empowered to place such patients at Rutland as may be fit for treatment there. In other words there should be co-operation between the state hospital for incipient cases and the city hospital for advanced cases. To constitute another hospital in Boston for early cases in the present state of the problem would therefore undoubtedly be a step backward, and would defeat what should prove a most beneficent means of further combating the disease. The need of a hospital for the chronic cases cannot be exaggerated; it is the unanimous opinion of all who have looked into the problem from a broad standpoint; it rests with the board of trustees to fulfil an obligation which it owes to itself and the entire community.

MEDICAL NOTES.

BEQUEST TO GERMAN HOSPITAL, PHILADELPHIA. — Among the charitable bequests left by the will of Andrew J. Dotger, a wealthy New York merchant who died recently, is \$10,000 to the German Hospital of Philadelphia.

PATERSON OPPOSED TO VACCINATION. — The city of Paterson, N. J., appears to be rather a benighted community. The board of health recently ordered that all the teachers and all the pupils in the public and parochial schools should be vaccinated, and it is stated that, in consequence of refusal to submit to this order, twenty teachers and several hundred children have been suspended.

BEQUESTS TO THE UNIVERSITY OF VIRGINIA. — It has recently been announced that gifts amounting to \$60,000 have been given to the University of Virginia. Fifty thousand dollars of this amount is from Charles Steele of the firm of J. Pierpont Morgan & Co., an alumnus of the university, and the remaining \$10,000 from Miss Helen Gould. This latter gift is to provide a ward for negroes at the hospital, and the entire amount will be used to complete the University Hospital, which will ultimately consist of five buildings.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, April 4, 1906, there were reported to the Board of Health of Boston

the following cases of acute infectious diseases: diphtheria 46, scarlatina 46, typhoid fever 2, measles 218, tuberculosis 50, smallpox 0.

The death-rate of the reported deaths for the week ending April 4, 1906, was 19.98.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending Saturday, March 31, 1906, was 222, against 246 the corresponding week of last year, showing a decrease of 24 deaths and making the death-rate for the week 19.45. Of this number 124 were males and 98 were females; 214 were white and 8 colored; 137 were born in the United States, 79 in foreign countries and 6 unknown; 41 were of American parentage, 152 of foreign parentage and 29 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 41 cases and 1 death; scarlatina, 44 cases, 1 death; typhoid fever, 2 cases and 1 death; measles, 159 cases and 3 deaths; tuberculosis, 33 cases and 26 deaths; smallpox, 3 cases and no deaths. The deaths from pneumonia were 42, whooping cough 1, heart disease 22, bronchitis 7, and marasmus 3. There were 4 deaths from violent causes. The number of children who died under one year was 38; the number under five years, 65. The number of persons who died over sixty years of age was 50. The deaths in public institutions were 71.

There were 2 deaths and 1 case of cerebro-spinal meningitis reported during the week.

NO FURTHER TREATMENT OF CONTAGIOUS DISEASE AT RHODE ISLAND HOSPITAL. The trustees of the Rhode Island Hospital at Providence have decided that cases of contagious disease will no longer be admitted. It has furthermore been decided that a contagious ward erected on the hospital grounds by the city must be vacated on or before Oct. 1, 1906.

BILL AGAINST ADVERTISEMENTS OF VENEREAL DISEASES. The bill introduced before the Massachusetts Legislature by Dr. Richard C. Cabot and others looking to the prohibition of printing offensive details in connection with certain advertisements has been favorably reported by the Committee on Public Health. The bill is aimed especially against advertisements of cures for venereal disease with descriptions of symptoms.

BEQUESTS. In accordance with the will of the late Dr. William T. Bacon of the Yale class of 1868, and at the time of his death a resident

of Hartford, Conn., Yale University, the Hartford Medical Society and the Hartford Hospital will be the beneficiaries of his estate on the death of his widow. An amount approximating \$200,000 will be distributed between these three institutions.

GIFT FOR YALE UNIVERSITY.—It has been announced that the Anthropological Department at Yale is to be given the archeological collection of Dr. T. Mitchell Prudden of the class of '72. This collection was made in South Utah, Colorado, New Mexico and Arizona, and is made up of various fabrics, pottery, ornaments and objects of religious significance of the ancient Cliff Dwellers of those regions. Dr. Prudden also gives his notes and a map of the region covered. The collection is regarded as of very great value.

NEW YORK.

MEETING OF NEW YORK STATE ASSOCIATION FOR PROMOTING THE INTERESTS OF THE BLIND.

At a large public meeting held on March 29, under the auspices of the New York State Association for Promoting the Interests of the Blind, Mark Twain presided, the Hon. Joseph H. Choate made an address, Richard Watson Gilder presented an original poem, and a letter was read from Miss Helen Keller.

REMOVAL OF GERMAN POLIKLINIK. The German Poliklinik, a free dispensary, now located in East Seventh Street, is about to remove to the more capacious building at 137 Second Avenue, which was erected by Mrs. Oswald Offendorfer, and presented by her to the German Hospital and Dispensary Society, about thirty years ago. The Poliklinik, which was founded in 1883, is unique among the medical charities of New York in that its board of trustees is almost entirely composed of physicians.

DEATH-RATE. According to the completed records of the Health Department, which have just been made public, the death rate in the city in 1905 was 18.31 as against 20.34 in 1904. In 1903 the death rate was 18.19, the lowest as yet recorded. The lowest rate was in the Borough of Queens, 16.04. In the other boroughs the rate was as follows: Brooklyn, 17.57; Manhattan, 18.74; Richmond, 19.01; the Bronx, 20.25. The higher rate in the Bronx is accounted for by the presence of several large institutions, the majority of whose inmates are residents of other boroughs. The total number of deaths in the city was 73,714, in an estimated population of 4,024,780. The number of deaths from some

of the most prominent causes was as follows: Pneumonia and broncho-pneumonia, 9,783 (of which 4,126 were due to broncho-pneumonia); pulmonary tuberculosis, 5,535; Bright's disease and nephritis, 5,944; diarrhea and enteritis (under two years of age), 5,877; organic diseases of the heart, 5,140; violent deaths, 4,476 (of which 660 were suicides); congenital debility and malformations, 4,341; congestion, hemorrhage and softening of the brain, 2,891; cancer and other malignant tumors, 2,875; cerebrospinal meningitis, 2,025; diphtheria and croup, 1,544; 103,881 births and 6,352 still-born were reported during the year.

STATE BRANCH OF THE NATIONAL RED CROSS SOCIETY. — The Central Executive Committee of the New York State Branch of the National Red Cross Society announces that branches have now been established in New York, Kings, Westchester, Albany, Suffolk, Monroe, Oneida and Onondaga counties, and that similar branches are to be organized as soon as practicable in many other counties. The membership is composed of two classes, those who pay \$1 a year, or a life fee of \$25, and those who are willing to volunteer their services under Red Cross direction in great calamities.

JUSTICE TO A PHYSICIAN. — Before Judge McCarty, in the City Court, on March 23, Dr. Thomas E. Satterthwaite, Professor of Medicine in the New York Post-Graduate Medical School and a specialist in diseases of the heart, won a suit for \$160 for attendance in the case of Dr. Egbert Guernsey, a homeopathic physician who died about three years ago. Dr. Guernsey, who left a very large estate, was at one time prominent among the homeopaths of the city, but for some years before his death had practically retired from practice and was engaged in a number of business enterprises. The defendants attempted at first to show that the alleged services had never been rendered, and then, having been completely worsted in this contention, pleaded exemption on the score of the code of ethics of the American Medical Association, of which Dr. Satterthwaite is not a member. At the time of the latter's attendance the code had not been modified, as at present, and it certainly seemed grotesque that the old code should be advanced to cover the case of a homeopath. During the trial of the suit it was shown that both Drs. Neesen and Barclay, who, under the direction of Dr. Satterthwaite, carried out the Nauheim-Schott treatment for Dr. Guernsey,

who was affected with chronic heart disease, had presented bills and received payment for their services. Yet the estate absolutely refused compensation for the attendance of Dr. Satterthwaite, who for nearly fifteen years has abandoned general practice and devoted himself to special office and consultation work. Judge McCarty gave a very fair charge to the jury, and the latter, which was out less than five minutes, rendered a verdict for the full amount of Dr. Satterthwaite's bill.

DR. SARGENT ON WOMEN IN ATHLETICS. — At a meeting of the Public School Physical Training Society, held March 30, Dr. Dudley Sargent of Harvard was the principal speaker. In discussing the question, "What athletic games, if any, are injurious for woman in the form in which they are played by men?" he said, that in physical education women should not be expected to excel in exercises which are adapted to men; nor should they be required to teach athletics to men and boys, as is the case in some of the schools in the West. Such a requirement is not only injurious to the women, but equally so to the men. Let woman rather confine herself to the lighter and more graceful forms of gymnastics and athletics, and make herself supreme along these lines, as she has already done in esthetic dancing. Among the athletic sports and games likely to prove injurious to most women, if played in the form in which they are played by men, Dr. Sargent mentioned football, ice hockey, basket ball, pole vaulting and heavy gymnastics. These games prove injurious to women, he said, because of the limitations imposed by their physical configuration, the tendency to become masculine in form and character if they try to excel in masculine pursuits, and their inability to bear prolonged mental and physical strain. Nevertheless, such sports could be so modified as to meet the peculiar requirements of the sex, with the result that they could be played by women with reasonable hope of physical, mental and moral development. In a paper on "Athletics from a Biological Viewpoint," Dr. Luther H. Gulick, president of the Society, struck substantially the same note by saying: "I believe that athletics for women should for the present be restricted to sport within the school; that it should be used for recreation and pleasure; that the strenuous training of teams tends to be damaging to both body and mind; and that public general competition emphasizes qualities that are, on the whole, unnecessary and un-

desirable in women. Let us, then, have athletics for recreation but not for serious public competition."

Obituary.

DR. SELWYN A. RUSSELL.

By the death of Dr. Selwyn A. Russell, which occurred at his home in Poughkeepsie, after an acute illness of three days in which his physicians alternated between hope and fear, the world has lost a man who, by reason of rare mental ability, Christian character and refined personality, was beloved and respected by all who knew him.

After graduating from the Albany Medical College and studying in Vienna, Dr. Russell spent some time in travel. He was one of the intellectual men of Poughkeepsie, and his wide and intelligent view of the affairs of the world marked him as a conversationalist of unusual interest.

That those who knew him best felt that the world was better through his unselfish and spotless life, seems but a fitting tribute to his beautiful character.

Miscellany.

A MEMORIAL TO THE LATE DR. CHADWICK AT THE MEDICAL LIBRARY.

At a special meeting of the Boston Medical Library held on March 30, it was voted to accept the report of the committee appointed at the annual meeting in November to consider the subject of a suitable memorial to the late Dr. James Read Chadwick, the founder and for thirty years the librarian of the Library and to authorize the committee to raise funds to carry out its recommendations.

It is well known that Dr. Chadwick's chief interest was the periodical library. He worked early and late to complete the files and carried his want book constantly with him. Therefore the committee recommended that the periodical room be called the Chadwick Periodical Room and that a bust or a portrait of him with a suitable tablet be placed in the room.

The committee recommended further that a book fund to be known as the Chadwick Book Fund be raised to provide for the purchase of periodicals, completion of files and the housing of periodicals, a department in which the Library has always been lacking in means, a suitable book plate to be placed in every bound volume.

It was also recommended that a memorial window be placed in Holmes Hall Reading Room if the members of the Library shall approve a design presented and now to be seen in the hall.

The committee now appeals to the many friends of Dr. Chadwick in and out of the medical profession, for contributions to accomplish these

objects. A considerable sum is needed. In the single matter of the book fund it is pointed out that the purchase alone of the periodicals last year cost over \$1,500, the amount, by the way, of the Library's deficit for that year, and this takes no account of the binding. A book fund devoted to this purpose would be of the greatest assistance to the Library so dear to Dr. Chadwick's heart.

Contributions of any amount, large or small, may be sent to Dr. Clarence J. Blake, Treasurer, 226 Marlborough Street, Boston, or to any member of the committee consisting of Drs. Walter L. Burrage, Clarence J. Blake, Charles M. Green, James G. Mumford, Ernest B. Young.

"AMERICAN MEDICINE" BECOMES A MONTHLY.

As the result of action taken at the last annual meeting of the stockholders of the American-Medicine Publishing Company, *American Medicine* is to be transformed from a weekly into a monthly publication. The present able and vigorous editor, Dr. Geo. M. Gould, accompanies this announcement with the following editorial comments:

"The cause of independent medical journalism is growing more important each year, and recognition of its value and necessity is becoming more general in the profession. The professionally-owned journal conducted in the interests of untrammelled opinion and speech usually the sole medium of expression for the minorities through whom progress has always come, must necessarily encounter more difficulties than those periodicals which represent interests solely commercial, or are the mouthpieces of societies or other organizations, whether great or small. It is a matter for congratulation that there is always an emergence from such conditions into greater freedom and progress. Experience has shown, moreover, that most of what is best worth while in the profession has been accomplished through the efforts of independent professional journals, though too frequently the final details of the measures they have inspired or inaugurated must be left to the publications which, representing large professional bodies and hence more powerful financially, aided naturally with measures which have become popularized and thus represent 'majority' views. The profession is vitally concerned in the existence and power of its professionally owned journals, and a large part of this concern must be directed if it is fortified and directed to the cause of the independent medical journal. No effort should be spared to make recognition of these facts more general.

The editor needs a continuance and increase of professional sympathy and support. As a weekly, *American Medicine* has stood for the best of independent medical journals, and worse publications could be better pardoned. As a monthly it will flourish in the face of better ones and our best wishes go with it.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 24, 1906.

CHANGES IN THE MEDICAL CORPS U. S. NAVY
FOR THE WEEK ENDING MARCH 31, 1906.

J. P. TRAYNOR, passed assistant surgeon. Detached from the Naval Hospital, Boston, Mass., April 10, and ordered to the "Southern" and to additional duty at the Navy Yard, Portsmouth, N. H.

F. M. MUNSON, assistant surgeon. Detached from the "Lancaster," April 12, and ordered to the Naval Medical School, Washington, D. C., for instruction.

—SHAW, assistant surgeon. Detached from the "Southern," April 11, and ordered to the Naval Medical School, Washington, D. C., for instruction.

J. W. BACKUS, assistant surgeon. Detached from the "Hancock," April 12, and ordered to the Naval Medical School, Washington, D. C., for instruction.

B. F. JENNESS, assistant surgeon. Detached from the Naval Hospital, Navy Yard, N. Y., April 12, and ordered to the Naval Medical School, Washington, D. C., for instruction.

E. R. MARSHALL, assistant surgeon. Detached from the Naval Medical School, Washington, D. C., March 31, and ordered to the Naval Station, Guantanamo, Cuba, and to additional duty on the "Monongahela," sailing from New York April 6.

T. G. FOSTER, assistant surgeon. Detached from the Naval Medical School, Washington, D. C., March 31, and ordered to the "Chicago."

F. M. SHOOK, assistant surgeon. Detached from Naval Medical School, Washington, D. C., March 31, and ordered to the Naval Hospital, Mare Island, Cal.

T. W. REED, assistant surgeon. Detached from Naval Medical School, Washington, D. C., March 31, and ordered to the Navy Yard, N. Y., April 10.

—HOEN, assistant surgeon. Detached from Chicago and ordered home to wait orders.

H. T. NELSON, JR., assistant surgeon. Detached from Naval Medical School, Washington, D. C., and ordered to the Naval Academy, April 10.

W. S. FROST, JR., assistant surgeon. Detached from Naval Station, Guantanamo, Cuba, and ordered home to wait orders.

G. S. HATHAWAY, G. H. McCUNNOX, assistant surgeons. Detached from Naval Medical School, Washington, D. C., March 31, and ordered to the "Constellation."

J. L. TAYLOR, assistant surgeon. Detached from Naval Medical School, Washington, D. C., March 31, and ordered to the "Yankee," sailing from New York, April 4.

G. M. OLSON, E. O. J. EYTINGE, F. E. SELLERS, assistant surgeons. Detached from Naval Medical School, Washington, D. C., March 31, and ordered to Asiatic Station, sailing from San Francisco, Cal., April 14.

C. B. MENGES, assistant surgeon. Detached from Naval Medical School, Washington, D. C., March 31, and ordered to the Naval Training Station, San Francisco, Cal.

M. E. LANDO, assistant surgeon. Detached from Naval Medical School, Washington, D. C., March 31, and ordered to the Naval Station, Tutuila, Samoa.

F. W. S. DEAN, J. R. DYKES, assistant surgeons. Detached from the "Oregon" and ordered to Washington, D. C., for special duty, thence home to wait orders.

F. G. ABEKEN, assistant surgeon. Detached from Naval Station, Tutuila, Samoa, and ordered home to wait orders.

P. S. ROSSITER, assistant surgeon. Detached from Naval Station, Honolulu, H. I., and ordered home to wait orders.

E. C. WHITE, F. H. BROOKS, R. A. WARNER, P. R. STALKER, E. U. REED, J. E. MEARS, F. L. WOODS, assistant surgeons. Detached from the Naval Medical School, Washington, D. C., March 31, and directed to wait orders.

E. O. HUNTINGTON, surgeon. Discharged from treatment at Naval Hospital, N. Y., and ordered to the Naval Recruiting rendezvous, New York, N. Y., April 12.

D. B. KEIR, surgeon. Ordered to Naval Medical School, Washington, D. C., April 14, for instruction.

E. H. MARSTELLER, surgeon. Ordered to Naval Recruiting Station, St. Louis, Mo.

F. A. ASSERSON, passed assistant surgeon. Detached from Navy Yard, N. Y., April 12, and ordered to Naval Medical School, Washington, D. C., April 14, for instruction.

J. M. MOORE, passed assistant surgeon. Detached from Naval Recruiting Station, New York, and ordered to Naval Medical School, Washington, D. C., April 14, for instruction.

U. R. WEBB, passed assistant surgeon. Detached from the Naval Academy and ordered to the Naval Medical School, Washington, D. C., April 14, for instruction.

G. M. MAYERS, assistant surgeon. Detached from the "Constellation," and ordered to the Naval Medical School, Washington, D. C., April 14, for instruction.

R. H. MICHELS, assistant surgeon. Detached from the Naval Recruiting Station, St. Louis, Mo., and ordered to the Naval Medical School, Washington, D. C., April 14, for instruction.

C. K. WINN, acting assistant surgeon. Detached from the Naval Hospital, Washington, D. C., and ordered home to wait orders.

C. G. SMITH, passed assistant surgeon. Detached from the Naval Hospital, Mare Island, Cal., April 10, and ordered to the Naval Station, Honolulu, H. I., sailing from San Francisco, Cal., April 14.

J. A. GUTHRIE, surgeon. Having been examined by a retiring board and found incapacitated for active service on account of disability incident thereto, is retired from active service, March 25, 1906, under the provisions of section 1453, Revised Statutes.

RECENT DEATHS.

DR. H. HOYLE BUTTS, a well known nose and throat specialist, died on March 27, in consequence of a deplorable accident. While shaving himself he was seized with an attack of vertigo, to which he was subject, and in the act of falling gashed his throat with the razor so severely that death resulted in a short time. Dr. Butts was graduated from the medical department of the University in 1885, and for a considerable time was an instructor in diseases of the nose and throat at the New York Post-Graduate Medical School. At the time of his death he was surgeon to the Manhattan Eye, Ear and Throat Hospital and Brigade Surgeon of the New York State Naval Reserve, with rank of lieutenant-commander.

DR. ALLEN H. OLIVER, for the past eight years assistant superintendent of the Presbyterian Hospital, New York, died suddenly in that institution on March 27. He was fifty-eight years old, and a native of New Orleans. A considerable portion of his life was passed in France, where during the Franco-Prussian War he served in the Garde Mobile. On his return to America he studied medicine, and was graduated from the University of Pennsylvania in 1882.

DR. GEORGE S. DEARBORN of Rockaway, Borough of Queens, N. Y., died from pneumonia on March 26, at the age of seventy-one years. He was born in Wintthrop, Me., and was a graduate of the Albany Medical College. He served as a surgeon in the Civil War and afterwards practised for twenty-five years in Oxford, Chenango County, N. Y. In 1889, he removed to Rockaway.

Address.

THE METHODS AND AIMS OF THE PHYSICIAN.*

BY EDWARD H. OTIS, M. D., BOSTON.

THE life of the active physician deeply interested in his profession is one so strenuous and exacting, and one which makes such insistent demands upon his time and strength, that there seems to be but little leisure and energy remaining to devote to general culture or to the development and practice of any favorite pursuit or wholesome pastime—a hobby of any kind outside of his profession. He is in danger (and a danger I think it is) of merging in one both his avocation and his vocation, the man and the profession, of becoming a physician and nothing else, or, at any rate, of reversing the order, as Emerson gives it, "first, man; second, citizen, and then doctor"; or of eliminating altogether the first two while devoting his energies to the last—the doctor.

True, it may be, that he is a very successful physician, and one of much reputation. That is the laudable ambition of all in the profession; but the cultured man, the man of broad sympathies and interests is unduly dwarfed. "Professional work of any sort," says Osler, "tends to narrow the mind, to limit the point of view, and to put a hall mark on a man of a most unmistakable kind. On the one hand are the intense, ardent natures absorbed in their studies and quickly losing interest in anything but their profession, while other faculties and interests (first) unused. On the other hand, are the bovine brethren who think of nothing but the treadmill and the corn. From very different causes, the one from concentration, the other from apathy, both are apt to neglect those outside studies that widen the sympathies and help a man to get the best there is out of life.

Of course, from the very nature of a physician's work, being so constantly associated with human life in all its infinite variety, he acquires a certain broadness of view and knowledge of human life which in a sense develops the man. He can never be as narrow as the recluses or hermits. Nevertheless, unless some time and effort are devoted to self-culture, physical and mental one is likely to become "a more or less well running misshapen machine," and not "rise above the common levels of professional existence."

Furthermore, the physician, in common with all other members of the community, has a duty as citizen, the second place in Emerson's triad, doctor, "first, man, second, citizen." He owes an obligation to the community in which he resides as well as to the state and nation of which he is an integral part. He is bound to do his duty as a citizen and contribute something in influence and effort to the welfare of his community. The opportunities for doing this are manifold and always at hand. For example,

in matters of public health, the physician is peculiarly fitted by his training to be useful.

It has come to be a common observation with us how, in many cases, the practice of medicine leaves its earmarks upon the physician, and so insidiously has this taken place, that he is quite unaware of it; and, moreover, these are not altogether pleasing or attractive stigmas. Like the dry-goods clerk, whose fingers unconsciously feel for the scissors in his vest pocket when away from his counter, so the physician may exhibit the shop habits which, as I have said, are not altogether attractive, outside of his office: the anxious look, the apparent inattentive attitude, certain inarticulate expressions of approval or dissent, the uncomfortable impression of always being in a hurry, and neglect of many of the fine little courtesies in intercourse with others are some of the common shop habits into which the physician may insensibly glide. In brief, it is carrying over into the general relationships of life the professional habits, the shop; the medical machine obscures the gentleman and dislocates his manners.

Again, in professional life itself one may be content with a very narrow and inadequate conception of what the aim of the physician ought to be. The lowest aim is simply that of acquiring as much practice as possible. In addition to obtaining the practice, the next degree is to acquire as much personal skill and experience as possible; and, thirdly, and the highest aim is, while endeavoring to acquire by all legitimate means the first two, to endeavor to contribute something to the sum of medical knowledge, to strive to render some return, however small it may seem, for the immeasurable contributions of those who have preceded him in the profession, and by which he is profited.

No physician ought to regard his mental capacity, and his professional equipment so humbly, or his opportunities so restricted, as not to think himself capable of doing some original work or following out some line of investigation. To spend a little time each day in thinking on new lines will develop the habit of originality, the rest for creating if I may so express it, and stimulate independent thought. "The habit of trying to take new views of things," says Dr. Weir Mitchell, "to regard nothing stated as beyond some one's bettering, perhaps yours. . . I assure you a good plan."

The experience and available opportunities of every physician will afford abundant suggestive material for such work. To verify or refute certain accepted or suggested methods of treatment or procedure, for example, through one's own carefully observed and recorded experience, is a certain work of some value, and adds to the patient's protection as well as relieving it of that imaginary shadow of doubt sooner or later overtaking the physician who only follows the practice of practice and never goes beyond it.

The allegation has sometimes been made that the physician is less religious than other men.

*Read before the Rutland Clinical Club, Feb. 22, 1906.

that, in common with those of other scientific pursuits, he is inclined to agnosticism or skepticism: faith comes hard to him; he has so constantly to do with the seen that it is hard for him to see that which is invisible.

That such is the fact, I can hardly believe, though the exigencies of his profession may prevent him from regarding outward religious ceremonies. "Doctors, if they are men," said Dr. Gordon recently in speaking to a company of physicians, "are in the sanctuary all the time." Of all men, the physician would seem to be in constant need of a sustaining power above and outside of himself. He is so frequently confronted with situations before which he stands helpless, that he must instinctively look above and beyond himself for strength and guidance. He must so often feel his utter helplessness in the presence of disease and death, and unless he recognizes an all-wise and overruling power, life must seem to him an inscrutable enigma, and the issues of life and death the mere play of chance. The great discoverer of mediate percussion, Laennec, "affords in his life," says Flint, "an instance among many others disproving the vulgar error that the pursuits of science are unfavorable to religious faith." "Atheism in any proper sense," says Dr. Emerson, "will seldom be the goal reached by the man before whose eyes the mysterious sacraments of birth and death, and all sad and tender relations of humanity daily occur, or who, by strong lens, extends his view into the hidden region where cells wander and divide and crystals form."

In making the plea for a broad and general culture in the physician, the objection may be urged, that his energies which ought undividedly to be devoted to medicine which to-day demands so much of its votaries, are dissipated, and by becoming better all-around men, we become less skillful and learned doctors.

A moment's reflection and a reference to the careers of physicians conspicuous for their professional eminence will, I am sure, show the fallacy of this objection. Diversity of mental occupation, change in intellectual activity, is quite as necessary as variety in physical exercise. No physician can concentrate his mind upon medicine the whole time without sooner or later becoming so "stale" that his mind loses its keenness of perception and ready power of analysis and synthesis. He must needs rest the medical thought center of his brain by giving it another form of exercise. Gladstone, as we know, had an incessantly active mind, and he maintained it in healthy working condition by a diversity of mental activities. It is said that when asked how he managed to be so constantly engaged in such engrossing intellectual problems and yet retain such vigor of mind, he replied that there was one road leading out of London which was straight and perfectly level, and he had observed that more horses fell exhausted in traveling this road than by the other avenues of exit from the city which were tortuous and hilly.

Let us call to mind some of the eminent physicians who were also more or less eminent in other departments of learning; Sir Henry Thompson was a distinguished special surgeon, and he also exhibited his paintings at the Royal Academy. Dr. John Brown, of Edinburgh, besides being a faithful and beloved physician, gave us those exquisite mosaics, "Rab and His Friends," and "Marjorie Fleming." Da Costa, in this country, gave the world perhaps the best book on "Medical Diagnosis" that has ever been written, and he was also an accomplished scholar, and in his charming address on "The Scholar in Medicine," he says; "It is the scholar through whom we are linked with sympathetic interests to other pursuits." The pre-eminent scholarship and learning, *general*, as well as professional, of Osler is an inspiration and example to us all. Dr. Holmes was a professor of anatomy and an original investigator of no mean repute, and we are all familiar with his literary contributions. Of an earlier period one can mention Boerhaave, Morgagni, Harvey, Watson, Trousseau, all scholars as well as eminent physicians. Doubtless we can recall men of our own medical time, who, while devoted to the highest ideals of their profession, were learned in some other department of human knowledge, science, literature, etc.

Let us now consider a little more closely and in detail the plan of the ideal physician's life, and, first and most important, his professional methods and routine.

Of course, the daily medical work will and should occupy the greater portion of one's time. Our avocation is the discharging of our duties to our patients with the best skill we possess, ever striving for greater skill, and with the fidelity of an acute conscience. But when this is done, we have not done all that our profession demands of us. In the remnant of time which remains, something in the way of professional advancement is required of us. To-morrow and ever to-morrow must find us possessed of a little more medical skill and knowledge than to-day. Some special investigation or research in that department of medicine which, for the time, has a special interest for us may occupy this remnant of time that I have previously referred to; or the reading of the recent medical literature in the journals or reviews, or some new book upon a subject which attracts us; or the works and biographies of the past masters in our profession may bring us wisdom and broadness of thought. Though new discoveries have introduced new and what we consider modern methods of investigation and treatment (though we shall discover that some of them are not so modern after all), yet the old masters, we must remember, possessed just as acute and well-trained minds as any of the modern investigators, and we can learn much, very much, from their acute and original way of observing diseased conditions and drawing conclusions. I have only to refer to Dr. Jacob Bigelow's "Expositions of Rational Medicine," published in 1858,

and "Nature and Art in the Cure of Disease," by Sir John Forbes, published a little earlier, to illustrate what I mean.

It is not only what a writer tells about disease and its treatment which is of value to us, but often quite as much his methods of thought and analysis; it is not only the thing done, but the mechanism by which it is done; not only the completed investigation, but the method of thought by which it was developed. Ambroise Paré's luminous experiments, John Hunter's original and varied investigations, Koch's incomparable discovery of the tubercle bacillus and his simple and lucid exposition of his results, all illustrate this.

No age has a monopoly of broad minds or original thinkers, although the thought material differs from one period to another.

Besides what is at hand for us in medical literature in our own vernacular, two other languages offer us treasures of inestimable value; namely, French and German. An easy reading knowledge of these two languages is not difficult to acquire, and a half hour daily with a grammar and lexicon, even without a teacher, will soon enable us to accomplish this, so that we can read medical German or medical French. At the present day no physician can aim at a high standard of medical excellence without the ability to read authorities in these two languages. Furthermore, a new language introduces us to a new world of thought, customs and traditions, and renders accessible the great masterpieces of literature of the respective countries. To read in the original Schiller's "Song of the Bell," "William Tell," or the "Piccolomini" is worth all the labor of learning the German language.

It is a legitimate ambition of the enthusiastic young physician to write something to report an important or exceptionally interesting case or series of cases, or a carefully worked out investigation, and whether or not one publishes such a piece of work, it is excellent practice to write it out, for there is nothing like writing to clarify one's ideas of a subject and enable him to present them in a lucid and logical way. "The use of the pen is, for many minds," says Mitchell, "needed to give definition to thought," and Ruskin says, "The greatest thing a human soul ever does is to see something, and tell what it is in a plain way." To acquire what is called "style" in writing, for without the style nothing either in medicine or other writing will be widely read, is of the utmost importance if one purposes to do much writing. But with practice, clear thinking and a definite knowledge of the subject, this can be attained; indeed, it finally almost comes of itself.

The working day is inexorably limited, and how soon the night cometh when no man can or ought to work, though many of us do encroach upon the hours of the night, when we can read or write without interruption. What, then, remains, one pertinently asks, for general culture, literary pursuits, or mental diversion? If we can do no better, we can follow the sugges-

tion of Osler and start a "bedside library" and "spend the last half hour of the day," as he says, "in communion with the saints of humanity." "A liberal education," he continues, "may be had at a very slight cost of time and money, well filled though the day may be with appointed tasks; to make the best possible use of your one or of your ten talents; rest not satisfied with this professional training but try to get the education, if not of a scholar, at least of a gentleman. Before going to sleep read for half an hour, and in the morning have a book open on your dressing table. You will be surprised how much can be accomplished in the course of a year." Osler gives a list of ten books which are admirable, but which naturally will not appeal to the taste of us all.

This list of Osler's is as follows: The Old and New Testament, Shakespeare, Montaigne, "Plutarch's Lives," Marcus Aurelius, Epictetus, "Religio Medici," "Don Quixote," Emerson, Holmes's "Breakfast Table" series.

As I have said, each one would vary this list somewhat according to his individual taste and liking. My list I should arrange something as follows: First, the Old and New Testament; second, Shakespeare; third, some favorite book of poems, as Tennyson, Whittier or Longfellow; fourth, some biography or autobiography, as, for example, that of Franklin, Boswell's "Life of Johnson," Hoar's or White's Autobiography; fifth, some portion of history which may for the time have a special interest for us; sixth, some book of travel or adventure; seventh, some favorite book of fiction, such as Scott, Thackeray, Cooper, Hawthorne, Mark Twain, "Lorna Doone"; eighth, "Don Quixote"; ninth, Schiller; tenth, Holmes's "Breakfast Table" series.

I used to know an austere old Calvinistic clergyman who told me that his pleasure and diversion came from reading Scott's novels through once a year.

Of times the physician will feel so weary and so mentally exhausted that he will gain the most refreshment from a good novel of action, like "Lorna Doone," or "The Three Musketeers," or find rest in the world of adventure such as Parkman or Prescott offers, for example, and so for the moment be transported to a new and strange world. For others under like circumstances, a familiar poem will soothe the nerves and ease "the cares which infest the day" to "fold their tents like the Arabs, and as silently steal away." And worth a exposure "Daffodils" and Tennyson's "Sweet and Low" will soothe the soul of a worried mortal and cause it to reach with delicious harmony.

"If I read my effort is no more than innocent entertainment," says George Brantley; "it is a worth while matter, weariness and mental exertion of day life is not at all the same as that wisely controlled by the books that attract and hold us fast, being so they are exactly suited to these books are the good books for us." B. C.

it is well to place alongside of this advice the equally wise words of Mitchell, who says, that "it is the law of the mental life that man grows to like what he does long enough and . . . if your choice for comrades are the master books of the world, you will in time find their company wholesome and attractive." "Like the best of earthly friends these great books are hard to capture. They repay the effort." "More than all," says Dr. Emerson, "busy though we be, don't spare to medicine all our reading time. Read about the heroes—our craft has been rich in them. We find in our dull road the shining track, and forget that we are footsore."

In common with all mankind, the physician needs some form of daily physical exercise if he would postpone to the extreme limit that degenerative period of life which sooner or later awaits us all, though not for us all at the Oslerian arbitrary age of sixty, I trust. For some, physical exercise may be obtained, to a partial extent at least, in the performance of medical duties: walking on our medical rounds; driving and sundry duties about one's home, gardening, for instance, if one practices in the country. For most of us, however, and especially for the city physician, some definite form of muscular exercise, as such, must be arranged for, if we would maintain "the energy of full vigor," and the kind of exercise will largely depend upon one's taste and inclination. For one person, horseback riding will be a favorite exercise. "A good rider," as some one has said, "on a good horse, is as much above himself and others as the world can make him." For others, there is bicycling, tennis, hand-ball, golf, or various kinds of work in the gymnasium.

I know a certain professor, emeritus, of the medical school, a man now over seventy and still active in his profession, who is a daily attendant at the gymnasium.

Still others will take their exercise in connection with some manual occupation, such as carpentry, wood turning, iron working, horticulture, etc. You remember the great Laennec set up a lathe in one corner of his apartment and amused himself in turning objects, and used to make his own stethoscopes. I have a colleague, a specialist of repute, who is a skillful worker in wood and iron.

Whatever the form of exercise decided upon, it should be taken regularly and under open-air conditions, or, at least, pure air.

Whether or not the young physician's work is a remunerative practice, or whether or not he has much private practice, he will find opportunity, if he is ambitious, in some direction of medical art or science for strenuous and unceasing endeavor, for he has entered upon the long race of building up his reputation and practice. He needs, therefore, a yearly vacation, a decided change, physical, social and mental, and the nature of this change will largely and must be largely determined by his inclinations and tastes.

"Claim your right to a vacation," says Dr. Emerson, "and drop medicine like a hot iron.

Your patients may grudge it you, but will reap their gain in it." For one person the forest depths are the most seductive, where one can fish, hunt and live close to nature. I know of a hard-working city physician who every year takes his fishing rod and gun, with some light literature, and buries himself for a month in the northern Maine forests, forgetting that he is a doctor, and telling those who ask his occupation that he is in the drug business.

To another, the desire for travel is irresistible. He yearns to see new and strange places and faces, to lead for a little while an aimless life and be only a looker-on of life's activities. For him the change of travel is the most diverting and fascinating. To see new sights by land and sea is inexpressibly refreshing. For the time being the old familiar life has gone and he revels in the new and strange environment.

Still others prefer to combine with the change some form of physical activity: a canoe trip, a bicycle or horseback journey, a mountain tramping excursion, a yachting cruise, on which one performs a good share of the work; a camera or botanizing trip. In the preface to his charming book, "Animal Snapshots," Lottridge says he has spent his vacations for years in the fields and woods photographing and studying animals of "fur and feather" in their native haunts; entering into their lives as much as possible in order to know their habits and wild ways; finding in this form of vacation an endless and ever-increasing source of both knowledge and enjoyment. "My ideal vacation," he says, and it is so true, "is one that affords healthful pleasure not only for the time being but for the remainder of the year; that furnishes something to which I can turn for recreation and enjoyment after the working day is over."

In whatever form one takes his vacation, the essential thing is to take it in the way you like, and to take it thoroughly, forgetting for the time both patients and medicine.

We owe it to our patients quite as much as to ourselves to take an annual change and return to our labors with that vigor and eagerness which rest and new scenes bring, and then are we in condition to do our best for our patients.

Thus far we have been considering the physician in his development as doctor and man. "None of us liveth," however well he may live, "unto himself," but each one owes a duty to our neighborhood and country as citizens. "Second citizen," is Dr. Emerson's order, and he adds, "The town will be the better if he [the physician] feels the responsibility of citizen he owes to it."

The citizen of this republic too often forgets that he is an integral part of it and is under solemn obligation to do his duty towards it as an intelligent citizen. I remember hearing our present eloquent governor refer rather scathingly to a physician of his acquaintance who apparently recognized no civic responsibilities even to the extent of voting.

Besides voting intelligently, the physician, as citizen, should be ready to hold office if it

appears to be his duty so to do or if he believes that by so doing he can raise the standard of civic government, or carry through some needed reform in his own community or town. It may be in the capacity of health officer, a member of the school board, or of the city council or legislature, the trustee of some institution that he is called upon to serve. I know of a professor of a medical school who has been for several years a most valuable member of the legislature, where as a member of the health committee he was enabled to use his professional experience and knowledge for the benefit of the whole state.

Furthermore, the physician, from his extensive acquaintance in his community, and the regard in which he is held, is in a position to materially influence his fellow voters in securing wise and wholesome legislation. It is not, moreover, incompatible with a high degree of medical excellence, to attain also eminence in political life, as Virchow and others have shown us.

Outside of politics, there are innumerable opportunities in every community which will readily suggest themselves to the public-spirited physician, where he can be most useful. I know, for example, the superintendent of a state hospital who is a director of a savings bank in his city. Professor Welch of Johns Hopkins University is a conspicuous example of a man eminent in professional attainments who is also ready and always doing service to the community and state, being at the present time, as we know, president of the Maryland State Board of Health.

Let us, then, not forget to be citizens while striving to achieve a high standard of professional skill and reputation. A man is a man and a citizen from his birth, and one becomes a doctor later on. Let us, then, not permit our birthright to be absorbed by our avocation.

In conclusion, a word as to the personality or individuality of the physician, that *tout ensemble* of characteristics and peculiarities which present us to the world as this, that or the other individuality, and through which we either gain its good will or repel its good-natured advances, and by means of which very largely we succeed or fail. Although one's personality is largely a matter of inheritance, temperament and early environment, and perhaps to a very considerable degree a fixed quantity, still it is susceptible of being polished, cultivated and freed from unpleasant peculiarities so that a pleasing personality may, to a large extent, be attained which is of inestimable value to the physician who is brought in contact with such a variety of other personalities.

"Look three times at the figure of the ideal physician to once at our poor copy of him," says our Dr. Emerson whose wise words I have frequently before quoted, and what kind of a personality would we have our ideal physician to possess?

First and foremost, he should be natural, not his own original personality so far as it accords with the characteristics and conduct of a gentleman. "Every man of true genius," says

Dickens, and it is true also of us who are only of the average, "has his own peculiarity." If one possesses a keen sense of humor, it is to be cultivated as a priceless possession; there is nothing like it to relieve the heavy burden of the daily task. Of what inestimable value was it to Lincoln, staggering under his almost insupportable burden; how often his "That reminds me of a little story" illumined a dreary and oppressive situation. A cheerful disposition, if it does not naturally exist, should be assiduously cultivated. An abundant optimism, the child of cheerfulness, gains us more friends than a too serious and severe contemplation of life. Good physical condition and a well-supplied appetite contribute very materially towards a cheerful, happy view of life. It is a common observation that a man of *embonpoint* is generally a more cheerful man than a thin one.

"Let me have men about me that are fat,
Sleek-headed men, and such as sleep of nights,
Yond Cassius has a lean and hungry look."

"I do not know the man I should avoid
So soon as that spare Cassius."

"He loves no play,
Seldom he smiles, and smiles in such a sort,
As if he mock'd himself, and scorn'd his spirit
That could be mov'd to smile at anything."

Tact is another invaluable attribute, and if not a natural possession, much, nevertheless, can be done to cultivate it. I have known a most conscientious physician, with the highest ideals of professional work, fail in obtaining merited medical preferment because he was totally lacking in tact. When we analyze it, we see that tact is largely only a thoughtful and ready consideration of the feelings of others. It is the "putting yourself in his place."

The physician must be chary of much speaking, particularly when patients or colleagues come under consideration. Any reflections upon the conduct of a colleague from a one-sided statement of the case is unfair to him and derogatory to one's self-respect. Silence is a virtue which the physician needs to cultivate liberally. "He who holds his tongue for a minute," says an Eastern proverb, "is wise with the wisdom of all time." And yet silence may be carried to an excess and lead to misunderstandings, particularly when dealing with intelligent patients, and in consequence we may be unjustly and harshly judged. The truth is to be told, but gently and with tact, accompanied with all the expressions of hope that the case will permit. It is often difficult to maintain a true balance between tenderness of heart and firmness and insistency of purpose, both of which qualities are in constant demand in dealing with patients.

Sympathy is also another essential of the many-sided personality of the doctor, but not effusive or pretended. "Make-believe sympathy," says Mitchell, "is a false coin most easy of detection." Sympathy, moreover, costs in nerve strain and exhaustion, and as in every thing else we have to give, we should not permit every one who is too lazy or weak to straggle

against his own misfortunes to "tap" us for it that they may indolently enjoy its solace. Familiarity with patients, either on our part or theirs, is always dangerous and is very likely to lead to the loss of respect on the part of the patient for us and our professional skill. "As a rule," says the wise physician, whom Mitchell quotes, "you will do well to let your patients be friendly, but be yourself careful how you make friends of them."

Withal, we must have infinite patience, and be possessed of what Osler so highly extols, imperturbability. "In full development," says he, "as we see it in some of our older colleagues, it has the nature of a divine gift, a blessing to all who come in contact with it."

And so, as we have seen, the physician must be many-sided. He must be very much of a man, very much of a gentleman, a great deal of a citizen and have his chariot ever hitched to the star.

"Who comprehends his trust and to the same
Keeps faithful with a singleness of aim,
Whose high endeavors are an inward light,
That makes the path before him always bright;
Who with a natural instinct to discern
What knowledge can perform, is diligent to learn;
Abides by this resolve and stops not there,
But makes his moral being his prime care;
Who doomed to go in company with pain,
And fear, and bloodshed, miserable train,
Turns his necessity to glorious gain;
In face of these does exercise a power,
Which is our human nature's highest dower:
Controls them and subdues, transmutes, beverages
Of their bad influence, and their good receives;
By objects which might force the soul to abate
Her feeling, rendered more compassionate;
Is placable, because occasions rise
So often that demand such sacrifice;
More skillful in self-knowledge, even more pure,
As tempted more, more able to endure,
As more exposed to suffering and distress,
Thence also more alive to tenderness."

TRAUMATIC DEFECTS OF THE SKULL. THEIR RELATION TO EPILEPSY. A CLINICAL AND EXPERIMENTAL STUDY OF THEIR REPAIR.*

BY DUDLEY F. ALLEN, M.D.,

Professor of Surgery, Western Reserve University; Surgeon to Lakeside Hospital, Cleveland, Ohio.

HENRY L. SANFORD, M.D.,

Assistant Surgeon, Lakeside Hospital Dispensary.

D. H. DOLLEY, M.D.,

Former Resident Pathologist, Lakeside Hospital.

THE *Saturday Evening Post* recently said, "The main trouble with the man who announces a new theology is that he forgets his quotation marks." In a similar manner the medical man who thinks he has fallen upon a new idea usually finds he has been anticipated by some one wiser than himself. Often he finds his idea is not only old but valueless.

After spending considerable labor in elaborating a method for repairing skull defects, the

writer finds that in certain details he has been anticipated by the publication of the Koenig-Müller method of bone grafting. The first operation by the writer, after the method to be described, was performed in Lakeside Hospital, Aug. 22, 1900.

Before discussing the question of the repair of defects of the skull, it may be well to consider the conditions making such repair desirable. These conditions relate chiefly to epilepsy, the result of traumatism. They should include also periodical attacks of dizziness, headache, numbness, palpitation of the heart, etc.

To determine accurately the relation borne by traumatism to the production of epilepsy is by no means easy. Many grave injuries to the skull are not followed by epilepsy or ill effects of any kind. Sometimes manifestations of the sort are so long delayed that it is difficult to show that there is any relationship between them. Doubtless there are many cases of epilepsy following trauma in which the trauma has been forgotten.

That epilepsy may, and often does result from trauma, seems to be a universal belief. As bearing upon this belief the statistics of injuries to the head during our Civil War are of interest. Of 167 skull injuries, 23 or 13.7% are on the pension list as suffering from epilepsy. In the Franco-Prussian war there were 571 cases of recovery from gunshot wounds of the skull. Of these 25 cases or 4.3% developed epilepsy. If to the cases of epilepsy are added cases suffering from periodical attacks of dizziness, numbness, trembling, etc., the number is raised to 26.7%. The fact that epilepsy of non-traumatic origin usually develops early in life makes it highly probable that in these cases there is a causal relation between the trauma and the epilepsy.

In discussing traumatic epilepsy it must be borne in mind that the symptoms may result, not from injuries to the skull alone, but to the brain as well. They may result also from the formation of new scar tissue as well as from hyperostoses. The stimulus to attacks of epilepsy may also arise from irritation to peripheral nerves.

If the commonly accepted view be correct, viz., that epilepsy often follows skull injuries, the important questions before us as surgeons are five: (1) Can they be relieved by operative interference? (2) At what period should such operations be performed? (3) What class of cases are suited to operation? (4) What are the defects of methods commonly in vogue? (5) What operative procedures are best fitted to give permanent relief?

In discussing the first question, viz., the benefits to be derived from surgical interference, one is met at once by the unreliability of the statistics. The published experience of any one surgeon is too limited to permit of positive conclusions. The collected experience of different surgeons is widely at variance. Douglass and Walsham formerly reported from 60% to 70% of cures

*Read at a meeting of the Boston Medical Library, Dec. 6, 1905.

following operation. Graf and Braun, after careful study, accepting as cured only such cases as had remained well for three years after operation, report from 2% to 4% of cures. Kocher¹ in considering this subject credits Bergmann with 20 operations and 6 cures, or, if the three-year limit be insisted upon, with 4 cures or 20%. Discussing the subject further he points out that results vary greatly with the conditions found at operation. In 19 cases of trephining, in statistics collected for Kocher by Schär, in which there were found pressing upon the dura, splinters or corners of bone, abscesses or adhesions, and in which these were removed, there were 68.3% of cures. Still better results were found to exist in cases in which the splinters of bone or scars found pressing into the brain were removed by dividing the dura. In the latter cases cure resulted in 88.8% of the cases. It is to be remembered, however, that Kocher classified under the head of cured (*Heilungen*) cases showing positive improvement following operation, leaving out of consideration the question of final cure. In choosing the three-year limit as indicating cure, it must be remembered that there may be recurrence of epileptic symptoms after a still longer period of immunity.

Interesting as it would be to pursue still further a consideration of the possibility of curing epilepsy by operation, it would take us too far from the chief question to be considered in this paper, viz., *the prevention of epilepsy by the repair of skull defects*.

The second question is, At what period should operations for the relief of traumatic epilepsy be performed?

The prevailing opinion seems to be that early operation is highly desirable, and this is supported by such men as Champoussier, Gerster, Starr, v. Bergmann and many others.

There seems little question that by the continuance of any irritation which induces epileptic seizures, a condition is established which may continue even after the primary cause of the seizures has been removed. Thus, notwithstanding the fact that cures have been reported following operations for epileptic attacks recurring seven, ten and even eleven and seventeen years after injury,² still every consideration seems to point to the desirability of early operative interference in traumatic epilepsy, provided the cases seem to be suitable ones for operation.

The third question to be considered is, What class of traumatic cases is suited to operation?

The purpose of this paper is to show that all traumata to the skull resulting in bone defects should be repaired as soon as possible, not awaiting the possible development of epilepsy. This phase of the subject will receive consideration later on in the paper. The paper also seeks to show that should epilepsy follow trauma and the removal of bone be necessary

for its relief, the defect caused by operation should at once be repaired.

The fact is not forgotten that many of the gravest skull injuries may never develop epileptic or psychic disturbances. Two children operated upon, one by myself, and one by my late assistant, Dr. Nevison, fell from heights of about fourteen feet upon stone pavements, crushing in the entire vaults of their skulls and causing the most extensive fractures and depressions. In each case, by means of a sharp, curved, steel hook, the bone was lifted into place, the convexity of the cranium was re-established and the children recovered. One case I have followed about eleven years, and no ill effects of any sort have resulted. The second case has been lost sight of.

On the other hand, injuries apparently slight, may cause grave consequences. Unquestionably the cases promising most from operation are those in which the symptoms are the result of pressure upon the brain by spicules or edges of fractured bone, exostoses, scar tissue, etc. If the brain itself be injured, operative procedures promise less. Interesting as it might be to consider the benefits resulting from the removal of portions of the brain cortex as performed by Horsley and others in cases of Jacksonian epilepsy, it would take us too far from the purpose of this paper.

The indications for operation are well stated by von Bergmann.³

He says, (1) Operation is indicated in recent cases with infrequent attacks.

(2) In cases having manifestations described as Jacksonian epilepsy.

(3) In cases having upon the scalp, or skull evidences of previous injury.

The fourth question is, What are the defects of methods now in vogue?

Nothing will be said concerning the removal of brain cortex or of abscesses or cysts, and it is unnecessary to discuss the methods of removing bone.

For the removal of sections of bone, the exact area of which cannot be previously determined, and when the Omeca bone flap does not seem to be indicated, my preference is for the burr drill and the Lane bone forceps. The defective method to which it is desired to call particular attention is that of removing a portion of the skull and leaving the defect unrepaired. Kocher⁴ on the other hand, in closing his article on this subject, says, "Often it is not the opening, but rather the closing of the skull which causes harm." He advocates the incision and even the excision of the dura mater, in order to prevent the formation of a new bony covering of the defect, contending that the leaving of a vent (ventil) or even multiple openings tends to equalize intracranial pressure, and thus decreases the tendency to recurring attacks of epilepsy. In addition to his own experience he bases his opinion upon the observation of Schär and Beresovsky, of Moscow, to the effect

¹ T. Kocher, *Ueber einige Bedingungen objektiver Heilung des Epilepsie*, *Centralblatt für Chirurgie*.

² Bericht der Deutschen Gesellschaft für Chirurgie, 1899, pp. 40, 41.

³ Reported by Horsley, Taylor and Schiele. *Mitteilungen aus den Grenzgebieten der Medizin und Chirurgie*, 1899, p. 712.

⁴ *Handbuch der praktischen Chirurgie*, 8. Aufl., p. 321.

⁵ Kocher, *Loc. cit.*, p. 47.

that cases which have remained cured after operation for epilepsy were those in which defects in the bony covering had persisted.

Opposed to this view is the widespread experience that after operation epilepsy and allied conditions are often benefited temporarily, only to recur and be relieved again and again by subsequent operations. The conclusion seems evident that the recurring symptoms are the result of recurring pressure. To discuss this point at length would require more time than is at our disposal.

That epilepsy, the result of trauma, is to be relieved by a permanent skull defect seems wholly improbable. The establishment of the credibility of this view would require more facts than those advanced thus far by Kocher, much as his abilities are respected by every surgeon. In opposition to this view von Bergmann has pointed out the fact that epileptic attacks are often provoked by peripheral irritation, such as neuromata, foreign bodies in the ear, etc., conditions with which defects of the skull can have no connection. It seems probable that removal of pressure and the permanent repair of the skull, restoring its convexity and resistance to external injury, would be far more likely to be followed by permanent benefit.

The fifth consideration is, What operative procedures are best fitted to give permanent relief?

Many methods have been proposed for this purpose, and some of them have been employed for a long time. The method of closing defects in the skull by means of metal plates is one of long standing, but it is not satisfactory. Celluloid plates have also been used for the same purpose, but these also have not met general adoption.

Horsley in his operations for the removal of brain tumors employed the method of re-implanting the disk of bone removed by the trephine. This method has proved very successful and is applicable in cases where this disk of bone exists. The method does not, however, provide for the covering of old defects where there is no such disk of bone available. Macewen employed fragments of bone removed at the time of operation. These were placed in the defect and served as a scaffolding for the formation of new bone. This method has also proved successful in a certain percentage of cases, but numerous failures are reported.

Another method has been suggested by R. Porges.⁵ He reports a case in which as the result of cervical caries an opening in the skull existed 7 cm. long by 5 cm. wide. After incising and reflecting the skull the granulations covering the dura were removed. Over the dura two strips of celluloid were so placed that their extremities were wedged into the diploë, in order to retain them in position. The periosteum with the integument was then laid back over the strips of celluloid and the defect was thus covered and closed firmly.

⁵ R. Porges: *Centralblatt für Chirurgie*, 1903, p. 297.

Grekow⁶ of St. Petersburg, has made an extensive series of experiments in repairing defects of the skull. His method is to lay in the defect a thin sheet of thoroughly calcined bone. The bone may be obtained from any source. His observations are based upon a large number of experiments made upon various animals. By this means bone defects may be repaired. He says that bone under these circumstances grows from three sources: first, the diploë; second, the periosteum, and third, the dura. The calcined bone plate serves to prevent adhesions of the dura and periosteum and affords a scaffolding for the growth of new bone, which takes place generally from the periphery. He says that the method is effective in animals and in man, in lesions both old and recent. The process requires three months or more in animals and adult persons. His investigations are extensive and complete and seem to prove the success of his method.

Another method is that suggested by Müller,⁷ and employed by Koenig, being called the Müller-Koenig method. This method is, after laying bare the skull defect, to form a flap of similar size and outline from the adjoining portion of the skull. The skin and periosteum are left attached to the bone. By means of a cutting chisel the outer table of the bone lying beneath the flap is separated from the inner table and a flap thus created which is made up of integument, periosteum and fragments of bone, is transplanted so as to cover the defect.

Still another method has been suggested by Bunge.⁸ This is to form a flap in a similar manner, consisting, however, only of periosteum and fragments of bone similarly obtained. The base of the flap is preserved and the whole is transplanted so as to cover the defect.

At what time the Müller-Koenig method was first employed I have been unable to discover. That of Bunge is first described in 1903. Neither of the latter methods was known to the writer until a short time ago, long after the method to be described was successfully employed.

The method proposed by the writer for covering defects of the skull was first employed Aug. 22, 1900. It is as follows:

The scalp is removed from over the defect in the skull and the connective tissue covering the brain is carefully dissected away. Since the scar tissue and dura are often inseparable, the pia mater covering the brain tissue may thus be exposed over the entire area. In certain cases in which the injury to the brain tissue has occurred as the result of traumatism, it may be necessary to trim away a portion of the brain with the scissors, since the connective tissue may be firmly connected with the brain tissue itself. The borders of the opening are carefully examined to see if any portion of the bone projects downward, and if so it is removed by means of

⁶ Grekow: Contribution à l'étude des manques de substance osseuse du crâne, St. Petersburg.

⁸ Bunge: *Verhandlungen der Deutschen Gesellschaft für Chirurgie*, p. 37, *Centralblatt für Chirurgie*, 1903.

rongeur forceps. Any hemorrhage which occurs is carefully stopped, since it is an essential part of the operation that all hemorrhage should be controlled before the bone flap is inserted. When the surface upon which the bone flap is to be implanted has thus been made clear and hemorrhage has been checked, the scalp is removed from an added area of the skull of equal size with the opening. In doing this care is taken that the periosteum covering the skull be left intact. It is also important that the portion of skull laid bare be as thick as possible. Thus, the posterior parietal region is preferable to the temporal region. Upon the area thus laid bare a circular or elliptical incision is made, blocking out a portion of periosteum equalling in form and size the defect which is to be covered. A sharp, narrow chisel is then employed to split from the outer surface of the skull the portion of bone adherent to the overlying periosteum. To separate this bone from the skull the blows of the chisel should be short and quick so that the portion of bone split away reach no deeper than the diploe. In the removal of this area of bone with attached periosteum, the tendency, of course, is for the bone to be separated into small fragments, and to roll upward and outward. By placing the graft thus obtained between two gauze sponges moistened in warm normal salt solution and laying it upon the table, it may be flattened out by a few slight blows of the mallet. The plate of bone thus prepared is laid upon the opening in the skull, the bone being next to the brain. The wound is then closed by drawing over it the scalp and suturing it loosely in place. A cigarette drain made up of gauze and surrounded by gutta serena protective tissue is inserted through the incision at the dependent point, so that any excess of blood may be drained away into the dressing. The dressings are changed ordinarily on the second day in order to remove the cigarette drain, after which a second bandage is applied. This bandage remains in place for perhaps six or eight days longer or until the wound has entirely healed. By this method seven cases have thus far been operated.

ment greatly increased. The only hope of relief seemed to lie in the possible benefits of operation, the thought being that by relieving the pressure at the point of injury some benefit might accrue to the patient. He was admitted to Lakeside Hospital in March of 1898. His state of excitement was so great that it became necessary to place a guard over him day and night. At this time a portion of the skull, 4 cm. in diameter, in the right fronto-temporal region was removed,

FIG. 2.—Skull defect prepared for graft.

The opening was covered by the scalp and the patient was sent home. This general condition improved very greatly and he remained well for about two years, performing ordinary duties about his home. He came to the hospital again, however, on Aug. 22, 1900, the statement being made that he had recently developed mild excitement, in no way to be compared with that which had previously existed, but such as had made him desire to go to the State Hospital for the Insane at Massillon. In thinking the case over it occurred to me that since the patient had been so greatly relieved for the period of two years following his first operation, this might have resulted from the removal of the pressure upon the brain. Later, as the scar tissue contracted, it could have renewed pressure upon the brain, and thus have caused a return of excitability. In considering how the patient might be relieved, the method of bone grafting which has been described suggested itself. The operation was performed on Aug. 22, 1900, and the patient left the hospital on Oct. 6.

On June 27, 1903, nearly three years after this operation, he returned for re-examination, saying that since the last operation he had been entirely well. He further said that after he returned home the defect in the skull, which on discharge had been hard, appeared to grow softer, but that after a time it had become hard again. From this report it seems probable that the chips of bone adherent to the dura mater had been absorbed, but that later bone had been reformed. Examination at this time showed that the former defect was covered by solid material through which no pulsation could be felt and that there was no indication of increased pressure. The case, however, is therefore of interest because of the following facts: The patient remained perfectly well until the 25th of July, 1903, having occupied a respectable position, with entire satisfaction, to his employers. The responsibility

FIG. 3.—Section of skull, showing site of bone graft, case No. 2.

CASE I. F. H. Male. Aged, nineteen years. The patient had been injured on the right side of the head in November, 1892. After four and a half years, in July, 1897, he developed symptoms of excitability, which made it necessary to send him to the State Hospital in Newburg. Here his condition of excite-

was, however, large, and it seemed to be too much for him. He confided to a friend that he thought it would be impossible for him to be cured permanently and he deliberately ended his life.

CASE II. W. B. Male. Aged, seventeen years. The patient was admitted to Lakeside Hospital, July

FIG. 3. Graft removed from area covered with white paper and lying bottom upwards in operator's hand.

10, 1903. The night before admission to the hospital the patient fell from a street car, striking upon his head. He was unconscious from this time until admitted to the hospital, eighteen hours after injury. He was very restless, complained of severe headache and also of pain in the back of his neck. Patient was in good physical condition. On examination of the skull the scalp over the vault of the skull was found to be edematous, but no depression could be felt. The eyes showed nothing abnormal. The patient continued to have severe headache. He was, however, conscious and did not develop paralysis of any sort. The pain, however, was so severe, that it was decided, on July 13, to open the skull. A crucial incision was made over the vault of the skull in the anterior parietal region. On exposure of the skull no distinct fracture could be made out. There was, however, a seeming separation of the longitudinal suture and the sagittal suture. By means of a burr drill and rongeur forceps a portion of the right parietal bone, just to the right of the median line, was removed. The opening was 9 cm. long and 7 cm. wide. Underneath the skull, lying between it and the dura mater, was an area filled with a blood clot, separating the dura from the skull a distance of 1 cm. This was quite adherent to the dura and was removed with some difficulty. No attempt was made at this time to close the defect in the skull itself by bone graft. The reflected integument and periosteum were brought back, united by a few sutures and room was left between the flaps for drainage. The patient made a rapid recovery from this operation and was dismissed from the hospital on Aug. 11, 1903. The large size of the opening made it seem wise to close this later on by a bone graft. Accordingly, the patient was re-admitted to the hospital on Sept. 19, 1903. Since the first operation the patient had suffered much from headache, particularly over the eyes and around the ears. He had done no work. When he tried to read he had pain in the eyes and also increase of pain in the head.

He had had, however, no epileptic attacks. On examination of the field of operation a depression could be felt, which became even with the rest of the skull when the patient was lying down. The operation for the closure of the skull was undertaken Sept. 21, 1903. A bone graft, secured in the manner described, was removed from beside the original defect and laid in place. The recovery was uneventful and the patient was discharged on Oct. 31.

The patient was re-examined Nov. 17, 1905. There was an irregular depression to be felt, corresponding to the original defect of the skull. The defect was about 8 mm. in depth, representing approximately the thickness of the skull at this point. On firm pressure there was no yielding of the surface and no pulsation was to be felt. The defect appeared to be repaired by the formation of new bone. The patient had been entirely relieved from headache and was perfectly well in every respect since the time of the second operation.

CASE III. W. J. C. Male. Aged, thirty-five years. Single. The patient was admitted to Lakeside Hospital, July 30, 1903. Previous history negative. In September, 1894, he was struck by a locomotive, and in falling hit his head upon a piece of iron. He was not conscious of his surroundings for about two weeks. During this time he was in the West Penn Hospital at Pittsburg, Pa. He says that the doctors considered his condition hopeless, and did not operate in any way. He was in the hospital for three months. There were no paralyses of any kind. Seven months after injury he had his first epileptic attack. These attacks recurred at intervals of about a month until

FIG. 4. Graft laid in position filling defect. Piece of paper shown in Fig. 3 removed to demonstrate appearance of skull after upper table (graft) has been taken off.

August of the same year, when his skull was operated upon by Dr. Buchanan of the West Penn Hospital. After this time his fits came back at intervals of about two months. A year later he was referred by Dr. Buchanan to Dr. Keen of Philadelphia, who declined

to operate. On Feb. 22, 1897, he was operated upon by Dr. McGrew of the Allegheny General Hospital. After this he improved so that he had only six epileptic attacks in the next six years. The last one was in March, 1903. On admission to Lakeside Hospital he was found to have an opening in the skull 5½ cm. wide by 6 cm. long. This opening was 2 cm. to the right of the median line and in the parietal bone above the right auditory meatus.

Operation was performed July 31. Crucial incision. On exposing the defect in the skull it was found to be filled with a thick layer of fibrous tissue. Embedded in this tissue was found a piece of gold foil which had been inserted at the last operation to prevent the adhesion of the scalp to the dura mater. The cicatricial tissue was found adherent to the dura through a portion of the wound. A bone flap, the size of the opening, was secured toward the median line and placed in the defect. This was then covered with a skin flap which was sutured in place except for a small opening for a cigarette drain. On Aug. 17, the patient had an epileptic attack lasting for about one minute. No further convulsions occurred and the patient was dismissed from the hospital on Oct. 26, 1903.

In January, 1905, the patient was re-examined. Excepting for one very small point where the surface yielded very slightly on firm pressure, the entire defect seemed to be filled with new bone. The patient was persuaded to permit an incision to be made in the scalp in order to determine whether new bone had been formed. This was done under cocaine. The knife came down upon a firm tissue which had every appearance of bone, being hard so that it could not be cut with the knife, and having a white and glistening appearance. It seems that there can be no question that the tissue thus found was bone. Since the last operation the patient has had two attacks of epilepsy, one Feb. 19, 1904, and another July 20, 1905. Aside from this he has been perfectly well and able to work. He was last examined March, 1906.

CASE IV. G. N. Male. Aged, twenty-eight years. Single. Admitted to hospital Oct. 10, 1903.

The patient was well until seven years before admission to hospital. At that time he fell under a horse's feet, and the horse's shoe penetrated his forehead. He was told "there were cracks in other portions of the skull." There were no immediate symptoms. Two weeks after the injury two ounces of pus were evacuated. Details of this operation were not given. This operation was followed by apparent recovery.

On Sept. 30, 1903, while talking with a friend on the street, patient says he experienced a peculiar creeping sensation, as of a rush of blood to the head. This was accompanied by pain in the right parietal region and a sensation of intense weakness. He remembers being placed in a carriage and taken home, but nothing more. On Oct. 2 he had a similar attack. He thinks he did not lose consciousness, but felt very weak after the attack and slept for some time. His physician, Dr. Ashmun, says that the attacks began with rolling of the eyes toward the left side, drawing of the left side of the face to the left and drawing of the whole head to the left. On examination a cicatricial scar was found in the forehead above the right eye. At the center of this was a slight depression corresponding to the loss of bone following the previous operation. The opening was said to have been originally about the size of a dollar, but its diameter had been decreased. The site of the old injury was laid bare by a semicircular flap. The cicatricial tissue was removed from the site of the old injury and the edges of the bone were refreshed with the rong-

eur forceps. The surface of the brain was found to be infiltrated with connective tissue at the site of the former abscess, so that normal brain tissue was not seen. A bone flap was then secured above and to the outer side of the opening, and the wound was closed with suture except for a cigarette drain. On Oct. 14, the patient had a convulsion at 7 a.m., followed by six others during the day. His attacks resembled those occurring before operation. After that time patient had no recurrence of epileptic seizures. The recovery was uneventful and the patient left the hospital on Oct. 31. Examination at this time of the point of operation showed that there was considerable resistance to pressure and that there was no pulsation. Patient was examined March 21, 1906. He is in business and has been perfectly well since the time of his operation.

CASE V. H. C. Male. Aged, thirty-two years. Admitted to the hospital Nov. 21, 1904.

Patient had been in good health until fifteen months before admission to the hospital when he was kicked by a horse in the right temporal region. He was rendered unconscious and the skull was fractured. At this time an operation was performed and three pieces of skull were said to have been removed. The wound healed promptly. Four months after his injury he had his first convulsion. At first these occurred at intervals of about two months. The intervals then became shorter until it was but two weeks, but of late the time between the convulsions has been somewhat increased. The attacks came on with dizziness and a feeling of numbness over the entire body. He thinks that he also turned his head to one side as the attacks came on, but does not know which side. He remained unconscious for about twenty minutes and was light headed for two hours afterward. Patient is a well-developed man. There is a defect of bone in the right temporal region. It is about 1 cm. long and 1½ cm. wide. Operation was performed Nov. 26, 1904. The defect was laid bare by an incision through the scalp and pericranium. The edges of the bone were found to be markedly depressed and were removed with forceps. No scar was found in the dura mater. The original incision was then cleared, a bone flap was secured above the site of injury and placed in the wound. On Nov. 27, the patient had a convulsion at about 5 p.m. during which he was unconscious for fourteen and one-half minutes. This occurred at 9 a.m. From this time on the patient's progress was rapid, there were no more convulsions and he was dismissed with a firm cranium on Dec. 16, 1904. The defect was resistant to pressure and showed no pulsation.

A letter received from the patient Nov. 16, 1905, says that on July 24, of this year, he had an epileptic attack, the only one since his operation. Since that time he has not felt as well, being light headed.

CASE VI. L. D. Male. Aged, eleven years. Admitted to the hospital Dec. 5, 1904.

The patient was a well-developed child. When two and a half years old he was struck upon the head by a six-pound object that he had a distance of thirty feet. The child was unconscious for five or six minutes. There was a wound in the head which healed freely, but the mother closed it by the use of plaster. No physician saw the case. At six years of age, after this injury, the child had a convulsion. There were convulsions repeated every two or three months and bore the characteristics of epileptic attacks. The child had his first epileptic attack at eight months before admission to the hospital, and after that his mother says that he was "crazy" for three days. Patient has also had "fainting attacks," and when

seized with these he falls down, the attacks lasting but a few minutes, and after these the boy complains of not being able to talk easily. The mother says sometimes he stutters after these attacks. His last "fainting attack" was the latter part of November, 1904. The boy is high tempered but not malicious.

On examination of the patient's skull a small scar about 2 cm. in length was discovered at about the junction of the occiput with the right parietal bone. Nothing further could be felt. The operation was performed on Dec. 9, 1904. A horseshoe-shaped incision, 7 cm. in diameter was made in the scalp. By means of a burr drill and chisel a piece of bone, $3\frac{1}{2}$ cm. long and $1\frac{1}{2}$ cm. wide, was removed. Although there was a slight depression in the outer table, no depression was found upon the inner table. The dura mater was incised but nothing abnormal could be seen upon the surface of the brain convolutions. A bone flap was chiseled from the skull behind the opening made by operation and the wound was closed except for a cigarette drain. The boy's recovery was uneventful until Dec. 17, and he was up and about the ward. On this day he was noticed to be breathing rather loudly and deeply. On examination it was found that he was unconscious, that his eyes were widely open and slightly rotated to the left. Corneal reflex was present. The boy could not answer when spoken to. He had no convulsion and his muscles were not rigid. There was a hypersecretion of saliva. He remained in this condition for about thirty minutes when he gradually regained consciousness. His convalescence was otherwise uneventful and he was dismissed from the hospital on Dec. 29, 1904.

The patient was re-examined on Nov. 17, 1905. At that time the defect in the skull was found to be firm, not yielding on pressure and showing no pulsation. The surface was slightly irregular. Before operation his parents say the boy was dull and unable to study. At the present time he goes to school and his family report that he is bright in his studies and is perfectly well.

CASE VII. F. L. Female. Aged, twenty years. Married.

When a year old patient fell on a rusty iron, striking left side of forehead, driving nail into her head. After this she says she had meningitis for about six months. From that time she was well until sixteen years of age, when she began to have convulsions. In the convulsions she falls to the ground, bites her tongue and has foaming of the mouth. Her first convulsion came with the first menstrual period. She entered the hospital Sept. 10, 1905, and was operated upon for abscess of the breast. During her sojourn in the hospital she had repeated epileptic attacks. Patient had a small scar over the left frontal bone and on palpation the external surface of the bone was found to be somewhat irregular. On Sept. 21 a button of bone, 2 cm. in diameter, was removed with a trephine. Its inner surface was found to be somewhat irregular. The bone at the point of injury was thinner than normal, and there was no pressure upon the dura mater. On examination of the dura there seemed to be a marked increase of connective tissue. Before opening the dura and also afterward there was an escape of a considerable amount of clear fluid. The brain tissue was not normal, but showed in increase of connective tissue. None of the brain tissue was removed. A bone flap the size of the opening was secured just above the trephined bone and used to cover the defect in the skull.

There was a respite in the epileptic attacks immediately following operation, but they recurred at the next menstrual period, and recurred several times

again before her dismissal from the hospital on Nov. 5, 1905. The wound in the skull healed by first intention. A cigarette drain was left in place for two days. At the time of leaving the hospital firm pressure seemed to show that the opening was firmly healed.

The seven cases just reported would seem to demonstrate beyond question that defects of the skull can be repaired by the method which has been suggested. In every case operated upon, the wound has healed by first intention and the defect has been repaired by what seemed to be bony structure. The defects are firm on strong pressure, showing no pulsation, and in one case in which a secondary incision was permitted the incision came upon what bore every appearance of being bone.

In order to study more fully the process of repair, a series of observations were undertaken upon dogs. These were carried on by my former assistant and present associate, Dr. Henry L. Sanford, to whom I am greatly indebted. The following is his account of his investigations.

In endeavoring to carry out bone grafting on the skulls of dogs, several obstacles were encountered. The same precautions for securing asepsis were taken that would be employed with human beings, but still it was found difficult to secure and maintain an aseptic field for operation, and

FIG. 5. Skull of dog. Internal surface showing bone graft two weeks after insertion. Rectangular defect made by removing bone for microscopic examination.

it was also hard to devise a dressing which the dogs could not succeed in pulling off. Crinoline bandages put on wet and extending down well on to the nose and back over the neck gave the best results. When dry the dressing hardened into a cast in which the dog seemed very comfortable.

The extremely irregular topography of a dog's skull also reduced the available operating area to the temporal fosse on each side of the median ridge. Here was found a fairly level space, large enough to yield a graft, and here, too, the formation of the dog's skull most nearly approxi-

mates the diploë of the human skull. Medium sized, short-haired dogs with broad skulls were found best adapted for the experiments.

The technique of the operation consisted in turning back from the median line the skin and temporal muscle in a horseshoe flap, taking care not to injure the periosteum. As large an area as the curving contour of the skull admitted was

one month, two months, three months, four months and five months after grafting.

I wish, especially, to thank Dr. McHenry for assistance in these operations. As in successive cases we alternated as operator and assistant, one half of what has been accomplished in these experiments is due to him.

SUMMARY.

March 17, 1905. Black cur dog. 30 pounds. Graft left side. Single flap. Killed at five months.

March 21, 1905. Brown setter dog. Thirty-five pounds. Graft left side. Single flap. Killed at four months.

March 31, 1905. Cocker dog. Forty pounds. Graft left side. Single flap. Killed at three months.

May 3, 1905. Bull dog. Thirty pounds. Graft left side. Single flap. Killed at two months.

Sept. 18, 1905. Bull dog. Twenty-five pounds. Graft left side. Single flap. Killed at one month.

Oct. 2, 1905. Black cur dog. Thirty pounds. Graft left side. Single flap. Killed at two weeks.

I herewith lay before you the skulls of the five dogs operated upon by Dr. Sanford. The specimens were prepared by Dr. Dolley. I am indebted to him for this work and also for the histological sections.

The following description of the sections is by Dr. Dolley.

MACROSCOPICAL APPEARANCE OF EXPERIMENTAL GRAFTS.

In the two weeks dog the graft is movable. This is less marked in the one month dog, and in the rest of the series the graft is firmly united to the peripheral bone. Partial calcification can be detected with a knife point in the two weeks and one month dogs. In the one month and two month dogs, the dura is adher-

FIG. 6. Skull of dog. External surface showing bone graft four months after insertion.

then marked out and chiseled off, so that the graft amounted to a sheet of periosteum, to the under side of which was adherent a layer of bone chips. It was at first attempted to transfer such a graft from one side of the skull to a previously prepared defect of corresponding size in the opposite temporal fossa, but the dogs stood the shock of what was practically a double operation poorly, owing to the enormous bleeding from a particularly large intra-osseous vessel which was met with in every case, and which was necessarily opened in getting off the graft in this only available location.

It was thought that the requirements of the experiment would be fulfilled if, after freeing the graft, the skull defect should be completed rapidly down to the dura in the place from which the graft had been taken and the graft then laid into practically its original position under the new conditions. This proved very successful.

Quite a number of dogs were lost through anesthesia, shock and sepsis, but after certain lessons had been learned a series of successful cases followed in which all the dogs lived and recovered promptly.

In order to judge the rate and character of bone repair in the grafts the dogs were killed at graded intervals after operation, and the series now represents the skulls at two weeks,

FIG. 7. Skull of dog. External surface showing bone graft one month after insertion.

and in several places about the edge of the peripheral bone. Apparently this only occurs within the normal interval between the graft and the peripheral bone. In the rest of the series the bone is non-adherent in the region of the graft.

MICROSCOPIC.

The tissue was fixed in Zenker's fluid and formalin, and stained with hematoxylin and eosin, and with Von Gieson stain.

TWO WEEKS DOG.

The interval between the peripheral bone and the graft, which is about 2 cm. in the piece taken for microscopic examination, is filled with connective tissue which has undergone a partial calcification. This connective tissue has its origin from the periosteum

FIG. 8. Edges of graft at two weeks. 1. Superior surface. 2. Inferior surface. 3. Edges of graft. 4. Small bit of graft. (Cam. Luc., Leitz, oc. iv, obj. 3, x 105 $\frac{1}{2}$, Zenker's fluid, hematoxylin and eosin.)

covering both the superior and inferior surfaces of the peripheral bone and from that covering the superior surface of the graft, from the diploë of the peripheral bone, which in this dog is fairly well marked, and to a slight degree also from the overlying fascia. It has a reticulated appearance with small empty interspaces, irregular in shape, and lined usually with a layer of osteoblasts. Some of the spaces are full of osteoblasts. The connective tissue is faintly fibrillated and very cellular. The cells consist of connective tissue cells proper with fusiform and small spindle nuclei and of osteoblasts. In part the fibrillated character of the connective tissue is lost, and it is homogeneous in appearance. This is more evident about the interspaces just mentioned, and indicates where calcification has occurred. In one block the edges of both the peripheral bone and the graft still remain partially uncovered by cellular periosteum, but in the second, the edge of the peripheral bone is almost entirely covered by osteoblasts, though that of the graft is not. Upon the surfaces, and particularly in the diploë of the peripheral bone, the osteoblasts are actively proliferating. The outermost lacunae of the graft are also filled with osteoblasts. A few osteoblasts lie on the surface of the peripheral bone, but only an occasional one appears on the graft.

ONE MONTH DOG.

In sections from this the most striking feature is the active growth at the edge of the peripheral bone. The new formed bone contains numerous lacunae, some of which open upon the surface. They are filled with osteoblasts. The free edge is covered with an actively proliferating cellular layer of periosteum. The edge of the graft shows the same appearance of growth but it is not so marked. Lying in the fibrous

periosteum on the superior surface of the graft proper are several isolated areas of true bone which possess lacunae and are covered with a layer of osteoblasts. These are probably fragments which were accidentally imbedded at the operation and which remained viable. Their structure is too dense and the bone corpuscles are too few and too contracted for the areas to be new formed bone. As in the two weeks dog, the interval between the graft and the bone, which macroscopically was almost solidly calcified, is composed of connective tissue. It differs from the earlier stage in that it is less cellular, and the interstices are larger and all empty. Judging from the paucity of osteoblasts, there is little absorption of the graft.

FIVE MONTHS DOG.

The graft and the peripheral bone have grown to within $\frac{1}{2}$ mm. of each other but both are still sharply defined. After decalcification, the interval between them is composed of connective tissue whose origin from the periosteum of the superior and inferior surfaces can still be traced, but which has almost entirely lost its fibrillary character between the two edges, being homogeneous, with a few contracted osteoblasts and spindle nuclei. No osteoblasts are seen. Periosteum covers the edge of both the graft and the residual bone, and in each for a short distance from the edge the appearance is that of newly formed bone, with numerous osteoblasts. The initial process of calcification is evidently being replaced from both directions by true bone.

CONCLUSIONS.

1. The initial process is the filling of the gap between the graft and the peripheral bone with connective tissue, which arises principally from

FIG. 9. Edge of peripheral bone at one month. Shows rapid growth of bone. 1. Connective tissue filling gap between edge of bone and edge of graft. 2. Dura mater. (Cam. Luc., Leitz, oc. iv, obj. 3 x 105 $\frac{1}{2}$, Zenker's fluid, hematoxylin and eosin.)

the periosteum of each, and which at two weeks has already undergone considerable calcification.

2. The graft remains viable and intact, and begins to grow both in thickness and at its edges.

3. Growth of the free edge of the peripheral bone is more marked than in the graft.

4. The growth of these gradually replaces the initial calcification, and at five months only a trace of the process remains. The probabilities are that after longer time there would be a true bony fusion.

The final conclusions reached by this paper are:

1. Defects of the human skull can be covered by bone.

2. The bone may be secured from a portion of skull adjoining the defect.

FIG. 10. Edges of graft and peripheral bone at five months.
1. Edge of bone. 2. Edge of graft. 3. Superior surface.
4. Inferior surface. 5. Calcified connective tissue. (Cam-
bium. Left). 6. (by 4, 5, 100 \times). Formation, hemat. xviii and
cervix.)

3. This bone graft represents essentially the outer table of the skull, with the periosteum covering it.

4. No pedicle need be preserved in order to insure the viability of the bone graft.

5. Experiments on dogs show the graft to be solid at three months.

6. Histological examination shows that the bone remains viable and grows into its new position.

The object of this paper is to show that defects of the skull should be repaired promptly in order to avoid the occurrence of epilepsy and allied conditions.

THE DEFENSIVE PROPERTIES OF THE ORGANISM.⁶

BY R. C. JACKSON, D.D., M.D., NEW BEDFORD, MASS.

It is an incontrovertible fact that the progress and science of medicine and the therapeutic applications for the relief of pathological conditions incident to disease, are the results of epoch like growths. Although we must candidly and freely admit, while there are many impor-

fections and false conclusions inevitable in a science so intricate and so broad, based as it is on so many theoretical premises, still if we are patient, earnest and honest seekers after truth, we cannot fail to gather here and there, valuable and helpful facts from these pure hypotheses.

As you know, the causative agents of disease were anticipated through hypothetical reasoning and deductions, long before their discovery. And since, through the valuable work of Devaine, Koch and others, the germ theory of disease has become an established fact.

No age, no epoch in the progressive evolution of medicine has been able to solve all the problems, or any considerable part of them; and hence the solution of one problem leads to the probability of others. No sooner, therefore, were the causative agents of certain diseases established, than that very important and perplexing problem, "In what way does the body protect itself from these invading foes, and what are the defensive elements concerned?" arose.

This theoretical explanation of the defensive properties of the organism or the theory of immunity is the subject we intend to discuss in this paper.

In order to explain the theories of immunity, it will probably be more interesting and clear to begin with the defensive properties of the organism against soluble toxins like those of diphtheria and tetanus. In this class of infectious diseases the microbes become localized, elaborate their poisons, which are carried to distant parts of the body. The question naturally arises, "What is the nature of these protective elements?"

The answer to, and the elucidation of, this question will shed considerable light on the defensive power of the organism in this class of infection. To answer this question satisfactorily, Ehrlich's side-chain theory of immunity must be brought into requisition. Ehrlich's attempt at standardization of diphtheria toxin gradually led him to this conception of immunity. He claims that the cells have side-chains or receptors which will combine with toxins. When a poison, tetanus, for example, enters the body and is not sufficiently powerful or concentrated to destroy the cells, these cells are stimulated to reproduction of the receptors corresponding to the particular toxin. According to Weigert's law of Havers compensation, the receptors are produced in excess, and are then thrust off into the blood stream, and are known as antitoxin. Now what happens when the toxic elements enter the blood? They come in contact with the circulating receptor or antitoxin and their affinity is satisfied.

H + T = N

H = N

By a series of experiments, Weigert has shown that there are three things necessary for the production of antitoxins or antibodies.

1. The combining of the bacteriogenic group of the toxin to the receptor.

⁶Read before the New Bedford Medical Society, Jan. 7, 1906.

Second, an increased production of the receptors following the binding.

Third, the thrusting off of these increased receptors into the blood stream.

Wassermann has recently demonstrated the existence of these three stages experimentally.

It is a well-known fact that if a powerful toxin is heated to 145° to 150° C., or is kept for a long time exposed to heat, light and oxygen, it loses its toxic power. But it still has the power of satisfying through its haptophorous group the corresponding receptor. This innocuous toxin is known as a toxoid, $H + (T) + X$.

Some tetanus toxin which Wassermann had kept since 1896, and which had lost its toxic property, was used in the following experiments:

He injected this tetanus toxoid into a guinea pig, and from one to two hours afterward some fresh tetanus toxin was injected. He found that the lethal dose would have to be increased, because a part of the receptors were occupied by the toxoid (according to Ehrlich's theory). When, however, he waited somewhat longer, one to three days before injecting the fresh toxin, less than the minimum lethal dose tetanized and killed the animal, for in this case Weigert's Law of Hypercompensation had come into play, producing an increased number of receptors, without any formation of antitoxin, that is, freely circulating receptors as no antitoxin was found in the blood after injecting the toxoid; therefore Wassermann claims that the toxoid brings about a (1) binding of the haptophorous group with the receptors of the cell, and (2) an increased production of these receptors which remain attached to the cell, or sessile, and hence the toxophorous group is needed to bring about the necessary stimulation for the thrusting off of the receptors into the blood stream or the formation of antitoxin. This is a very important observation as you can see, since so many investigators claim that antitoxin can be produced by the use of toxoids.

The nature of the neutralization of the toxins by the antitoxins has been and still is productive of a great deal of discussion, and a wide difference of opinion. Ehrlich maintains that the neutralization is the result of a chemical reaction, supporting his views on the following observations:

1. Antitoxin and toxin can be titrated like an acid and an alkali.

2. Their union is hastened by heat and delayed by cold.

3. That combination takes place more rapidly in a concentrated solution.

Equally capable observers, Buchner being the chief exponent, oppose the chemical nature of the reaction, and explain it on purely physiological grounds. He claims that there is no interaction between the toxin and antitoxin, but when both are present in the body of an animal, the antitoxin stimulates the cells to resist the toxin.

The limitations of this paper will not allow me to enter into this discussion, but the evidence based on experimental observations seems to

support Ehrlich's view. Permit me to call your attention to one experiment which seems to me conclusive proof of the chemical theory.

From the researches of Meyers and Ramson it has been shown that tetanus poison is not absorbed via the blood or lymph channel, but reaches the central nervous system via the nerves; but the tetanus antitoxin, unlike the toxin, is not a neuropathic substance but follows the blood and lymph channels. Adrenal, as you know, strongly contracts the capillaries and thus blocks a particular area. Wassermann using a neutral or innocuous mixture of tetanus toxin and antitoxin, if he injected the hind paw of a guinea pig no tetanus developed. But if he injected some adrenal in a similar sized guinea pig, and waited till the capillaries were contracted, and then injected his neutral mixture, tetanus developed. His explanation is as follows: The path of the antitoxin was blocked, while the neuropathic path for the toxin was open, and hence the toxin was torn loose from its combination with antitoxin and hence produced tetanus. Wassermann found, however, if he waited two or three hours before using the mixture, the combination was so firm that the substances could no longer be torn apart. He could hasten the firmness of this union by using an excess of antitoxin. As suggested by Wassermann, the possibility of increasing this affinity by means of large doses of antitoxin is a point of considerable practical value in serum-therapy.

In passing from toxic immunity to anti-microbial, or immunity against infectious agents, we find the problem more complex, and the evidence and explanations to justify conclusions based on hypothetical deductions greatly at variance. This phase of immunity, like the toxic, is largely dominated by Ehrlich's views. Pfeiffer's reaction gave the initial impulse to investigations which have played such an important rôle in anti-microbial immunity. If a guinea pig immunized against cholera virus be injected with a virulent culture of the same into the peritoneal cavity, a clumping, finally disintegration and dissolution take place. Bordet's work on hemolysis, together with a great number of experiments, have shed considerable light on Pfeiffer's phenomena, which is the basis of the modern theory of immunity.

Bordet injected a horse's with a rabbit's xanthocytes, and found that the horse's immunized serum produced lysis of the rabbit's red blood corpuscles. If, however, this serum be heated to 55° C. for one hour, the hemolytic power was destroyed. But hemolysis could be restored by adding some fresh normal serum. Therefore the presumption arose that there are two bodies concerned in hemolysis and bacteriolysis. Ehrlich has demonstrated, the body destroyed by heat is the complement, while to the more resistant body he has given the name of amboceptor, intermediary body, or immune body. Therefore, lysis, according to his theory takes place by the amboceptor combining through its haptophorous group with the bacterial

or other alien cells, after which the complement unites with the corresponding Haptophorous group of the amboceptor causing the disintegration and finally solution of the foreign cells

$$H + N + X = \text{Red blood corpuscles}$$

$$H + H + X = \text{Amboceptor}$$

$$H + (L) + X = \text{Complement}$$

The lytic element (L) dissolves the red blood corpuscles.

Formation of amboceptor

$$H + N + X = \text{Red blood corpuscles}$$

$$H + H + N + X = \text{Tissue cells} = H + H + X$$

$$H + L + X = \text{Complement}$$

Investigators differ widely with regard to specificity of the immunity agents in hemolysis and bacteriolysis. There is considerable unanimity of opinion as to the specific nature of the amboceptor, but even this Ritchie claims is not unquestionable, because, "on the broad view of the theory of immunity the conception of specificity of the amboceptor is questionable, especially when we consider that the immune bodies are derived from the receptors or mediators concerned in normal metabolism; therefore, the assumption that the affinities of these side chains may be satisfied by other cells than the red blood corpuscles and bacteria."

As to the specific nature of the complement opinions are extremely divergent. Ehrlich believes that each series of immune bodies has a corresponding complement, while Bordet maintains the non-specific nature of the complement. It would be interesting, if not profitable, to enter into this discussion, but the limitation of this paper will not permit.

Observations of Weech and Neisser seem to indicate the specific nature of the complement in bacteriolysis, for if below a certain number of immunity bodies, or a great increase over a certain number be used, no bacteriolysis. But any increase of immunity bodies over the normal number has no effect in hemolysis.

Also anti-complements seem to prove the specific nature of the complement.

Oppenheimer claims that the complement is non-specific with reference to its action on cells but is specific with reference to its affinity for amboceptors.

There is considerable dispute with regard to the nature of the reaction between the bacteria-immune bodies and complement. Ehrlich believes that the amboceptor has no improving effect on the invading cells, but are merely mediators, or go-betweens for the complement. Buchner and Metchnikoff however believe the amboceptor not only is bound to cell but induces it, and that the alexine or complement merely completes the process.

Another important phase of this question is the origin and source of formation of these defensive elements of the body. Metchnikoff and his followers maintain that the phagocytes are the

chief protective agents of the organism against infection. His general phagocystic theory is so well known that we need not enter here into its discussion. New facts based on experimental investigations have caused a considerable revision of his first theory. Recently he contended that the origin and source of these immunity agents are the protoplasm of the leucocytes which attracts, kills and then englobes the invading cells. As you can readily see, the virtue of this theory is based on chemotaxis, the pathogenic effect of which depends on the fact whether the bacteria attract, do not attract, or repel the phagocytes. On this theory, natural immunity can only be accounted for on the ground that "the phagocystic reaction is very pronounced and so effective that an infecting agent is invariably destroyed. In artificial immunity the immunizing process produced by the administration of small doses of bacteria, or bacteria in a state of diminished virulence, enables the phagocytes to become accustomed to them so that they can ultimately endure and dispose of a dose fatal in another animal of the same species." Therefore, according to the phagocystic theory, the destruction of the morbid agent, if recovery takes place, occurs within the cell.

Metchnikoff claims, however, that the immunity body may escape into the body fluids, and there sensitizes the invading cell, but its destruction takes place chiefly through the action of the cytase which remains in the cell. This view is hardly consistent with the finding of both the complement and amboceptor in the body fluids. But here again, contending for his intracellular destruction of bacteria, he regards the presence of the immunity agents in the fluids of the body, due to degeneration of the leucocytes, supporting his contention on the observation: When the peritoneal cavity is injured by injection of foreign substances, there is almost complete disappearance of the leucocytes, a process of phagolysis, which is soon followed by hyperleucocytosis, mainly macrocytes if the foreign cells are xanthocytes; microcytes if they are bacteria.

Pfeiffer, however, denies the freeing of the immunity agents through phagolysis, basing his opposition on the fact that exudates rich in leucocytes, his or Pfeiffer's reaction takes place more slowly than where it is poor in white blood corpuscles.

Bordet does not concur in Pfeiffer's observation, claiming that the Pfeiffer reaction does not occur where phagolysis does not take place, e.g., anterior chamber of the eye, subconjunctival tissue and passive clama.

The experiments of Gengou seem to me to throw some light on this contention. Blood was drawn from a guinea-pig presenting a certain degree of secondary tuberculosis, allowing coagulation in the central gel and the plasma exhibited little or no bactericidal power, while the serum had definite bactericidal power. If Gengou's experiments prove positive in a

large number of experiments in both normal and immunized animals, the inference would be that there is little or no bacteriocidal power in the circulating blood, thus making the white blood corpuscles the chief source of the protective or defensive elements. Still Wassermann's experiments seem contradictory to the above conclusion.

Guinea pig + typhoid + immunized serum = no typhoid.

Guinea pig + typhoid + immunized serum + anti-complement sufficient to neutralize the complement = death to the animal.

He concludes that the complement is not confined within the cell but naturally exists free in the guinea pig's blood.

Gentlemen, it would lead us too far into meshes and entanglements of the many theories proposed, to discuss them all, but the probability is in a problem so complex and perplexing, that there is a certain amount of justification in the contention of each. That in some infections; *c. g.*, pneumonia, septicemia, the leucocytes are the main defensive agents; remember, I say, the chief, because we cannot say that other cells are not brought into requisition. Hoekton in some recent investigation found that the serum of pneumonia patients has very slight if any bacteriocidal properties, but leucocytosis was very evident, and you know that leucocytosis is of considerable prognostic value in pneumonia. Still there are other factors probably concerned that future investigation will discover. Hoekton and Reudiger in some recent studies on the antilytic action of salt solutions and other substances, conclude that those antilytic salts like CaCl_2 , BaCl_2 , $\text{K}_4\text{Fe}(\text{CN})_6$, "prevent hemolysis and probably bacteriolysis by virtue of their action on the complement:

"1. Because in nonlytic serum salt mixtures corpuscles freely take up amoebocytes whose complementophile groups remain free.

"2. Because precipitation of the antisalts restores the lytic property of the complement.

"3. Because of the quantitative relationship between complement and antisalts."

These observations together with the additional discovery that disintegrated typhoid bacilli have anti-bacteriolytic properties, open the way for an explanation of many clinical and experimental facts not in harmony with the accepted theories of immunity.

It has always been difficult to reconcile relapses and reinfection to the prevailing theories of immunity, but these experiments of Hoekton and Reudiger on salt solutions and disintegrated typhoid bacilli indicate that it is possible for the disintegrated bacteria or other substances to occupy the complement and by the introduction of fresh germs, reinfection or relapse may occur.

Another important observation is that a normal salt solution enhances the value of the lytic properties of an immune serum. This is of great practical value in view of the fact that a normal salt solution is so freely used in septic cases and abdominal operations.

I cannot better serve you in closing this paper than in the final words of Ritchie: "The consideration of the theories advanced at the present day to account for the phenomena of immunity thus leads on to results which have a deep biological significance. If looked at from the clinical standpoint alone, they form a contribution to our understanding of the complex processes by which living matter manifests itself as active. Not only so, but they lead to the possibility of understanding functions of cells, the laws which govern their activity, and the way in which groups of cells in the complicated household of the animal body contribute to each other. Thus not only the pathologist but the biologist and physiologist are concerned in the solution of the problems which are opened up."

Like Moses, we have a mere glimpse into the Promised Land of medical problems whose complexity has baffled the most acute scientific minds in all ages. As the explanations and understanding of the fundamental factors underlying the absolute defensive properties of the body become more evident, this glimpse of the "Promised Land" will change into an occupation. Then, and not till then, will many of the biological questions incident to the pathology of the individual be solved—the solution of which will generate a newer and better therapeutical armamentarium of the physician. The light is dawning, and in order to reach the highest coefficient of medical service, there must be a hearty co-operation of the laboratory worker and the clinician.

Clinical Department.

A CASE OF LANDRY'S PARALYSIS.*

BY W. D. ALSEVER, M.D., SYRACUSE, N. Y.

Mr. M., forty-eight years of age, a resident of Syracuse and a native of New York state was by occupation a metal polisher, but he had been out of work for several months, because of a strike, until ten days before he called on me. He was then working at his trade and was handling only one metal, namely, iron. He confessed to being a light drinker and he surely did not exaggerate. He used tobacco freely and also tea and coffee. At twenty years he had a soft chancre caused by an abscess of the left groin. A careful physical examination and cross-questioning about his subsequent history did not lead me to doubt the accuracy of this diagnosis or to think that he had suffered from other venereal disease. At twenty-eight years he was in bed nineteen weeks with inflammatory rheumatism but he entirely recovered and had no recurrence of the trouble. He habitually rose once or twice at night to urinate but micturition was rarely painful. One brother died of alcoholism and rheumatism, one sister of heart disease at thirty-five years, and another sister died in infancy. His wife was well and vigorous excepting for a rarefying osteitis of the bones of the right ankle which was first noticed after the disappearance of swelling of the legs which accompanied pregnancy during the previous year. There were several healthy children.

This man first consulted me on Saturday afternoon

*Read before the Syracuse Academy of Medicine, Feb. 6, 1906.

in September. He said that he felt perfectly well until the preceding Wednesday evening when he was unusually tired. Thursday night he was very weak and noticed some tingling of the fingers. On Friday he was still weaker and at 2 P.M. he quit work because his feet were heavy, his fingers tingled and he felt generally weak. On Saturday he went back to work but in the afternoon his knees became so weak that he fell down, soon after which he started for home stopping in my office on the way. He used a cane and his gait was that of a feeble man, it was neither talietic nor spastic in character. Beside weakness and tingling he complained of rather severe aching pain between the shoulder blades and beneath the sternum and of slight right-sided earache. There was some wax in the ear and a little tenderness behind it. These ear symptoms he remembered to have had before. Temperature and respiration were normal; pulse was 100, regular and not tense; the radial arteries were not perceptibly sclerosed. The pupils were equal and reacted to light and accommodation. There was no paralysis of motion or sensation, but motion was much enfeebled and sensation was a little delayed in the extremities, particularly the lower. Subcutaneous glands were to be palpated in the groins but not elsewhere. The organs of the chest and abdomen were examined but no abnormality was detected. No tenderness was detected in the body or extremities. Knee reflexes were absent and plantar reflexes present. There was neither toe nor wrist drop.

On the following day, Sunday, I saw him at his house and found him practically unchanged excepting that the ear symptoms had disappeared. On Monday he was weaker and there was slight tenderness in the middle of the back of the left arm; but nowhere else in his body, either over nerve trunks or muscles, could tenderness be elicited. On Tuesday I found him unable to walk and he even had some difficulty in handling himself in bed, not being able to pull up his knees without using his hands. The tenderness noted on the previous day had disappeared. The pain between the scapulae continued unabated, but the numbness and tingling, which were never very annoying, had diminished somewhat being still most marked in the feet and hands. Pulse was 80 and temperature and respiration were normal. The urine examination showed sp. g. 1020, acid reaction, amber color, no albumin and no sugar. On Wednesday I found that the pain in the back had been so severe as to prevent sleep; appetite was much impaired and any voluntary motion of the legs was impossible. Cutaneous sensation was still accurate but a little delayed. There was a little tenderness in the calves and over the spine between the scapulae. Koeng's test, performed by setting the patient up in bed, was negative but produced pain behind the knees. Respiration was easy and was not affected by position. Pulse was 100 and temperature was 97.2. The heart was still normal in size and action but there was a soft systolic blow just below and outside the nipple and a harder diastolic blow just above the nipple. The lungs and abdominal organs were unchanged. On Thursday the pulse had risen to 120. There was no power in the legs and very little in the arms and the other muscles were so weak that the patient found difficulty in hawking. The heart murmurs were fainter. The pupils reacted sluggishly. Sensation was the same but the feet and hands were objectively rather cold. On Friday the legs, arms and abdomen were completely paralyzed as were some of the thoracic muscles. Towards evening the diaphragm ceased to contract and the head was motionless. Throughout the day the voice failed so that by evening whispering was an exertion. Respiration was not rapid nor was there

struggling or gasping for breath, but the respirations became gradually shallower and shallower until each inspiration was marked by only the faintest movement of the clavicular regions. Sensation was apparently normal and the mind was perfectly clear and calm as it had been from the beginning. The two heart murmurs were heard with increased intensity but otherwise the chest and abdomen were as heretofore. On this day there was no pain. Death came at midnight, nine days after the appearance of the first recognized symptom. Throughout the sickness there was perfect control of the bladder and rectum. The drugs given, which were the iodide of potassium and ergot, seemed to produce no effect whatsoever. Unfortunately an autopsy could not be obtained. Several doctors saw the case and all concurred in the diagnosis of Landry's paralysis.

The diagnosis was arrived at by exclusion. It was first of all evident that the trouble was in the lower segment of the nervous system for had the lesion been in the upper segment the paralysis must have been spastic. If the lesion were of the cells of the cord, it must have been diffuse or confined to the anterior and posterior columns. Any transverse or local myelitis could not explain the symmetrical involvement of the whole body. Diffuse myelitis was excluded by the insignificance of the sensory disturbances and the absence of rectal and bladder symptoms. These same reasons were sufficient to exclude degeneration of the posterior columns. Acute anterior poliomyelitis rarely appears in adults and still more rarely involves both sides completely and symmetrically. So many of the symptoms of multiple peripheral neuritis were lacking that if this case were to be classed under that head it must be ranked as very atypical. The insignificance of the sensory symptoms, the absence of any period in which the muscles were spastic or the deep reflexes exaggerated, the absence of wrist and toe drop and the absence of the abnormal mental state seen usually with neuritis of alcoholic origin spoke strongly against a diagnosis of neuritis. The absence of fever suggested a degenerative rather than an acute inflammatory process.

Most diseases of this class are supposed to be due to toxemias. The only poisons which were under suspicion in this case were, first, those of syphilis, because of the confession of venereal disease and the existence of an obscure bone lesion in the wife, second, alcohol, because of the history and the appearance of the patient, and third, some metal other than iron which in a pure state or in an alloy the patient might unknowingly have handled.

The pathology of Landry's paralysis is so obscure as to impeach its right to exist as a clinical entity, yet those who saw this case were unable to establish a diagnosis which would have a firmer pathological basis.

J. C. HUBBARD, M.D., SECRETARY.

DR. DUDLEY P. ALLEN, Cleveland, read a paper on
TRAUMATIC DEFECTS OF THE SKULL. THEIR RELATION
TO EPILEPSY. A CLINICAL AND EXPERIMENTAL
STUDY OF THEIR REPAIR.³²

DISCUSSION.

DR. W. N. BULLARD: In considering the question of operative treatment in traumatic epilepsy it is best to make a division of the subject and to distinguish between prophylactic operations or operations performed after injury with a view to the prevention of epilepsy in the future, and operations performed after the event of epileptic attacks with a view to the relief or cure of epilepsy.

In regard to the first class, that is, the prophylactic operations, while our views are decided, we have had few reliable statistics on which they may be solidly based. It is my purpose this evening to show what grounds we have for our beliefs and what real scientific basis there is. The view commonly held, and as I believe the true one, is that trephining should be performed, roughly speaking, in all cases of compound fracture of the cranium. Operation is advisable in my opinion in practically all cases of fracture of the vertex or sides of the cranium in adults. One reason among others for this, is the prevention of epilepsy in the future by the removal of any source of irritation which may exist. Epilepsy is so serious and so terrible an affection when fully developed and we are still so uncertain as to the exact traumatic causes which produce or tend to produce it, that any procedure which renders the patient less liable to it and which is not seriously dangerous is advisable.

But, on the other hand, we do not wish to exaggerate the danger. We must look at the subject with all the light we have. What do our statistics show? How often does epilepsy follow fracture of the skull? How much more often does it occur after non-operated than after operated cases? We know practically nothing definite on this subject. In 1897, I published the results of investigations as to later symptoms in the case of patients with fractures of the skull. Out of 70 cases there was only one who had had convulsions. This was a man seen forty-seven (47) years after a fracture of the right frontal bone, which had occurred when he was eight years old. He had convulsions daily for a time, but had had only one during the last twelve years. He came to the hospital on account of a posterior sclerosis of the spinal cord not connected with his injury.

As far as these figures go, epilepsy is not a very frequent sequel of fractures of the skull, but from our general clinical experience, we are convinced that it occurs often enough to make it a serious danger.

Thus far I have no personal statistics on the comparative freedom from epilepsy in the operated and nonoperated cases.

The frequency with which epilepsy so follows injuries of the brain that we may consider them as a cause, or, in other words, the frequency of true traumatic epilepsy is not as great as is often supposed.

Out of the 845 cases of epilepsy at the Massachusetts

Hospital for Epileptics at Palmer, only 61 or 7.2% have injury to the head given as a probable cause.

"Examination of the records shows that of these 61 cases there are 22 cases (14 men and 8 women) whose epilepsy was probably not caused by trauma. This leaves 39 cases (23 men and 16 women) or 4.6% in which trauma may have been the cause. Of these 39 cases there are 19 cases (9 men and 10 women) in which the histories are deficient and it is impossible to say that trauma was the true cause. This leaves 20 or 2.4% of all the cases admitted to the hospital in which there is little doubt of the traumatic origin of the disease. Of the 20 cases probably caused by trauma, 14 were men and 6 women. The percentage of probable cases of traumatic epilepsy among the men is 2.9% and among the women 1.6%."

These figures must be accepted as fairly correct. We have on the one hand the well-known tendency of patients and their families to attribute any affection to a preceding accident or injury. On the other hand we have a certain number of cases in which no satisfactory history is obtainable and some of these may have been due to trauma.

In regard to operations for the relief of traumatic epilepsy there has been much discussion and much writing of recent years. Very few surgeons have had a large personal experience in this matter, and data collected from the literature are not reliable. The examination of the records of the Massachusetts General Hospital made last year showed only 21 cases of operation for epilepsy, most of them "post-traumatic." Out of these 9 received benefit and 12 received no benefit. (Report of Dr. J. J. Putnam.) In the Boston City Hospital there were 18 cases of trephining for epilepsy of which 12 were traumatic. Of these 8 were relieved, in 1 the result was doubtful and 3 were not relieved. I made full reports of these cases before this society last year.

In 1903, Dr. John C. Munroe reported the results of 11 cases of trephining for epilepsy before the National Association for the Study of Epilepsy and the Care and Treatment of Epileptics at a meeting in Philadelphia. He considered the outlook far from encouraging. Out of these cases 4 were distinctly improved; in 1 the influence of the operation was doubtful; in 2 there was no relief; in 1 temporary relief, but return of convulsions later; 2 cases were reported too early to ascertain results; 1 case was probably not epilepsy. These cases included 2 of Dr. Lund's and 5 were done at the City Hospital and are included in their statistics.

In regard to the time when the operation should take place, I think we would all agree that the operation should take place as soon after the injury as possible. After a number of attacks the chance of relief is less. Nevertheless, of the cases which were reported here last year, one which was relieved was apparently due to an injury received eighteen years previous.

DR. G. L. WALTON: I have been much interested in the paper and in the discussion. Both tend to emphasize the desirability of free and early operation in fracture of the skull without stopping to analyze too closely the conditions under the fracture. In point of fact we cannot accurately determine the underlying condition, but we do know that autopsies show that an injury of sufficient violence to fracture the skull is likely to cause more extended fracture and more widespread injury beneath than can be determined by external examination. Dr. Sachs in a recent paper voiced the neurological sentiment in stating that it was no longer advisable to follow fixed rules for operation, but the question must be in each case answered,

* See page 396.

"Is there probable injury to the brain, localized, accessible, and likely to do better under operation than if left alone?" If we are in doubt upon this point but are sure there is fracture, the benefit of the doubt should be given to operation.

Dr. Allen's very ingenious and very successful device for closing the skull is certainly worthy of trial in those cases in which it seems desirable to close the defect, though in my experience the cases are comparatively few in which this seems a sufficiently important indication to call for the additional operation.

Dr. E. L. SOUTHWICK: It is encouraging to find a few men approaching the field of epilepsy by experimental paths. The experimental outlook for the solution of the problems of genuine epilepsy has been until late years very dark. One point has been gained, however, by microscopic methods: no neuropathologist departs contented from the microscopic examination of the brain of an epileptic without discovering lesions. These injuries, which are notably exhibited in the outer layer of the cerebral cortex and often maximally in the Ammon's horn, affect the neuroglia as well as the nerve cells and are of such a nature that we are left in doubt whether they are causes or effects of the epileptic discharges. The fibrillary gliosis which characterizes the injured lesions has much in common with scar tissue found elsewhere in the body and has therefore seemed of trifling consequence in the big problem of epilepsy.

The trifling value of these findings by pathologists in the brains of epileptics has been due to our inability to follow the natural history of such injuries in the lower animals. The histopathology of the neuroglia in the lower animals has failed to advance in the past through the lack of good technical methods. The first technical step in advance was Weigert's neuroglia fibril stain of 1895. This stain, although well calculated to differentiate neuroglia from nerve tissue, was not so well adapted to the differentiation of neuroglia from the connective tissues of mesodermic origin. The latter differentiation is particularly desirable in the interpretation of traumatic lesions in lower animals. The histological complications in this kind of injury are well studied by the recent methods of Mallory.¹

What can be hoped from the use of modern histopathological methods? A few fragments only of these processes can be obtained by the examination of human tissue alone. In animals all the steps of the process of gliosis can eventually be followed. Not in the lower vertebrates, however, since their neuroglia supply is not great enough. The work by the Harvard Pathological Department has shown that the monkey possesses appropriate neuroglia tissue. In several varieties of monkey the neuroglia supply approaches that of man. We are approaching histopathology of the neuroglia which shall not be purely speculative. It is evident that a few non-speculative elements are desirable in the field of epilepsy.

Dr. J. COLLIER WEAVER: In undertaking to say something there coming on the subject of the paper by Dr. Allen, I was of opinion that my object was to investigate a part of the Massachusetts General Hospital, and I thought that the subject of the case was rather an interesting one, rather than a very common one.

We all had heard when we were young that the case that we were going to have something akin to the great success which we had been having in previous decades in working out cases of the abdominal cavity. It

¹E. B. Mallory, A Contribution to the Histopathology of the Central Nervous System, The C. V. Mosby Co., St. Louis, 1908.

²E. F. Southwick, A Case of Epilepsy in the Monkey. B. C. H. Med. Surg. Papers, 1905.

does not seem that that hope has been borne out by subsequent experience. But in watching the success of various other surgeons in operating for traumatic epilepsy I have experienced a certain degree of relief. It does not seem to me that mine appear so very bad as they did before I heard what Dr. Allen had to say upon the subject. I collected about eleven cards of cases of operations for epilepsy, but of these several were not of a traumatic character, and in one or two cases it was not possible to get the end results, and consequently have only about 6 cases in which results can be given you.

The first of these was a case that had come into the Massachusetts General Hospital in 1863, operated upon by one of the generation of surgeons previous to our own. The patient had experienced very little relief from what had been done for him at that time, and he had all the horrible conditions which follow epilepsy from pressure of the bone and formation of adhesions and cystic formation, etc., with brain degeneration. He had repeated fits and life was practically unendurable for him, and I operated upon him with perhaps the best result that could be wished for. The result was fatal. The operation was one of extensive trephining. There was severe hemorrhage from the bone with difficulty controlled by a wax plug which led to supuration.

Another case is that of a boy twelve years of age. He had a severe injury at the age of one, followed within a year by epilepsy. He was operated upon in 1890. Trephine was placed over left motor area where there was a marked depression with escape of much clear serum. The bone was removed and a cyst as large as an English walnut was found and removed. There were spurs of bone on inner side of button with dura adherent above and below. Ten years later heard of patient's death during a convulsion.

The next case has unfortunately a very short history. A man, forty-eight years of age, twenty-seven years ago had a very extensive portion of the skull shot away by an accidental shot wound sustained by himself. Facial paralysis and loss of speech followed at the time, but motion and speech subsequently returned. Epilepsy appeared for the first time four months ago. There was a scar five inches long and under the depressed bone there was a cyst and a great many adhesions. June 10, about six months after the operation, there had been no return of the attacks of epilepsy, but no subsequent history could be obtained. It seemed he had obtained considerable relief from the operation.

Another case was in a man thirty-four years of age. Blow on left side of head when a small boy. Two years later attacks in right hand sometimes associated with difficulty of speech; attacks daily, sometimes with loss of consciousness. Large trephine opening over fissure of Rolando. In 1894 had a large trephine, adhesions of dura to pia. Two years later attacks appeared as before operation, rather more excessive, but he has never had since the operation any loss of consciousness.

The next case was that of a young man, thirty-two years of age. He had been kicked by a horse and had a fracture over the right occipital protuberance. There was some tearing of the bone at the point that practically no definite scar of the injury. He had some slight motor deficits. The bone was trephined and a portion removed and he had been free from any further attacks.

Another case, that of a girl, twelve years of age, who had had epilepsy for four years before the operation. She had been operated upon during which she had epilepsy

sociated with other conditions. On June 3, 1891, a large trephine was placed over hand center. Dura found adherent and separated from pia by dark, soft, organized clot, very extensive; small piece of dura with a bit of the cortex removed. After operation left hand paralyzed, also to less degree left leg and face. The attacks returned but there was gradual improvement. The attacks were much less frequent. In 1905, he is reported to me by Dr. Putnam, whose case it was, as well, and must be regarded, therefore, as a cure.

Of these six cases there are two cures, — one a severe and one a slight case.

In regard to the method of operation in the early cases, I used the very large trephine, but in later years I have been in the habit of using the osteoplastic resection of the bone and replacing the flap over the operation.

In one case, which was not one of those that I have just reported, I had an experience which will be interesting perhaps to Dr. Allen. That was in a patient about ten years of age who was trephined over the right shoulder center and a large button was taken out and carefully kept in a warm solution of carbolic during the operation. There were also a large number of small masses of bone which had been bitten away in the attempt to enlarge the opening made by the trephine. The bone was replaced and the various fragments were dove-tailed together with great care about it. The wound healed by first intention, and I saw the patient several years after the operation, and there had been apparently a complete closing in of the bone. I do not feel sure that replacing the bone is so very important an indication in the operation. I remember the case of a member of my family who at the age of ten fell over a fence, sustaining a compound fracture of the skull. Fragments of bone were removed by the surgeon at the time, I should say covering a space as large as a silver dollar and a silver half dollar side by side. The boy grew up to be an old man, and there was a large, soft "fontanelle" on the side of his head, but he never experienced the slightest inconvenience from the injury.

DR. F. B. LUND: I wish to show a patient nine years old, who five years ago had had a fall causing a short period of unconsciousness, and a depressed fracture of the skull. The depression, contrary to the usual practice, was not elevated. One reason for showing the case was to emphasize the point that it was desirable to elevate all depressed fractures of the skull in order to prevent the appearance of epilepsy later. This little boy was seen by Dr. Lund last March, five years after the injury. Six months before he saw him he had had a convulsion; two months later another; then the convulsions became more frequent until in March he was having them every two weeks. He was seen at the Out-Patient Department, referred to Dr. Monks, who on was on duty at the time, and who operated. The operative findings were interesting. A flat piece of bone projected inward from the posterior edge of the depression, which was about an inch in length, a distance of about three eighths of an inch. The edges of this piece of bone were smooth and scalloped, not rough as would be the edges of a fresh fracture. Surrounding and covering this bony spur was a sac containing serum which lay between it and the brain, making a distinct cushion so that the bone did not project in any sense into the brain, but the sac of fluid or cyst which surrounded it made a distinct depression in the brain surface. The pressure of this fluid against the bone had probably smoothed and rounded it. The cyst walls were removed, the bone which projected inward was removed, and the edges of the opening in the skull thoroughly smoothed. The

boy early in his convalescence had two convulsions, but has since remained entirely well and had no recurrence. Nine months have elapsed since the operation.

In regard to the statistics for operation for epilepsy, Dr. Lund said that he found the histories very difficult to follow, and the ultimate results impossible to ascertain from the hospital records. A great many of the patients who were discharged relieved had convulsions afterward. The most favorable results in operations for epilepsy which he had seen in his personal experience had been the cases where cysts were found pressing upon the brain, sometimes in conjunction with bony depressions, sometimes not. In cases where scars or adhesions are found the result is apt to be poor because when scars or adhesions are excised with perhaps temporary relief of symptoms, as time goes on they are replaced by other scars and other adhesions. In cases where cysts are found, however, if the cyst is drained, and sufficient of the bony wall of the skull removed to prevent the fluid re-accumulating, excellent results may be obtained. It has seemed to him that instead of attempting to replace the bone in these cases the essential point is to remove so much of the bone that the cyst cannot reform. A case which Dr. Munro had reported in his most interesting paper on trephining for epilepsy² was a case in point. This boy had had a fall causing unconsciousness in childhood. Five years ago he began to have epileptic attacks. At the time he was operated on, Nov. 14, 1902, he was having attacks every day, or two a day. He had an attack on the way to the railroad station going to Boston, and when the doctor went to the station to meet him he found him in the police station; he had been arrested for having an attack on the street. There was a scar on the left side of the forehead, no depression of the bone. The bone was found thinned by the pressure of the cyst, filled with partly coagulated serum causing a distinct depression in the brain. The cyst was drained, and the attacks completely relieved for three or four weeks. Then they recurred, and his physician, Dr. Morrissey of Unionville, Conn., removed the bone clear to the edges of the cyst so that it was impossible for it to re-accumulate. Relief for a considerable period followed this interference, and the boy has made marked improvements, and improvement has continued ever since the operation. In studying the cases which Dr. Bullard made the basis of his statistics, it seemed to the writer that the only ones in which real relief had been obtained and which could be ascribed to the operation were the ones in which the cyst either on the surface or directly beneath the cortex of the brain had been found.

Epilepsy is a disease which is so discouraging to all methods of treatment that in every case it seems to the writer where there is a distinct history of injury, especially in childhood, or an old scar, an exploratory operation should be performed. If we are fortunate enough to find a condition which can be relieved we have done the only thing that offers our patient any hope, and if not, we have done no harm. Whether it is worth while, not finding cysts, to excise scars or adhesions in the brain is a legitimate matter for argument. Depressed bone should, of course, always be elevated.

HOSPITAL FOR THE TREATMENT OF ACUTE ALCOHOLISM. — According to the *Medical Record*, an ordinance in the Chicago City Council has been introduced by Alderman Scully, providing for the construction and maintenance of a hospital for the treatment of acute alcoholism.

AMERICAN DERMATOLOGICAL ASSOCIATION.

TWENTY-NINTH ANNUAL MEETING, HELD AT THE ACADEMY OF MEDICINE, NEW YORK CITY, DEC. 28, 29 AND 30, 1905.

(Continued from No. 14, p. 379.)

THE EVOLUTION OF A CASE OF MYCOSIS FUNGOIDES UNDER THE INFLUENCE OF ROENTGEN RAYS.

DR. CHARLES J. WHITE and DR. FREDERICK S. BURNS, of Boston, Mass.: This paper gave the clinical details of a case of mycosis fungoides in a man fifty-two years old, a farmer by occupation, and a native of the United States. The patient had always enjoyed the best of health until the onset of his present illness, in March, 1902. He was admitted to the Skin Ward of the Massachusetts General Hospital on June 26, 1905, and three days later, x-ray treatment was begun. The treatment was repeated at intervals of two or three days, until Aug. 21, 23 exposures being given in the course of fifty-four days. The total time of the exposures was eight hours and twenty minutes. Under this treatment, in addition to local and internal remedies, the skin lesions rapidly disappeared, but coincident with their disappearance the patient suddenly developed severe toxic symptoms. He gradually lost flesh and strength, and died on Sept. 7, 1905, apparently of toxemia. The autopsy showed a fibrino-purulent bronchitis and pleuritis; hyperplasia of the spleen and dilatation of the heart, with evidences of streptococcus septicaemia, which was attributed to the presence of bed sores in the final stage.

In connection with the report of this case, Dr. White reviewed the literature upon the subject of the toxic effects produced by the x-rays, due to the occasional rapid disappearance of various tumors under the influence of the rays, and the absorption by the system of the broken-down tissue products.

DR. J. NEVINS HYDE reported a case of mycosis fungoides in which no lesions had recurred in the regions treated by radiotherapy, and in which the patient was still in very excellent condition at the present time, after the disease had lasted eight years. He thought the prognosis depended largely upon whether the treatment was begun in the fungoid or pre-fungoid stage of the disease.

DR. S. PORTITZER thought the death of Dr. White's patient might possibly have been due to septicaemia, resulting from streptococcus infection.

DR. WILLIAM A. PRUSE said that while he was willing to admit that toxic symptoms might result from the rapid dissipation of a tumor under the influence of the x-rays, his personal experience seemed to indicate that their occurrence was of extreme rarity.

THE ERYTHRODIPYRIA.

DR. J. NEVINS HYDE, of Chicago, Ill., said his paper was an additional contribution presented by the author and his colleague, Dr. Ernest F. McEwen, at the preceding meeting of the Association, entitled, "On the Relation of Certain Dermatoses to Each Other and to Changes in Vascular Equilibrium." The title selected did not refer to any brittleness of the nail tissue, but was chosen because of the exact presentation in the nail-plates of the purplish-white hue visible on the inner face of the shell of a cherry egg. Four cases were reported as illustrative of this modification of the nutrition of the nails. The following features were common to all. The patients were all young women, below the standard of sound health. In none was there any distinct affection of the circulatory system. All exhibited marked interference with the stability of the vascular equilibrium, and all suffered from hyperidrosis of the hands and feet. In some of the cases there were distinct changes in the hue not of the nails only, but also of the skin of the hands and feet, the bluish and purplish shades being recognizable in the integument of those organs at some distance from the nails, and also in the nail-beds. The nails were thin, but never coarse in structure. There was a distinct tendency in all to curving of the nail plate away from the axis of the bed. The changes in the nail were thought without question to be intimately associated with the hyperidrosis.

latory system. All exhibited marked interference with the stability of the vascular equilibrium, and all suffered from hyperidrosis of the hands and feet. In some of the cases there were distinct changes in the hue not of the nails only, but also of the skin of the hands and feet, the bluish and purplish shades being recognizable in the integument of those organs at some distance from the nails, and also in the nail-beds. The nails were thin, but never coarse in structure. There was a distinct tendency in all to curving of the nail plate away from the axis of the bed. The changes in the nail were thought without question to be intimately associated with the hyperidrosis.

A CASE OF PSYRIASIS RUBRA OF HEBRA'S TYPE.

DR. F. H. MONTGOMERY and DR. PETER BASSETT, of Chicago, Ill.: The patient was a man, forty-six years old, a farmer, whose family history was unimportant with the exception of the fact that one sister had died of tuberculosis. The patient had typhoid fever seven years ago, and for twenty-seven years had suffered more or less from asthma. For fifteen years with the exception of six years during which he had abstained wholly, he had used alcoholic stimulants periodically to excess, indulging in sprees of three or four days' duration on an average of once in ten days or two weeks. His skin disease began in February, 1901, as a large blister on the plantar surface of the right foot. This spread to almost the entire sole of the foot, and in a few days an erythematous and slightly vesicular eruption appeared on the left foot, then on the buttock, and ultimately almost the entire surface of the body was covered with a red and slightly scaling rash. For the first few weeks this gave rise to severe itching and burning. Soon after the exanthem became generalized, exfoliation was pronounced, and for the past sixteen months the skin had remained simply red and scaly, showing no other type of lesion. Two months after the eruption became generalized, the pubic hairs fell out. Those of the eyebrows were also lost, but returned. The plantar and palmar surfaces showed a markedly thickened skin. The patient died on Aug. 22, 1905. This case, in common with others, in its clinical history and in the autopsy findings, suggested that a primary infection of the skin was the cause of, first, the cutaneous disorder; and, second, the general marasmus. It had to be admitted, however, that the etiology and pathology of psoriasis rubra were as yet unsolved problems. The relation of the disorder to tuberculosis, suggested by Jadassohn, was not at all clear. It was highly improbable that this cutaneous affection was a rare manifestation of so common a disorder as tuberculosis, but it was quite conceivable that the marasmus accompanying the skin disease might render the patient more liable to tubercular infection. The necropsy findings did not throw much light on the nature of the skin affection, and also left doubt as to the cause of death. The conditions found suggested a terminal infection, either uræmic or toxic, secondary to the skin disease.

DR. E. A. DEMME, of Philadelphia, said there was no doubt that under the name psoriasis rubra a number of different clinical types of case were grouped. His own experience had been that a psoriasis rubra was extremely rare in this country. He could not recall a single case of the Hebra type, with all its classical symptoms, at a fatal termination.

DR. JAMES C. WORTH, and he considered a psoriasis rubra, as described by Hebra, a very rare disease. Furthermore, that case of a cutaneous dermatosis, which resembled in many features Hebra's psoriasis, were not of so very infrequent occurrence, and he

was sure that Hebra did not recognize them as distinct; he called them all pityriasis rubra, and gave the type to the extreme cases which lived long enough to undergo atrophy.

EXHIBITION OF LANTERN SLIDES.

DR. JOHN A. FORDYCE and DR. GEORGE H. FOX gave a lantern slide exhibition of various lesions of the skin, both gross and microscopic.

BULLOUS AFFECTIONS AND THEIR CLASSIFICATION.

DR. EDWARD B. BRONSON, of New York City, in presenting this paper, said the term bullous diseases should be taken in a very restricted sense, inasmuch as a bullous eruption was nearly always the concomitant of some other disease. Of bullous affections there were two fundamental divisions: (a) Obstructive forms, in which bulle occurred as the result of obstruction in the sweat follicles or in the lymph channels, with mechanical distention at the point of escape in epidermis. (b) Acantholytic forms, in which a vital impairment of the cohesion between the prickle cells enabled a relatively slight effusion of serum to force its way between the cells and produce a lacuna. Acantholysis might be a consequence: 1. Of external injury. 2. Of absorption into the epidermis of venomous or infectious matter. 3. Of some other cutaneous affection, which might be either symptomatic or idiopathic, and of which the bullous lesions were only an incident. 4. Finally, of some internal disease, transmitting an injurious influence directly to the prickle cell layer of the skin, in which case the bullous eruption might be a pathognomonic sign either of a localized skin lesion or of some more general disease referred to the skin through the nervous system, but even in such cases the immediate cause of the bullous effect was very often some more or less slight and commonly overlooked local external injury.

THE CLASSIFICATION OF BULLOUS DISEASES.

DR. J. T. BOWEN, of Boston, Mass., said it was generally conceded in the dermatological world to-day that the word pemphigus could no longer be accepted in its old sense as representing almost all bullous eruptions not due to traumatism, or which represented a stage in the evolution of some well-known dermatosis. It was equally certain that while an advance had been made in eliminating many forms from this class, no unanimity had been reached, and the subject was very far from being scientifically settled. The group that had been so ably described by Duhring as dermatitis herpetiformis had come to be regarded by almost all as entitled to its own place, although there were differences of opinion as to just what should be included in that group.

Dr. Bowen said he would propose dividing the bullous dermatoses into the following provisional groups: 1. Acute infectious bullous dermatitis. This was the form that had been described as acute infectious pemphigus. 2. Chronic hereditary bullous dermatitis. 3. The form of bullous dermatitis which was described first by Neumann under the title of pemphigus vegetans. 4. The form of bullous dermatitis described as pemphigus foliaceus. 5. Dermatitis herpetiformis. The boundaries of this form could not at present be strictly drawn. 6. There remained a class of cases characterized by the more or less constant recurrence of pure bullae, without signs of multiformity, and with a certain symmetry of the lesions, which were frequently found on the mucous membrane. The affection was accompanied by very few subjective symptoms, and pursued a chronic and usually fatal course. This was the form

described as chronic pemphigus by Brocq and Besnier, and was the prototype of the German pemphigus.

The discussion of the subject of the classification of bullous diseases was opened by DR. JAMES C. JOHNSTON, of New York City, and continued by Dr. Samuel Sherwell, of Brooklyn, N. Y.; Dr. L. A. Duhring, Dr. M. B. Hartzell, Dr. Ravogli, Dr. J. Nevins Hyde, Dr. Jay F. Schamberg, Dr. Charles W. Allen, Dr. H. W. Stelwagon, Dr. William A. Pusey; Dr. H. C. Baum, of Syracuse, N. Y.; Dr. Charles J. White, and was closed by Drs. Bronson and Bowen.

ERYTHEMA PERSTANS, WITH REPORT OF TWO CASES INVOLVING CIRCINATE LESIONS.

DR. GROVER W. WENDE, of Buffalo, N. Y., read this paper, in which he offered the following conclusions: 1. That we were dealing with a variety of skin affections which might be included under the general name of "erythema perstans" which had points both of similarity and dissimilarity. In some, there were simple, chronic, inflammatory patches; in others, diffused patches, papules or nodules. Frequently, evolution began in the center, and left annular or gyrate figures. 2. There seemed to be no law governing their duration, since they might last weeks, months or years, or even during the entire life of the patient. The etiology might still be considered as obscure. No age was exempt, cases having been reported in children and in those advanced in years. The condition seemed to be more frequent in men than in women. 3. A study of the cases reported showed that the condition might be caused by intestinal toxemia, a gouty or rheumatic diathesis, or atmospheric changes. 4. The limited number of microscopical examinations that had been made revealed slight differences. All of the cases showed a superficial inflammation, dilatation of blood vessels, infiltration of cells and an edematous condition of the tissues.

CONSIDERATIONS ON PEMPHIGUS VEGETANS.

DR. A. RAVOGGI, of Cincinnati, Ohio, read this paper, and reported the following case: The patient was a married woman, twenty-five years old, a native of Russia, who had lived in this country for five years. She was married when she was twenty-three years old. Four months after her marriage, she noticed an eruption on her chest, which, according to her description consisted of red, erythematous patches, and later on of hard pimples, extending from the chest to the anterior part of the neck. These gave rise to a burning and slightly itching sensation. On Sept. 23, 1904, she gave birth to a healthy child, and from that time on she was free from any eruption until April, 1905. Then her navel was covered with a blister, which broke, leaving an excoriated surface oozing serum. Soon afterwards, her genitals began to itch and burn, and the whole pubic region and groins were covered with small white lesions containing clear water, which later became turbid. Bulle of the size of hazel nuts began to appear under her breasts and in both axillae, and these, on breaking down, left raw surfaces, oozing, and then granulating. Bulle also appeared in the mouth and on the lips. Both axillae subsequently became filled with masses of grayish-brown vegetations, resembling cauliflower-like growths. Death occurred on Oct. 25, 1905, of diarrhea and exhaustion.

TWO CASES OF MULTIPLE TUMORS OF THE SKIN IN NEGROES ASSOCIATED WITH ITCHING.

DR. JAY F. SCHAMBERG and DR. ROSE HIRSCHLER, of Philadelphia, Pa.: The paper gave the clinical histories of two cases of long-standing nodular growths in the skin of negro women. The disease was possibly

the same as that described by Dr. W. A. Hardaway, under the name "Multiple Tumors of the Skin Accompanied by Intense Pruritus." The essential features in the two cases, which were almost identical, were as follows: 1. The development of tubercles and tumors in the skin, principally of the extremities, accompanied by more or less severe itching. 2. The horny, resistant character of the epidermis overlying the growths. 3. The persistence of the tubercles and itching for many years. 4. The recurrence of the nodules after extirpation. The two nodules which were excised in the first case were replaced by tumors of the same character as those removed. The cause of the disorder was undetermined. The theory that the growths might be the result of traumatism from scratching was neither borne out by the statements of the patients nor by the appearance of the lesions. Pathologically, the sequence of events appeared to be as follows: dilatation of the cutaneous blood vessels; cell infiltration, chiefly in sharply circumscribed masses; proliferation of the fixed connective tissue elements; formation of new collagenous fibers. A feature of more than passing interest was the great abundance of mast cells present.

TWO CASES OF PAGET'S DISEASE TREATED BY THE X-RAYS WITH A REPORT OF THE MICROSCOPIC FINDINGS IN ONE OF THEM AFTER PROLONGED TREATMENT.

DR. M. B. HARTZELL, of Philadelphia, Pa., said that from the results obtained by the treatment in the two cases of Paget's disease reported in this paper, and more particularly from the microscopic study of one of them after treatment had been continued for a considerable time, he believed we might conclude that the careful, systematic and prolonged use of the x-rays might completely and permanently cure the disease of the areola and nipple, but he also believed that this agent had very little effect upon the epithelial proliferation in the ducts of the nipple, and in the alveoli of the mammary glands. If Paget's disease was in the beginning limited to the areola and surface of the nipple, the ducts and mammary glands becoming involved only after some considerable time, then we might hope, by the early and persistent use of the x-rays, to bring about a complete and lasting cure; but if the ducts and glands were involved in the process from the beginning, the knife of the surgeon should be the first, and not the last resort. Which of these two views of the malady was the correct one, had, in the writer's opinion, not yet been definitely settled.

DR. CHARLES W. ALLEN thought that Paget's disease probably existed much as did mycosis fungoides, in a variety of stages, and that it passed through various degrees of malignancy, just as an innocent eczema of the lip might develop into a malignant lesion. The speaker could recall at least two cases in which the lesions looked very much like Paget's disease, but which cleared up under simple treatment, and the patients had remained well. In every case where the diagnosis of Paget's disease was beyond doubt, the breast should be removed.

DR. THOMAS C. GEORGE, of Baltimore, Md., said that Paget's disease, marked with epithelioma of the lip and tongue in the early lymphatic enlargement that it gave rise to, and he agreed with Dr. Shepherd that the breast should be ablated as soon as the diagnosis was established.

DR. HARTZELL in closing said that while ablation of the breast was the first consideration from the surgeon's point of view, the operation was a very serious one for the patient. Take, for example, a woman with a superficial excoriation of the nipple,

with redness and swelling of the areola. Probably, the lesion represented the early stage of Paget's disease, and it was in cases of that character that the question of treatment was surrounded with difficulties.

A CASE OF CHRONIC ULCERATION IN THE PUBIC REGION.

DR. S. FOLLITZER, of New York City: The patient was a married man, thirty-five years old, a native of the United States, and a railroad employee. His present illness began in Richmond, Va., on Oct. 29, 1901, when his attention was attracted to a small papule on the glans penis. Ten days later the papule was transformed into an ulcer, and within a few days a number of small "mattery sores," as the patient described them, appeared on the glans. Shortly afterwards he noticed a small papule on the pubic region over the symphysis, from which a sanious fluid was discharged. A small papule, like that on the pubis, also developed on the left side of his forehead. This broke down and ulcerated, but eventually healed. The sore on the pubis, however, proved rebellious to treatment, increasing in area and attaining the size of a silver dollar. In March, 1905, the patient went to Hot Springs, Ark., where he spent nearly three and a half months under the care of Dr. H. P. Collings, who regarded the ulcerations as chancreoidal. The patient for a short time was given mercury and the iodides, but under this treatment the ulcers seemed to grow worse. Locally, a variety of applications were made, and the condition would improve at times and then again grow worse. Repeated microscopic examinations gave negative results, and spreads and cultures yielded only the usual crop of saprophytic organisms, excepting a single colony of a bacillus which the speaker said he had not been able to identify. It was apparent from its characteristics that it did not belong to the pyocyanous group, with which, however, it shared some important features. A histological examination of sections cut from the border of the ulcers gave the usual picture of granulomatous tissue in a chronic inflammatory process of the skin. As the case was evidently not improving under external applications, it was excised. The patient was subsequently operated on at the Garfield Hospital, in Washington, D. C., for a tumor of the testis, which upon histological examination was apparently syphilitic. In concluding his paper, Dr. Follitzer expressed the opinion that this chronic ulceration in the pubic region represented a hitherto undescribed form of disease. That the bacillus had been isolated was the cause of the ulceration had not been proven, but there was a certain degree of probability in favor of that view.

DR. A. RAYGARD said he could recall quite a number of cases of ulcerative lesions involving or surrounding the genitals, in which it had been very difficult to establish whether they were tubercular or syphilitic, or the result of a mixture of both these diatheses.

DR. L. DESSAU BRIDGES said that in many of these cases the original lesion was much modified by the ordinary pus organisms, which were everywhere present.

DR. J. NEVINS HYDE referred to a number of similar cases of his own in which the ulcerative processes were not syphilitic, as they had resisted the most vigorous and thorough anti-syphilitic treatment. They had been described under the title of chancreoidal or lupoid ulceration of the genitalia and the most satisfactory treatment that he had had any experience with was continued immersion. The patients were placed in a carefully regulated hot bath, which they left only for necessary purposes until the ulceration had healed.

DR. CHARLES W. ALLEN said he agreed with Dr. Hyde in regard to the efficacy of the permanent bath in the treatment of this class of lesions, which had been described under the name of porosis, and were probably the result of a mixed infection.

A CASE OF RECURRENT BULLOUS ERUPTION OF THE FACE:
PROBABLY PEMPHIGUS HYSTERICUS.

DR. FRANCIS J. SHEPHERD, of Montreal: The case was that of an unmarried girl of twenty, who for the past eight years had suffered from a recurrent eruption on the face. This appeared first as small, inflamed blisters on the forehead, chin, cheek and nose; these soon increased to the size of a ten-cent piece, became filled with bloody serum, then discharged and formed scabs. There might be half a dozen or more of these blisters at one time. As a rule, the bullæ came out in successive crops, and lasted about a month. They gave rise to burning, but no itching. There was no regularity as to where the spots might come out, but they had never appeared on the hairy scalp. The blisters left a pigmented mark after healing. Dr. Shepherd said the cause of the eruption was obscure. It was possibly connected with menstruation. The girl's general health was excellent, and the speaker said he could not divest himself of the feeling that the eruption might be self-induced. At any rate, he was inclined to regard it as a tropho-neurosis.

DR. L. DUNCAN BULKLEY said he had a list of over ninety cases of skin lesions of various kinds, collected in private practice, which were apparently more or less directly connected with disturbances of the function of menstruation, and a thorough review of the literature would doubtless reveal many more.

DR. L. A. DUHRING said he was inclined to attribute these eruptions to different causes, in which the nervous system was more or less implicated. While menstruation was doubtless an important factor in some of them, there must be other factors as well, as the same types of eruption were met with in boys.

DR. ARTHUR VAN HARLINGEN mentioned the case of a colored girl in whom there were beginning blebs appearing at the time of the menstrual epoch. In that case, there was probably a hysterical element, together with a morbid condition of the skin.

The final session of the Association was devoted largely to the presentation of patients.

DR. C. T. DADE gave a demonstration of the uses of liquid air in the treatment of skin diseases.

carefully sifted and considered, before being set down in type. We heartily recommend the volume to those of whatever calling who desire to know the details of the seamy side of life.

Life Insurance Examinations: A manual for the Medical Examiner and for all interested in Life Insurance. By BRANDREITH SYMONDS, A.M., M.D., Medical Director Mutual Life Insurance Company of New York, etc. New York and London: G. P. Putnam's Sons. 1905.

Dr. Symonds is a lecturer in life insurance examinations at the University and Bellevue Hospital Medical College, and has embodied in this small volume of 214 pages the substance of his lectures, somewhat amplified. The book is a simple statement of the main facts necessary to the insurance examiner and may certainly, in a general way, be used with profit and safety. Certain statements regarding the nervous system are likely to leave a somewhat false impression with the reader.

Organotherapy, or Treatment by Means of Preparations of Various Organs. By H. BATTY SHAW, M.D. (Lond.), F.R.C.P., Lecturer in Therapeutics, University College, London; Assistant Physician to University College Hospital and to the Hospital for Consumption and Diseases of the Chest, Brompton. Illustrated. Chicago: W. T. Keener & Co. 1905.

This small volume of two hundred and fifty-six pages gives an excellent summary of the present status of Organotherapy. The author is conservative in his acceptance of extraordinary claims for such treatment and thus enhances the value of the book. Reference is made by footnotes to articles quoted and the bibliography of the subjects covered is fairly complete. The book is almost wholly a compilation from the literature. It is well written and will prove useful to the general reader and those carrying on research in organotherapy.

Handbook and Atlas of Orthopedic Surgery. By JAS. K. YOUNG, M.D. Philadelphia: P. Blakiston's Son & Co. 1905.

If the measure of the dignity and importance of any subject is given by the evidence of valued effort in the production of a treatise dealing with it, the ample work of Dr. Young, if for no other reason, merits careful attention. Dr. Oliver Wendell Holmes was fond of calling the attention of his class to the magnificence of the illustrations of the old Italian masterpieces of anatomy in which the human figure was superbly engraved, often holding out to the beholder the internal organs in attitudes of artistic grace.

The superb steel engraving in medical publication has given place to the more commonplace but more accurate halftone, but certainly even Aldus or Plantin would have been proud to have published a book of such attractive excellence. The book is a large and expensive one for the ordinary student, but it is one which the orthopedic surgeon will be glad to have in his library for reference and enjoyment.

Recent Literature.

Poverty. By ROBERT HUNTER. New York, London: The Macmillan Company. 1904.

In this volume of 382 pages is presented an assemblage of facts regarding the various aspects of poverty, from the pen of a man who knows whereof he writes. An attempt is made to define poverty, to estimate its extent in the United States, to bring to general knowledge its evils, and finally to suggest remedies. The headings of the chapters will indicate the scope of the book: Poverty, The Pauper, The Vagrant, The Sick, The Child, The Immigrant. The author writes with much sympathy of the conditions which he has met and studied. Particularly for the social economist, and also in less degree for the physician, the book should be stimulating, and useful as a compendium of facts, evidently

THE BOSTON
Medical and Surgical Journal.

THURSDAY, APRIL 12, 1906.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 705 Faddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE, (Incorporated),
 27 and 29 BROMFIELD STREET, BOSTON, MASS.

THE CENTENNIAL OF THE BOSTON MEDICAL
 ASSOCIATION.

THE Boston Medical Association was formed in 1806 to take the place, apparently, of the short-lived Boston Medical Society formed in 1780. The original members of the Boston Medical Association numbered thirty.

The main object of the society was to establish rules which should guide physicians in their relation to each other and to the public. Accordingly, at the annual meeting in 1807 the standing committee, consisting of Drs. John Warren, Lemuel Hayward and John Hunt, were "instructed to propose a code of medical police to be submitted to the consideration of the Association at their next annual meeting."

The report was made at the appointed time and was accepted, and it was then recommended to the committee with instructions to print five hundred copies, to present to each member of the Association three copies and to distribute the remainder to other physicians of the state.

This report is an interesting document, admirable in style and should be read entire. The headings are, Consultations, Interferences, Differences of Physicians, Discouragement of Quackery, Conduct for the Support of the Medical Character, Fees, Exemption from Charges, Various Offices and Seniority.

Consultations are recommended but in connection with rivalry and jealousy are deprecated, while candor, justice and due respect are recommended towards the physician in charge, and it is stated he should be the one to deliver to the family the directions agreed on.

The consulting physician is not to visit without

the attending physician except at the latter's request or in an emergency. Whatever their private resentment or opinion of each other, physicians should divest themselves of all partialities and think only of those under their care. Mutual confidence between the physicians concerned is considered a necessity and in its absence a consultation should be declined. Punctuality is enjoined and fifteen minutes is made the limit of reasonable waiting. Expectation of business or employment is to be based on degrees of qualification, not on artifice and insinuation, and so "a certain undefinable species of assiduity and attention to the families under the care of another" are decreed as well as "meddling inquiries," etc.

Differences of physicians, if they cannot immediately be terminated and do not come under rules already made, should be referred to arbitration of the other members, but should not be made public.

The warnings against quack remedies and "secret nostrums," sound not unnatural just now.

Esprit de corps being held to be "a principle of action founded on human nature and being duly regulated, both rational and laudable," care is recommended to avoid contumacious representations of the faculty, all general charges against their selfishness or improbity and an affected or joocular skepticism regarding the healing art.

As to fees, it is deemed a point of honor to follow the established rules of the community, except in case of the poor, though no new fee-table was made out until later. Clergymen and physicians and their families are to be exempted, except under certain conditions.

"Whenever a physician officiates for another by his desire, in consequence of sickness or absence, if for a short time only, the attendance should be performed gratuitously as to the physician, and with the utmost delicacy towards the professional character of the gentleman previously connected with the patient."

Though questions of seniority and precedence do not disturb us now, the Association found it necessary at that time to provide that "seniority among practitioners of this town should be determined by the period of public and acknowledged practice as a physician or surgeon in the same." Apparently this arrangement was mostly aimed against "troublesome interlopers," by new settlers, perhaps not long stationary in the place.

Nowadays, many of these questions seem so well settled by long-established custom that we hardly feel the necessity for rules, but no doubt this is largely because this excellent code started the very customs on which we depend for guidance. Perhaps, too, it would be better if we adhered more closely to some of the rules that are now regarded as somewhat antiquated.

In 1830 Rules and Regulations, including a fee-table, were added to the Police Code. It was intended at that time that the Association should include all regular practitioners, and it was the rule that no member should consult with a physician not a member of the Association. But this rule must soon have become a dead letter and in 1864 it was changed so as to provide only against consulting with "irregular practitioners."

The fee-table of 1830 was revised in 1864 and again in 1884 (and perhaps oftener), and the rules and regulations have also been changed, but every report of the Association presents the Police Code, now one hundred years old, in its original form.

REPORT OF THE MASSACHUSETTS GENERAL HOSPITAL.

THE annual report of the Massachusetts General Hospital for the year 1905 is the ninety-second in the history of the institution and fills two hundred and seventy-five octavo pages. Although not so many changes have been made during the year as in certain years immediately preceding, nevertheless, the report shows the constant growth which the hospital is undergoing and the attention to details which tend to increase the total efficiency. No new buildings have been erected at the general hospital, but the Townsend and Bigelow wards have been completely renovated and thereby much improved. At the McLean Hospital at Waverley a new building for women, to be known as the Codman House, is being constructed as a result of the bequest of the late Edward W. Codman. The chapel at this department of the hospital has been completed and will soon be ready for use. A house for nurses is still needed. At the general hospital somewhat fewer patients were treated than in 1904, the total being 5,096, and somewhat fewer free patients were treated than during the preceding year. Upwards of three thousand fewer patients were treated in the Out-Patient Department than in 1904, the number being 21,874. How completely our

large hospitals have been given over to the treatment of acute cases is indicated by the fact that the average number of days during which patients have remained at the hospital is between nineteen and twenty. At the McLean Hospital also the number of patients treated was less than in 1904, although the average daily number of patients was 184 as against 183 in 1904. As improvements in administration should be mentioned the surgical apparatus shop which is self supporting and particularly useful in connection with the Orthopedic Department. Through a plan worked out by Dr. F. A. Washburn, absorbent gauze, formerly thrown away after a single use, is now used over and over again after a special system of washing and sterilization. Soap has also been manufactured at the hospital during the last year, and both of these measures have tended to reduce expense.

From the historical standpoint this report of the hospital will be looked back upon with interest as containing a statement regarding the resignation of Dr. John Collins Warren, who retired in January, 1905, thereby for the first time in the history of the hospital removing the name of Warren from the hospital roll. In accepting this resignation the following minute was placed on the records:

"John C. Warren and James Jackson inspired the efforts that led a generous public to establish this Hospital in 1814. Dr. Warren remained in the service of the Hospital until the year 1853. J. Mason Warren became a member of the Surgical Staff in 1846 and died in the service of the Hospital in 1867. John Collins Warren's name first appeared on the rolls of the Hospital in 1865, and with his resignation there closes for the present this illustrious succession through our whole history, of three men, father, son and grandson, who each in turn have been conspicuous for able, conscientious and devoted service to this great charity, — a service which deserves and receives the grateful notice of the Trustees, and the thanks of unnumbered patients who have profited by their skill and devotion."

THE JOURNAL OF ABNORMAL PSYCHOLOGY.

A NEW publication appeared last week under the editorial management of Dr. Morton Prince, of Boston, with whom are associated such well-known names as Professor Münsterberg and Drs. James J. Putnam, August Hoch, Boris Sidis, C. L. Dana and Adolf Meyer, to be known as the *Journal of Abnormal Psychology*. As its name implies, the *Journal* is designed to subserve the interests of both medicine and

psychology, with special reference to work embodying clinical and laboratory research in connection with abnormal mental states. The *Journal* will, therefore, discuss such topics as hysteria, amnesia, fixed ideas, obsessions, automatism, multiple personality and similar subjects which are now attracting attention as never before. It is evident that this field, although in a measure covered by periodicals already in existence, lays stress upon certain phases of the mental life which have hitherto been in a measure neglected or lost in publications devoted essentially to other branches of research. The general subject should appeal to physicians far more than it ordinarily does, since there can be little doubt that the future has in store for us revelations in this department of research which will be of the utmost social as well as medical importance. Dr. Prince's work in this line is well known, and it is fitting that he should represent it as it will now appear in the form of a bi-monthly periodical. This first number contains articles by Dr. Pierre Janet, Professor Von Bechterew, Dr. J. J. Putnam and Dr. Prince. The papers are all of interest and are a most fitting introduction to a publication which we hope will have a long and useful life.

REPORT ON THE RUTLAND HOSPITAL.

THE Massachusetts Executive Council, upon whom devolved the duty of submitting a report regarding the status of the Rutland Hospital for Tuberculosis, has sent in through its committee two reports, the first signed by all the members of the committee, and the other by two members. The general result of the investigation as embodied in the main report was that the summary dismissal of Dr. A. Y. Bowditch was very unfortunate; that the theories of management of the sanatorium varied, that the time has come when a resident expert should take the place of visiting physicians; that the Rutland Institution should not be further enlarged, and that more attention should be given by the trustees to the advice of the visiting physician. A minority report condemns in strong language the dismissal of Dr. Bowditch, and considers that radical changes in the management of the institution are desirable. The council voted to accept the reports of the committee and refer them to the Governor. A later rumor is to the effect that the trustees of the sanatorium are likely to resign when the official copies of the report are sent them. In

this connection it should be remembered that one member of the Board of Trustees, Dr. Getchell, has persistently opposed the policy of the majority, and has throughout upheld the position taken by Dr. Bowditch and the medical public in general.

MEDICAL NOTES

TYPHOID AT PITTSBURG.—An unusually large number of cases of typhoid fever have been reported at Pittsburg, Pa.

BUBONIC PLAGUE AT THE PHILADELPHIA QUARANTINE.—A steamer from Bombay is held at quarantine at Philadelphia having on board four cases of bubonic plague. Two lascars of the crew died on the voyage from this disease.

THE WISTAR INSTITUTE OF ANATOMY.—Important problems connected with the organization and promotion of anatomical research will receive the consideration of the committees of the advisory board of the Wistar Institute consisting of ten leading anatomists of the country at a meeting to be held from April 16 to 18 in Philadelphia. It is desired to establish relations with the International Association of Academies, thereby bringing the work of the institute into close touch with that abroad. Although the work to be undertaken is chiefly in the line of neurology, other departments of anatomy will not be neglected and it is hoped that students of promise will be sent from various institutions to the laboratories of the Wistar Institute for special investigation. Competent investigators, however, even though not affiliated with other institutions, will be welcome. For the present the institute will not undertake an independent publication but will make use of existing scientific journals.

RETIREMENT OF COL. JOHN D. HALL, SURGEON, U. S. A.—After thirty-eight years of honorable service, Col. John D. Hall, chief surgeon of the Department of California, was retired from his position and from active service in the Army on Saturday, March 17. Colonel Hall entered the service as an assistant surgeon on Dec. 14, 1868, having received his training at the Harvard and Columbia Medical schools. During the period of thirty years preceding the outbreak of the Spanish-American War Colonel Hall saw varied and active service in the Indian wars of Arizona, Texas, Montana and Dakota. In December, 1898, he was ordered to San Fran-

cisco to take charge of the medical supply depot, a position which he held until 1902, when he was ordered to the Philippines as chief surgeon of the department of the Visayas. In 1904 he was sent to Manila as chief surgeon of the department of Luzon, and in July of that year was appointed chief surgeon of the Philippines division. On his return to San Francisco in 1905 he received his last appointment.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, April 11, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 42, scarlatina 46, typhoid fever 5, measles 157, tuberculosis 43, smallpox 0.

The death-rate of the reported deaths for the week ending April 11, 1906, was 20.77.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending Saturday, April 7, 1906, was 247, against 232 the corresponding week of last year, showing an increase of 15 deaths and making the death-rate for the week 21.65. Of this number 138 were males and 109 were females; 242 were white and 5 colored; 147 were born in the United States, 95 in foreign countries and 5 unknown; 46 were of American parentage, 173 of foreign parentage and 28 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 52 cases and 2 deaths; scarlatina, 47 cases, no deaths; typhoid fever, 4 cases and 1 death; measles, 206 cases and 1 death; tuberculosis, 57 cases and 29 deaths; smallpox, no cases and no deaths. The deaths from pneumonia were 31, whooping cough 0, heart disease 29, bronchitis 11, and marasmus 3. There were 9 deaths from violent causes. The number of children who died under one year was 44; the number under five years, 62. The number of persons who died over sixty years of age was 62. The deaths in public institutions were 74.

There were 3 deaths and 4 cases of cerebro-spinal meningitis reported during the week.

NEW BOAT FOR THE BOSTON FLOATING HOSPITAL.—The new boat which is being built for the Boston Floating Hospital will cost, when fully equipped, \$95,000. This new boat has become an actual necessity, and the charitably disposed are strongly urged to support the enterprise by liberal contributions for its construction. The present boat, which is not self-

propelled, has become wholly inadequate to the needs of the service, as shown by the figures that in the first year 2,500 infants were cared for, whereas, the number last year was 9,763.

THE CENTENNIAL ANNIVERSARY OF THE BOSTON MEDICAL ASSOCIATION.—The celebration of the centenary of the Boston Medical Association will take place at Sprague Hall, in the Boston Medical Library Building, on Monday, May 7, at 8.15 P.M. There will be an address by Dr. David W. Cheever, a poem by Dr. J. Baptist Blake and reminiscences are expected from Drs. J. C. White, B. Joy Jeffries and F. H. Brown. Light refreshments will be served at the end of the meeting. A memorial pamphlet will be printed for distribution among the members. Application for membership may be made to Dr. Edwin H. Brigham at the Boston Medical Library. Members and non-members, resident in the Suffolk District of the Massachusetts Medical Society, are cordially invited to attend.

NEW YORK

GIFT TO A HOSPITAL.—Mr. and Mrs. Peter Quackenbush of New York have made a gift of \$10,000 to the Paterson (N. J.) General Hospital.

FELLOWSHIP FOR PATHOLOGICAL RESEARCH.—Dr. Benjamin Taylor Terry of Columbia University has offered Indiana University an endowment for pathological research in the form of a fellowship yielding \$750 a year.

CENTENARY MEDICAL SOCIETY, COUNTY OF NEW YORK.—The banquet in honor of the Centenary of the Medical Society of the county of New York was held in the large ball room of the Waldorf-Astoria Hotel on April 4, and the attendance was large and enthusiastic. The chairman of the committee having it in charge was Dr. Edward D. Fisher, a former president of the Society, and addresses were made by the President, Dr. Floyd M. Crandall, Dr. William M. Polk, the Rev. Dr. Fagnani, Judge Hedges and Dr. Samuel B. Ward, of Albany.

COMPLIMENTARY DINNER TO DIRECTORS OF SYDENHAM HOSPITAL.—On April 2 a complimentary dinner was given to the board of directors of the Sydenham Hospital by the medical board of the hospital. On this occasion a loving cup was presented by his fellow directors to Isaac Guggenheim, Chairman of the Finance Committee, in recognition of the generosity on his part which made possible the founding of the institution. It is stated that at the last meeting of

the board of directors Mr. Guggenheim expressed his willingness to duplicate his previous gift of \$250,000 to the Sydenham Hospital.

PRIMARY SCHOOL FOR FEMALE NURSES.—A primary school for women nurses, on the general plan of the Probationers' Home of the Johns Hopkins Hospital in Baltimore, was opened on April 5 in connection with the Bellevue Hospital Training School. The pupils will have a course of three months in such matters as the care of the sick room, cooking and the feeding of patients, and at the end of it will be required to pass an examination in these preliminaries as a qualification for entrance to the regular training school. The object of the new department is to relieve the school of its primary classes, and during the three months' course the probationers will receive free board and lodging at the Nurses' Home.

HOSPITAL FOR CONTAGIOUS DISEASES, JERSEY CITY.—The Jersey City Board of Health, at a meeting held April 6 at which there was a prolonged discussion, adopted a resolution excluding all visitors from the Health Department's hospital for contagious diseases on the Hackensack Meadows. The original resolution, as offered by Dr. William McLaughlin, called for the exclusion only of the parents of children in the hospital. He expressed the opinion that, while it was hard to deny a mother the consolation of seeing her child when possibly it might be near death, such a rule was necessary to prevent the spread of disease. An amendment, which was finally adopted with the original resolution, to the effect that no persons whatever should be admitted to the hospital to visit patients, was presented by Dr. Frank Gray, President of the board. He contended that the exclusion of parents would only partly guard against the danger of the spread of infection, and that the public safety demanded the exclusion of all visitors.

Miscellany.

ARSENIC IN WINES.

H. D. Gibbs and C. C. James, who, we are informed, are careful investigators, reach the following conclusions regarding the occurrence of arsenic in wines.

We find that arsenic, in small quantities, occurs as an accidental ingredient of some wines, and we have undertaken this investigation for the purpose of locating the source for the benefit of the wine industry. We are confident that as soon as the origin is discovered this

ingredient will practically disappear as a menace. Total number of samples examined, 329; number in which arsenic was found, 38.

Of the samples containing arsenic, nineteen were bottled wines and nineteen were taken from the cask.

The largest amounts found and measured quantitatively are one part in 20,000,000. The limit of tolerance set by the British Commission on Arsenical Poisoning for beer is 0.01 grain per gallon, about one part in 7,000,000. This limit as applied to wine would undoubtedly be considered too exacting, for wine is usually consumed in much less quantities than beer.

In all probability arsenic never occurs in quantities sufficient to produce toxic effects; however, much of that found can undoubtedly be excluded by care upon the part of those engaged in the wine industry.

The arsenic which is present in some samples of wine cannot, in our opinion, be attributed to one source.

The most probable sources of the major part of that found are, arsenical sprays when used upon the vines, sulphur burned for the purpose of sulphuring the vines and receptacles, and perhaps to some extent the lead shot used in cleaning the bottles.

AN ARMY FIELD HOSPITAL AT BOSTON DURING THE A. M. A. MEETING.

THE Surgeon General's office of the United States War Department at Washington granted the request of the Boston Committee of Arrangements of the American Medical Association to have a field hospital stationed at Boston during the coming annual meeting of the American Medical Association on the following grounds:

It is recommended that this request be granted as for the good of the service. The medical department, which in time of peace is too small for the needs of the army, is in the time of war absolutely dependent for expansion upon the medical practitioners in civil life, and each one of these should be regarded as potentially a reserve medical officer. It is, therefore, to the highest degree important that medical men throughout the country be brought to understand and sympathize as much as possible with the military medical service and be made familiar with its equipment and methods of work. The American Medical Association is the representative medical organization of the country, embracing, as it does, more than 2,000 state and county societies with an enrolled membership of 80,000.

The personnel for a field hospital could be provided by ordering Company A of the Hospital Corps, stationed in Washington, to Boston, and it has on hand all the field hospital equipment necessary with the exception of ambulances, a few of which could be procured from posts in the vicinity of Washington, or Boston, as may be most convenient.

RECORD OF MORTALITY

SOCIETY NOTICE.

ANNUAL MEETING MAINE MEDICAL ASSOCIATION.—By vote of the Board of Censors of the Maine Medical Association, the dates of the annual meeting have been advanced to the second week in June, June 13, 14 and 15. This change has been made so that our dates will not conflict with those of the American Medical Association, which meets in Boston during the first week in June.

WALTER E. TORIE, *Secretary*.

RECENT DEATH.

DR. JAMES W. SMITH, of Paterson, N. J., died from pleuro-pneumonia on March 29, at the age of forty-nine years. He was born in Paterson and was graduated from Bellevue Hospital Medical College in 1882. Later he served as an interne at St. Joseph's Hospital, Paterson, and ever since has been on the visiting staff of the hospital. He was assistant health officer of the City of Paterson, and was in charge of the Isolation Hospital which received the first prize at the Buffalo exposition. In 1893, he was appointed a member of the board of managers of the New Jersey State Insane Asylum at Morris Plains, and at the time of his death he was president of the board. He was closely identified with educational matters in Paterson, and for fifteen years had been a member of the School Board.

A CLINICAL AND ANATOMICAL STUDY OF RESISTANT FORWARD SHOULDERS.

BY G. W. FITZ, M.D., BOSTON.
Orthopedic Surgeon, Boston Dispensary.

HAVING had the inadequacy of the literature relating to round shoulders forced upon my attention through my inability to find any satisfactory discussion of its fundamental conditions, I was led to undertake its systematic study. The results of this study are based upon many dissections and experiments upon the cadaver which gave the necessary clue to the solution of the numerous perplexing problems disclosed by the examination of round shoulder cases.

The dissections and experiments upon the cadaver,* nearly one hundred in number, had for their object the determination of the causes of resistance to movements in the cardinal directions, downward, forward, upward, backward. By cutting away part after part, it was possible to determine the amount of resistance offered to the movements by each part successively.

All shoulder movements must necessarily be considered as centering at the sternal articulation of the clavicle, and, with the clavicle as a radius, as describing about this center arcs which may be considered as portions of the spherical surface which includes all the possible arcs traceable by the point of the shoulder through the range of motion permitted by the restraining tissues. These motions are controlled by the muscles running from the trunk to scapula, clavical and humerus.

Of these muscles, the ones of primary interest to us are the pectorals, the serratus, the rhomboids and the trapezius.

It has long been held by orthopedists that the pectorals are responsible for resistant round shoulders but in my dissections I early became convinced of what my clinical observations had led me to infer, viz., that it was rarely possible for the pectorals to limit the backward movement by their shortness for the reason that the upward stretching of the arms, of which constant practice keeps every one capable, stretches the pectoral muscles much further than they can possibly be stretched in the corrected backward position owing to the extensive raising of the shoulder in the upward arm stretch.

I found in my dissections that the excess of length of the pectorals in the upward stretch of the arms, as compared with that of the backward position with the arms down, varies from two to three inches, and that in no one of at least seventy-five regular dissection subjects examined was there any suggestion of a pectoral muscle not freely permitting the upward stretch of the arms. In striking contrast to this I found in all of the subjects a distinct elastic resistance to the backward movement of the shoulder when the pectorals were cut away and the serratus alone of the forward acting muscles remained. This elastic resistance disappeared wholly when the serratus was cut.

In most cases after the serratus was cut, the only limitation to the backward movement was caused by the clavicle resting upon the ribs. In certain cases, however, I found the backward movement of the shoulder prevented by the throwing inward of the posterior border of the scapula. Only by cutting the coraco-clavicular or the acromio-clavicular ligaments was it possible to get unrestricted backward movement of the shoulders. Their downward movement was resisted in these cases also by the pressure of the lower angle of the scapula against the ribs. This became free when the coraco-clavicular ligament was cut.

In almost all of the subjects there was much freer motion of the shoulder backward after the coraco-clavicular ligament was cut. It was easily possible to distinguish between the non-elastic resistance offered by this ligament and the elastic resistance of the serratus. In some cases there was also some resistance offered by the sub-clavicular fascia which passes mainly from the first rib outward and backward to the coracoid process and consists of a somewhat indefinite bundle of strong fibers attached to the inner side of that process.

Aside from these sources of resistance the movements of the shoulders were found to be free in their normal ranges as permitted by fascia, skin, etc. In no case did I find restriction to the forward or upward movement of the shoulders in the dissection subjects.

In order to determine to what degree similar conditions existed in living subjects, a systematic examination and record of round shoulder cases was made as opportunity offered upon a total of 56 cases of distinct round shoulders so marked as to require treatment, of which 18 were classified on clinical grounds as voluntarily correcting or postural cases and 38 as non-correcting or resistant cases. These cases were systematically measured as to all significant points in relation to natural position of shoulders, range of move-

TABLE I.

Zero stands for the angle when the subject is erecting the trunk of the body. Angle I stands for the angle when the subject is standing with the arms down. Angle II stands for the angle when the subject is standing with the arms raised to the right. Angle III stands for the angle when the subject is standing with the arms raised to the left. Angle IV stands for the angle when the subject is standing with the arms raised to the front.

In the tables III, I, II, III, IV, V, VI, VII, VIII, IX, X, XI, XII, XIII, XIV, XV, XVI, XVII, XVIII, XIX, XX, XXI, XXII, XXIII, XXIV, XXV, XXVI, XXVII, XXVIII, XXIX, XXX, XXXI, XXXII, XXXIII, XXXIV, ments in various planes, condition of muscles and ligaments, chest depths and girths, height, weight, diagnosis, age, etc.

Table I gives the number of cases occurring at each 5° of angular measurement for natural position, forward and backward swing of the shoulders. The measurements were made by means of a long armed protractor especially designed for the purpose (see Fig. 1), which was applied to the flat portion of the back of the shoulder where the ridge of the spine of the scap-

ula is nearly subcutaneous. This point was adopted for the reason that it lay in the transverse straight line across both shoulders when they were in correct position. Therefore, the angles measured between the line of the spine and this transverse line represent fairly the horizontal relation of the shoulder to the correct position.

It shows that the mean position of the resistant group is almost 25° forward of the transverse shoulder line; for the self-correcting group slightly less, and for the gymnasium group about 15°; also that the forward swing is slightly greater in the first group, whereas the backward swing is considerably less in both the resistant and the gymnasium group.

The range of movement in the three classes forward and back from the natural position and the total swing are shown graphically in Fig. II.

Table II shows the distribution of cases in relation to the range of angular movement of the shoulders and their natural position in a vertical plane. The line of reference used in the measurement of the angles is the horizontal transverse line across the shoulders at the level of the interclavicular notch. The angles of the shoulders in relation to this line were measured by means of a large celluloid protractor with a level glass (see Fig. III) especially designed to be applied to the interclavicular notch. Through

this protractor the shoulder could be seen and its level measured upon the graduated arc. The angles measure approximately the inclination of the clavicle in the different shoulder positions. Measurements above the horizontal line are considered negative; below, positive. It will be noted in the tables that there is a tendency in the observations to a distribution in the form of a binomial curve.

The Pectorals.—In the dissections I found, as I had always observed clinically, that the pectoral muscles were seldom tight but, on the contrary, were normally elastic when the shoulder was in corrected position. Even when the arm was raised over the head and the attachment of the pectoralis major thereby removed to an additional distance of several inches from its origin, the muscle rarely became tight. Apparently the upward stretching of the arms, an exercise from which no one escapes, is sufficient to keep the greater pectoral so stretched as to eliminate it as a factor in round shoulders.

FIG. 2. Average natural shoulder inclination forward and average forward and backward swing of shoulders plotted graphically for groups I, II and III. I' = Natural; I'' = Forward; I''' = backward. Range of swing: I = 40°; II = 44°; III = 33°.

TABLE III.

AVERAGE LENGTH OF PECTORAL MUSCLES IN THIRTY-ONE ROUND SHOULDER CASES.

| | Shoulder: natural position, arm down. | Shoulder: back, arm down. | Arm up stretch. |
|------------|---|---------------------------------|--------------------|
| Pect. Maj. | 13.5 cm. | 15.6 cm. | 21.1 cm. |
| Pect. Min. | 9.0 cm. | 9.7 cm. | 11.0 cm. |

By reference to Table III it will be observed that in round shoulder cases there exists the

FIG. 3. Protractor of transparent celluloid for measuring angular heights of shoulders: (a) knob or finger hole applied to interclavicular notch; (b) a spirit level for adjusting protractor. Scale = 4.

same conditions as to the relative lengths of the pectorals in the corrected shoulder position and in the arm-up-stretch position, and that freedom

from excessive muscle pull in the corrected back position is thus insured. It will be seen, also, that the pectoralis minor averages 1.3 cm. longer in the up position of the arm owing to the associated raising of the shoulders, and therefore is also not liable to be tight when the shoulder is put into corrected backward position. The clinical study of the condition of the pectoral muscles is shown in Table IV.

TABLE IV.
CONDITION OF PECTORAL MUSCLES IN ROUND SHOULDER
AND NORMAL CASES.

| | Pectorals. | |
|--|--------------|-------|
| | Normal | Short |
| I. Resistant Cases (38), 8 to 15 yrs., girls and boys, | 35 (92%) | 3 (7) |
| II. Voluntary correcting (18), 8 to 15 yrs., girls and boys, | 18 (100%) | 0 |
| III. Gymnasium Students (38), Normal class, 18 to 35 yrs., women | 38 (100%) | 0 |

The test of the condition of the pectoral was made by putting the shoulder into the corrected posture, taking pains to avoid voluntary contraction of the muscle, and then testing the elasticity by pressing with the thumb upon the muscle as it passed from the trunk to the arm. Repeated attempts were made with some of the cases before a satisfactory test could be secured, owing to the subject's inability to control the voluntary contraction. In most cases it was necessary to secure the corrected position passively by pressure upon the shoulder, since, when the subject voluntarily put the shoulder back, the pectoral was contracted thus giving deceptive results.

frequently to so much voluntary contraction of the muscles as to make the results extremely unreliable. The estimation of elasticity by the sense of touch enables one immediately to recognize contraction of the muscle while making the test and thus tends to eliminate error; at the same time it is quick and satisfactory since a little practice gives considerable accuracy of judgment.

The elasticity exhibited by the uncontracted shoulder muscles of normal living subjects, when the shoulders were forced back to a position of full extension, was taken as normal tonicity. Under similar circumstances when, in any case with a history of poor posture and with apparent resistance to shoulder extension, there was markedly increased tension in any of the forward acting shoulder muscles, it was assumed that such muscles were "short," i. e., that such use as they had received had not fully developed them in length of muscle fibers or tendon filaments or both, or in elastic stretch of the muscular substance.

The term short as applied to these muscles is certainly in many cases more appropriate than the term hypertonic² which has been used to describe a similar condition, for the reason that these muscles when stretched only their habitual amount are of normal tonicity, but when further stretched their elastic resistance increases much more sharply than in a normal muscle. This suggests that the elastic limit of the muscle is being rapidly approached.

That muscles do become shortened and resist stretching to their former length and yet show no increase of tonicity is shown in cases in which one set of muscles becomes paralyzed while the antagonists retain their power. After a time the non-paralyzed muscles become short, thick and resistant to stretching as in paralytic club foot, but the tonicity is usually found not to be greater.

These facts suggest that normal elasticity is developed and maintained in any muscle by the stretching which its antagonists give it. On the other hand, the tonic contraction is somewhat increased by the strengthening of a muscle through its physiological activity without in any way shortening the muscle or making it more than proportionally resistant to a stretching force.³

It will be seen that in only three cases of the most resistant type was tightness of pectorals discovered. In these cases, moreover, it was merely a slight suggestion of tightness, not nearly so marked as the tightness of the serratus in some cases which were not considered worthy of record. That pectoral tightness finds any record in this study is due to the fact that the emphasis laid upon it as a factor in round shoulders in orthopedic literature made it eagerly sought.

FIG. 4. Average natural positions of shoulders and average angular ranges of shoulder movement in a vertical plane upward and downward for groups: I, corrected children; II, normal children; III, normal adults. I, Natural position; I, upward, and I, downward.

In all cases the shoulders were pushed back to an extreme corrected position after preliminary manipulation to free the muscles from voluntary contraction. The amount of elasticity in each muscle was then determined by estimating the amount of force necessary to deflect the muscle when applied at right angles to the course of its fibers.

At first it was thought advisable to determine this elastic resistance quantitatively by means of a special dynamometer, but in experiments it was found that the use of any instrument led

² The term hypertonicity applied preferentially to cases in which there is little or no increase in the length of the muscle and in which the resistance to stretching is increased. The term short is applied to cases in which the length of the muscle is increased and the resistance to stretching is also increased.

It is not impossible that the bad reputation of the pectorals has been due to the fact that it is difficult to eliminate voluntary contraction especially since the test is ordinarily made with the arms raised, which, as I have shown, is faulty technique since it stretches the muscles about three inches more than the corrected posture.

The Serratus.—In marked contrast to the negative influence of the pectorals, I found in all of the dissection subjects a distinct recoil from the backward movement of the shoulder when the pectorals were cut away and the serratus alone of the forward acting muscles remained. This elastic resistance wholly disappeared when the serratus was cut, leaving only in certain of the cases a rigid resistance which was readily recognized.

The serratus was tested clinically by having the subject stand with one shoulder against the wall. The opposite shoulder was then pressed backward, downward and inward and at the same time shaken slightly to free it from voluntary muscular control. The fingers of one hand (the right when the left serratus was tested) were slipped under the lower angle of the scapula to a distance of one and one-half to two inches. The fingers were then drawn sidewise outward from under the angle of the scapula, so as to get the serratus muscle between the fingers and thumb freed from tissues other than the skin. It was thus easily possible in all cases directly to test the elastic resistance and the development of the muscle. When normal it could be easily raised from the chest and its elasticity measured by the muscular effort required. When short, the fibers of the muscle could be definitely recognized as tense bands and the degree of increased elasticity gauged.

TABLE V.

CONDITION OF SERRATUS MAGNUS IN ROUND SHOULDER AND NORMAL CASES.

| | Serratus: | |
|---|-------------|-------------|
| | Normal. | Short. |
| I. Resistant cases (38), 8 to 15 yrs., boys and girls, | 6 (16%) | 22 (84%) |
| II. Voluntarily correcting (18), 8 to 15 yrs., boys and girls, | 9 (50%) | 9 (50%) |
| III. Gymnasium students (38), Normal case, 18 to 35 yrs., women | 25 (66%) | 13 (34%) |

Table V shows how frequently a short serratus is found not only in resistant forward shoulder cases, but in those classed as correcting or postural, as well as in those ordinarily considered normal cases. The serratus, therefore, must be considered as the most important factor in forward shoulders. This is more fully realized when we consider that the insertion of the serratus upon the posterior border, and especially at the lower angle of the scapula, gives it a very powerful leverage effect upon the shoulder positions, since the muscular fibers act directly without having their force lessened by leverage reduction, such as exists for most of the skeletal muscles. In all forward exercise of the arms, the serratus is called into play to assist in supporting the weight of the arm as well as in

thrusting and lifting, and it is, therefore, well developed in all individuals of normal activity.

The chief antagonists to the serratus, the rhomboids and the trapezius, are, as a rule, sadly underdeveloped in these cases. This is natural inasmuch as the ordinary activity of civilized life not only fails to call them into active contraction but is constantly stretching them and thus stimulating them to greater adaptive growth in length. The obvious result is seen in the tendency for the shoulders to come to rest at the point of balanced elastic pull between these antagonists with great advantage in favor of the serratus since the weight of the arm and shoulders markedly aid it. This means, of course, a forward shoulder with short, strong serratus and long, weak rhomboids and trapezius. Naturally, when a child by an effort brings the shoulder to the correct posture, he is unable to maintain it owing to the rapid fatigue of these weak muscles, which are pitted against the tonicity and elasticity of the relatively well developed short serratus and the weight of arm and shoulder.

In cases with markedly shortened serratus, the lower angle of the scapula is rotated strongly outward. This outward rotation was found to be so uniformly associated with the condition of shortened serratus as to lead one to recognize it as a diagnostic sign. When the posterior borders of the scapulae were parallel to the spine, the serrati were usually found to be normal.

Since the bulk of the serratus muscle lies exposed to manipulation, it is possible to apply stretching force directly to it, if deemed desirable. It should also be possible in case of its inveterate shortening to incise the muscle or to partially free it from its scapular attachment. I have, however, as yet seen no case in which this could be considered justifiable. The shortened muscle can be easily stretched by the ordinary orthopedic methods, especially by the use of a proper brace or plaster jacket to include the shoulders and efficiently to hold them in corrected position.

The tightness of the serratus cannot be considered as a true hypertonicity, since it is due merely to the adaptive shortening of the muscle to fit the use demanded of it and not to any over-stimulation. When, therefore, the individual voluntarily attempts to stretch the muscle beyond its usual range by contraction of the rhomboids and trapezius, its elasticity is deficient and the normal physiological relaxation which should come when antagonists act is without effect; self cure, therefore, is difficult if not impossible. It is apparently for this reason that free-hand exercises, such as those given by the Germans and Swedes in their setting-up drills, are so frequently without effect in cases where the serratus is more than slightly shortened. The most effective exercises are those which involve the backward stretching of the shoulders with the arms down, such as some of the exercises with wands, and especially those with chest weights and rowing machines used with the subject facing the apparatus and making

his movements in the horizontal and lower, rather than in the upper, planes. Hanging by the hands has no effect upon the serratus since it is relaxed in that position; in fact, in forward shoulder cases it is almost wholly useless since the pectorals do not need stretching and no tissues which do need it are stretched thereby.

Rhomboids and Trapezii.—Owing to the habitual forward position of the shoulders these muscles in their growth become adapted in length to their stretched condition. This adaptation is an important factor in the cure of forward shoulders since it is necessary for the muscles to hold the shoulders back in correct position by constant effort against the increased pull of the elasticity of the serratus and also to support a part of the weight of the arm and shoulder in order to neutralize the tendency of the shoulder to slide forward. This work the muscles are called upon to do at a great disadvantage since their adaptive lengthening has made it necessary for them to contract through a greater proportional range than normal, and yet this range of contraction is required of them if they are to bring the shoulders fully back to the correct posture.

Even in moderate cases of habitual forward shoulders, I am convinced that this factor is in part responsible for the apparent hopelessness of getting children to hold their shoulders back.

On the other hand, the habit of allowing the shoulders to droop without muscular support is, of course, a habit of laziness on the part of the nerve centers having charge of the subconscious control of shoulder attitude. These centers have been trained to shirk their work and this habit is in most cases extremely inveterate.

The cure of this shoulder habit thus has two phases; first, shortening and strengthening the muscles which hold the shoulders back; and, second, training the nerve centers to do the continuous work of stimulating the muscles in order to hold them there. To shorten the muscles we must provide the conditions for adaptive growth in them. This necessitates that we keep the shoulder in corrected posture long enough for the change to take place in the muscles and prevent at the same time any stretching which might tend to prevent or retard the change. To strengthen them the muscles must be exercised in the shortened state up to the physiological limit of strength and endurance that the shortening process may be hastened thereby. The training of the nerve control may be accomplished later if necessary by the application of a device which will cause discomfort when the shoulders are allowed to droop.

Of course in practice the method of holding the shoulders by brace or jacket for the stretching of the serratus relaxes the rhomboids so that no special procedure is made necessary.

The Coraco-Clavicular and Acromio-Clavicular Ligaments.—After severing the muscles connecting the shoulders with the trunk, it was found in many subjects that there was a rigid resistance to the full backward movement of the

shoulders. When the coraco-clavicular ligament was cut, this resistance ceased, and the shoulder could be carried backward far enough to bring the clavicle against the first rib, or the scapula to the spine, and to lift the posterior border of the scapula several inches away from the ribs. The shoulder also could be pressed downward much more freely. This was especially marked in a number of cases with high shoulders.

There was found to be considerable variation in the length of both the coraco-clavicular and the acromio-clavicular ligaments, the former varying in functional length, as determined by the amount of motion between the parts, from 1 mm. to 8 mm.; the latter, from 0 to 5 mm. In some cases where one of these ligaments was short, the other was correspondingly loose, thus insuring mobility of the shoulder.

These two ligaments tie the clavicle and scapula together more or less tightly at two points distant from each other about 1 cm. As they are very strong and as the total length of the clavicle is only about four times and the scapula five times that distance, it can readily be seen that when both ligaments are tight the clavicle and scapula together form a fairly rigid unit and thereby become incapable of adjustment to the sloping chest wall as it enlarges downward. As a result there is mechanical interference with the movements of the shoulders in practically all directions, since there is a tendency to throw the posterior scapula border against the ribs in a downward movement, and to lift the scapula bodily from the ribs in a forward and especially in an upward movement.

The coraco-clavicular ligament can be directly measured as to functional length as follows. Raise the shoulder to its limit (arm down) thereby causing the coracoid to be pressed closely against the under surface of the clavicle, and measure the distance from the upper surface of the clavicle to the upper surface of the process. Then depress the shoulder as far as possible, thus separating the coracoid process from the clavicle as far as the coraco-clavicular ligament will permit, and again measure the corresponding distance. The ligament is thus put on stretch and its functional length for this motion is the difference between the two measurements taken.

See Figs. 5 and 6. In certain cases it is necessary to have the shoulder forward in this manipulation in order to have the clavicle clear the first rib in the downward position.

It is also possible to determine the length of the coraco-clavicular ligament by lifting the angle of the scapula away from the chest in the plane passing through the two ligaments. This special manipulation is, however, uncertain unless very carefully performed owing to muscular interference.

The acromio-clavicular ligament can be measured for lateral flexibility by grasping the outer end of the clavicle between the thumb and finger of one hand and the corresponding acromion process with the other hand. In the absence of muscular interference, the two may

be made to move independently so far as the ligament will permit and this motion can be easily estimated in millimeters.

TABLE VI.

FUNCTIONAL LENGTHS OF THE CORACO-CLAVICULAR AND ACROMIO-CLAVICULAR LIGAMENTS.

| | Coraco-Clav. | | | Acromio-Clav. | | |

I, Resistant cases; II, voluntarily correcting; III, gymnasium students.

In Table VI is given the results of these measurements in a form to show the distribution of the cases in relation to the lengths of the respective ligaments. These figures suggest a fairly satisfactory curve of distribution for the coraco-clavicular ligament in all classes except possibly Class II. For the forward shoulder children the apex of the distribution curve for the coraco-clavicular ligament is at approximately 5 mm.;

for the adult cases, at 4 mm. The acromio-clavicular curve has its apex in the corresponding cases at about 3.75 mm. and about 3 mm. These lengths give very fair movement between clavicle and scapula and permit free shoulder movements so far as the ligaments are concerned provided both are loose.

Those cases in which the length of the coraco-clavicular ligament is less than 3 mm. must be considered as defective in development of length of ligament, probably through insufficient stretching by activity during growth. The cases in which the length of the acromio-clavicular ligament is less than 2.5 mm. fall under the same head.

In studying the movements of the shoulders, it was found that the coracoid process projected

farther forward under the clavicle when the shoulder was forward, showing that the angle between the plane of the scapula and a corresponding plane of the clavicle had become less, as shown in the accompanying photographs of the dissected shoulder. Figs. 7 and 8.

I, Resistant cases; II, voluntarily correcting; III, gymnasium students.

In Table VII is given the measurements of this increase of length of the coracoid process as the shoulder moves forward.

The deformity usually associated with a very short coraco-clavicular ligament, high forward shoulders, is so disfiguring and so resistant to ordinary treatment as to demand extraordinary measures for relief. Two such cases had been in the Curvature Clinic at the Boston Children's Hospital for a considerable time without continued improvement. They both presented typical pictures of the coracoid process bound tightly to the clavicle with short serratus. Many operations on the cadaver had convinced me that it was perfectly possible to tenotomize the coraco-clavicular ligament and thereby free the scapula from its rigid attachment to the clavicle. For the operation⁴ I devised a double-edged knife with the blade curved so that the flat side of the knife would follow the upper surface of the coracoid process to the point of the attachment of the ligament. The cutting edge of the knife was directly in line with the handle, thus making it possible to apply considerable force without developing a tendency to rotation in the knife. This knife was introduced sub-cutaneously fol-

⁴This was made possible through the cordial cooperation of Dr. E. H. Bradford and Dr. F. G. Brackett of the staff of the Children's Hospital, for which I desire hereby to express grateful appreciation.

lowing the upper surface of the coracoid process until the resistance of the ligament was felt. By cutting carefully close to the coracoid surface, the ligament was severed at its smallest section, and the slightest ligamentous remains were

discovered by the resistance offered, and easily cut. This was facilitated by downward pressure upon the shoulder which made the ligament tense, and it was possible to determine the complete separation of the ligament by the yielding of the scapula when the angle was lifted from the ribs.

It was found necessary also to cut the sub-clavicular fascia which is attached upon the inner side of the coracoid process not far from its tip and therefore easily reached sub-cutaneously through the same opening.

There was almost no hemorrhage associated with the operation, and practically no after effect in the way of pain or disability. Twenty-four hours later it was possible to apply corrective braces and to push the stretching of the serratus vigorously.

The result of the operation was most satisfactory in the case of one of the patients, a girl of fourteen years, with high hunched forward shoulders. In the second case, a boy of ten who had had asthma for many years and who had an even greater deformity, the result was good, although some effect was lost through the boy's hyper-sensitiveness and the continuance of the asthmatic attacks which made him somewhat intolerant of treatment after the operation.

Although this operation is simple and the result most excellent, it is important to select one's cases by testing under etherization since one must be sure that the coracoclavicular ligament is actually short and not made to appear short through muscular contraction.

Clavicle — In a few cases of resistant forward shoulder, the clavicle comes to rest on the first rib and thus prevents full correction. If the

shoulders are forcibly corrected, the sternal ends of the clavicles are pried out from their articulations and become markedly prominent. This should always be looked out for in the routine examination for the reason that it may not be wise to push the stretching very vigorously, inasmuch as the main result may be the loosening of the sterno-clavicular joints.

A certain amount of stretching of these joints, however, is undoubtedly justifiable in a case of marked forward shoulders with the clavicle resting on the rib since in no other way without operation is correction possible.

The reason for this interference seems to be that the S curves of the clavicles are exaggerated especially at the outer ends and, therefore, throw the shoulder forward and at the same time narrow the shoulder breadth.

This deformity is found most frequently in children who have or have had rickets, but it also appears in cases with no signs and with nothing in their histories which makes rickets even probable. It is not at all impossible that an infant habitually put to sleep on its side with the shoulder under it taking the weight of the upper part of the trunk will thus acquire a shortened clavicle with deeper curves, even if there is no special softness of bone other than that which is normal during infancy and early childhood. It would be simply another instance of the adaptive growth of bone which plays so large a part in deformity.

The rational treatment of this condition of the clavicle is either to cause a green stick fracture at the outer third in such a way as to straighten it or to saw it through subperiosteally and retain it in straight position until solid.

One case which Dr. F. G. Brackett very kindly operated in this way at my suggestion in 1904 in the Boston Children's Hospital gave a very good final result in spite of the difficulty of maintaining simultaneously the necessary fixation and correction.

It is important in ordinary fracture of the clavicle to look after the shoulder position so as to avoid its coming forward and thus producing a resistant forward shoulder from interference

with the first rib. Fortunately, this is not a frequent complication in the routine treatment of forward shoulders.

TABLE VIII.

CORRELATION OF LENGTHS OF CORACO-CLAVICULAR LIGAMENT WITH THE AVERAGES OF OTHER SHOULDER MEASUREMENTS IN RESISTANT CASES.

| Length Range of Shoul- der of Cora-der. Movement of co-Clav. For. Upward. Coracoid Lig. mm. | Move- ment of Process. | Expansion of Chest, Depth. | Girth. | Length of Acromio Clav. Liga- ment. |
|--|------------------------------|-------------------------------|--------|--|
| 7 (3) | 37° | 40° | 5 mm. | 3 cm. |
| 6 (5) | 41° | 48° | 4 | 12. |
| 5 (13) | 44° | 45° | 6.2 | 4 |
| 4 (7) | 49° | 50° | 4.1 | 4.6 |
| 3 (8) | 31° | 45° | 3 | 3.5 |
| 2 (1) | 30° | 35° | 6 | 2 |
| 1 (1) | 40° | 30° | 0 | 3 |
| (38) | | | | 5 |
| | | | | 1 |

In Table VIII is given the correlation of lengths of the coraco-clavicular ligament with the averages of other shoulder measurements. These show very distinctly that there is practically no correlation of any marked degree between any of the different elements of possible constriction in the shoulders, a fact which accounts for the complexity of the problems connected with shoulder resistance. This emphasizes the fact which is apparent to any one making a careful study of shoulder conditions that each factor must be individually studied and all superficial generalization avoided. For this reason it is important that we should adopt a different nomenclature for these cases, and in our records eliminate the term round shoulders, substituting for this a definite statement as to the limitation of shoulder movements and the localization of the limiting cause.

Treatment.—The treatment of resistant forward shoulder cases after a careful examination and localization of the difficulty becomes a comparatively simple mechanical proposition. Its practical execution, however, may try both the patience and skill of the surgeon. Relatively few cases fall into the class of tight ligaments which permit of the above described operative treatment, and even in these the success of the treatment depends quite as much upon the after care as upon the operation.

In all cases, therefore, it is necessary to carry out with consistent detail the following plan of treatment:

The serratus, which is tight in all cases whether the ligaments are tight or not, and is especially tight when the ligaments are short, must be stretched in order to get an adaptive lengthening of the muscle which will permit the self-maintenance of the correct posture without undue fatigue. To accomplish this, an ordinary spring back brace with rigid or flexible loop to include the shoulder and to carry it steadily backward as strongly as can be tolerated by the subject, is efficient for mild cases, especially during periods of rapid growth.

In severe types with rigid resistance, more can be gained by means of a plaster jacket applied in such a way as to include the strongly corrected

shoulders. Several broad pieces of thick felt are put behind the shoulders, and the plaster is arched over the top of the shoulder so as to give an absolutely firm support.⁵ From time to time, at intervals of several days, or preferably even a week, the pieces of felt are removed one by one from behind the shoulder, and wedged in front, in order to throw the shoulder back into the space left by the removed pad. This procedure should not be hurried. It is probably wiser to allow an interval of a week between the changing of the pads, in order to permit the necessary adjustment to take place in the stretched tissues. If the treatment is pushed too rapidly, the shortening is much more liable to recur. The jacket should be continued, if possible, for at least two weeks after the last pad has been placed in front of the shoulder, in order thoroughly to establish the changes in the muscle. One should guard carefully against causing pain or such pressure as will produce numbness or paralysis of the arm.

After the use of one jacket for from four to eight weeks, one can usually depend upon a light retention brace worn for a few hours each day, provided that the serratus is vigorously stretched daily and the shoulder not allowed to droop forward.

Accompanying the treatment by the jacket and pushed strongly on its removal, there should be vigorous development of the rhomboids and the trapezius by means of exercises with chest weights or Whitely exerciser, dumb bells, or such other means as are at hand, in order to avoid the weakness of muscle consequent upon the confinement of the jacket and to increase the strength of the dorsal muscles that they may be enabled to oppose the tendency of the serratus to recontract when no longer opposed by jacket or brace.

No time limit can be set for a cure since there are a number of intangible factors which may control the result in any given case and so cause wide variation in duration of treatment.

If a case can be absolutely controlled, four to six weeks should be sufficient for the main treatment of a severe inveterate forward shoulder, provided there is neither hyper-sensitiveness nor asthma present. Such cases should be under close observation and adequate after-treatment for at least six months longer.

The deformity is serious in its reflex moral effect and it is important that it should not be ignored or left to be outgrown, as is so frequently done. Postural forward shoulders undoubtedly are outgrown since it is dependent chiefly on the laziness of the nerve control. Resistant cases, so far as my observation goes, do not markedly improve without vigorous treatment since self-cure is practically impossible.

CONCLUSIONS.

1. Resistant forward shoulders are symptomatic of anatomical conditions.
2. The commonly accepted statement that tight pectoral muscles are the cause is not tenable.

⁵ A device first applied, so far as known to the writer, two years ago by Dr. R. W. Lovett in the Curvature Clinic, Children's Hospital.

3. The most common factor in forward shoulders is the tightness of the serratus muscle.

4. An occasional factor usually associated in extreme cases with the above is shortness of the coraco-clavicular and acromio-clavicular ligaments whereby the union of clavicle and scapula is made so rigid as to prevent full backward and downward movements of the shoulder.

5. Systematic examination of forward shoulder cases is necessary in order to identify the definite causes of restriction of motion.

6. The early recognition and treatment of pronounced cases is important since self-correction is unusual and the reflex moral effect is serious.

7. When stretching and muscular development fail, it is possible to incise tight coraco-clavicular ligaments, and thus free the shoulder from rigid interference.

8. The term "round shoulders" is misleading. Forward shoulders (postural or resistant) is far more definite, but should be accompanied by a definite statement of the cause of resistance.

A CONSIDERATION OF THE TREATMENT OF AUTO-INTOXICATION OR AUTO-INFECTION WHEN THEY ARE THE CAUSE OF MENTAL DISTURBANCE.

BY L. VERNON BEECH, M.D.

Physician to the Mental Department of the Boston Dispensary.

ABOUT A year ago, I published in the BOSTON MEDICAL AND SURGICAL JOURNAL, a paper entitled, "A Consideration of Auto-Intoxication, and Auto-Infection as Causes of Various Mental Diseases." I then found that if I went into the treatment of such cases the paper would be far too long for a medical journal; as it was, it had to be cut in halves and published in two issues, Jan. 5 and Jan. 12, 1905. I considered that nothing would be lost in delaying publication for several months, as I could give a more satisfactory account of the outcome of certain cases which I then had under treatment. Again I find my paper beyond the length I had anticipated. I have, therefore, cut out all my melancholia cases, those being more easily demonstrated as directly due to auto-intoxication, and treatment along these lines is usually beneficial or curative. Later I intend to publish a paper on "Melancholia" which will include what I have cut out of this paper and the results, if possible, of several cases now under observation and treatment.

When I wrote my last article, few alienists were adherents to the theory of auto-intoxication, but during the past year, most of the prominent alienists of this country and especially abroad have become deeply interested in the subject. The consensus of their opinion seems to point to the fact that there is an auto-intoxication in most cases of mental disorders, although some prominent members of the profession still cling to the old idea that it is merely a symptom or effect, rather than a cause. When we have our hospital for observation in mental disorders in

their early stages (which is bound to come soon), it can then be more easily demonstrated that auto-intoxication is the beginning of many mental disorders, and this being corrected, the mind clears up and the symptoms disappear.

This is what we find in our private practice among those cases which come early enough to us, and such has been my experience in the Mental Clinic of the Boston Dispensary among many cases that find their way there during the early stages of mental disturbance. In the large institutions, and the insane asylums where patients are not admitted as a rule until their disorders have advanced far enough to require commitment, the early stages are so far remote that it is difficult for the men in charge of these institutions to recognize self-poisoning as a cause. Credit must be given to a goodly number of medical superintendents of insane institutions for having recently taken up this subject, who have not before seriously considered it. Many are to-day treating insanity, so-called, along these lines without knowing it or even admitting it to themselves.

Pathologists, ever fighting among themselves, all want to find the specific germ or toxin which causes the alienation of the mind. Ford-Robertson and Bruce (of whom Clouston told me that if he had not done anything else in this world he should feel fully satisfied to have discovered them) both claim to have isolated the bacilli in certain mental cases. Ford-Robertson showed me in his laboratory in Edinburgh, bacilli of general paralysis as he has found them in the lungs, in the urethra, throat and the spine of general paralytics. Dr. Lewis Bruce showed me in his laboratory at the Mutilley Asylum, Perth, Scotland, the bacilli that he has isolated in katatonias, also the bacilli he has isolated in cases of acute mania.

It is early to say much about these germs, but because some other pathologist has not found them does not prove anything. The fact that alienists treat cases of mental disorder in an antiseptic way and for auto-intoxication (or as Maudsley told me he preferred my paper to read, "self poisoning") and get results more quickly and permanently than in any other way makes the man who studies cases theoretically believe that he has hit the nail on the head. After successful treatment shall he stop treating cases with antiseptics because the pathologist has not found the particular toxin which causes the trouble? I should say not, but on the other hand he should continue treating the cases theoretically, not as to a toxin, and ask the pathologist to continue his research and prove why treating cases for auto-intoxication (or self poisoning) in their early stages or treaty benefits or cures them in their later stages.

In typhoid fever and in diphtheria, attempts to stimulate the heart and other organs to combat the poison. In cases of snake bites, there is about the only remedy we know that will enable the patient to throw off the poison. So chemical

disease, nux vomica, strychnine, gentian and other tonics are given to build up the patient and put him in condition to resist the poison while the antiseptics are killing the poison itself. This is the answer to many physicians who say, "You give antiseptics but you also give tonic; how do you know the tonic is not doing the work?"

There is no proof to-day that toxins, which are the cause of mental alienation, do not exist in the system. If there were proof, it would not be necessary for the most skilled pathologists of to-day to give so much time and thought to the discovery of toxins which they really in their hearts believe exists, and — what we alienists prove to them in a therapeutic way — do exist. We shall welcome the day when they discover either the bacilli or the toxins of the different mental diseases; and we depend upon them to do so and to give us some serums which we can inject into our patients and relieve them of some of the most distressing maladies mankind is subject to.

I have not the slightest doubt in my mind that in a very short time such discoveries will be made by the pathologists who are now so strenuously working on this subject.

From my notes I give ten cases just as they come which have been treated with antiseptics, some showing improvement; others no improvement; others cures, if there is such a thing as curing an ill of the human body not made immune, for, of course, the condition that brought about self-poisoning once may occur again if the patient is careless enough not to observe the general laws of health and surroundings which are necessary to his individual temperament or capacity. I have also given the treatment for auto-intoxication as carried out by some of the most prominent alienists of our time. Instead of giving the general treatment of the disease with references at the end, which is so common in most of the medical papers now written, I have given the authorities with their quotations, in the body of the paper.

In a general way, the antiseptics that I have used in the following and in other cases have been glyco-thymoline,¹ borolyptol,² betanaphthol, phosphate of sodium, benzoate of sodium, guaiacol, quinine, strychnine, nux vomica, creasote, naphthalin, calomel, salicylate of soda, peppermint, checkerberry, salol, bicarbonate of soda and antiseptic tablets put up by manufacturing chemists.

For treatment, colonic flushing or high enemas of normal salt solution, washing out of the stomach or lavage, salt baths, sweat baths, hydrotherapy, hot and cold packs. Diet, where the above remedies do not correct the fermentative processes at once, but a generous diet should be given as soon as evidences of fermentation from the bowels or stomach have disappeared. Milk or peptonized milk should alone be given at

first, gradually the whites of eggs may be added with possibly a little coffee, then the malted milks, grammes, Mellin's Food and egg-nogs, and finally solids until full diet is established, always avoiding the usual harmful foods like pastry, fried things, sweets, pickles, etc., until a year after the patient's improvement.

I give below a few of my cases, which were diagnosed as due to auto-intoxication, taking them in the order they came to me:

CASE I. In the summer of 1901, I treated F. B. Female. Age, twenty-two. Rather unfavorable heredity influences. Tendency to over work, especially in her music, practising hours beyond her normal capacity. Perplexity over a love affair, and worry and friction in her family. Becoming exhausted, her metabolism was disturbed, and she began secreting toxins. Her ideas became warped, also her judgment. Felt that she had done wrong, that she was not good enough to marry, etc. Her digestion became upset and her mother found that a milk diet made her bilious, but that lamb and chicken broth agreed with her. Breath became very foul. She grew worse, and was taken to a New Hampshire hospital with *acute mania*. Mercier, in his textbook of insanity on page 139, says that disorders of digestion are frequent in acute insanity, and "In any case in which it is ascertainably present, it must be treated. There are crises in which the contents of the stomach undergo putrefactive or fermentative changes which render them unspeakably foul and offensive, and when this is the case, or whenever the breath is very foul or especially when foul gases are expressed from the esophageal tube when the end reaches the stomach, benefit will be derived from washing out the stomach at regular intervals."

Her motor excitement at the New Hampshire hospital was so great that she could not be kept in bed without restraint, and she was covered with bruises where she had fallen from her cot and otherwise injured herself. When I first saw her, she could not stand on her feet, but sank to the ground and had to be carried to her room. Temperature and pulse were raised. There had been excessive waste of tissue and energy. She raved but her voice was inaudible most of the time, probably from exhaustion. Occasionally her remarks could be understood and were about horses riding over her and other unpleasant ideas which she had. Her mouth was dry; sordes had accumulated on teeth and gums. Eyes rolled up and back all the time. She took nourishment only in liquid form which when placed in her mouth caused her to swallow spasmodically. The physician who accompanied her said he did not consider she could live another twenty-four hours when she left the general hospital in New Hampshire.

In old times these acute cases of mania were called brain fever and their movements restrained which exhausted them, and if they survived at all, they usually became hopeless dementes.

I gave the patient a warm pack, then spread some blankets on the floor and allowed her to twist and roll over the room as she would, two nurses being in constant attendance to care for her, and see that she did not harm herself. Treatment: She was started on hyoscine hydrobromate 1-200 and calomel in $\frac{1}{2}$ gr. doses. Realizing the seriousness of the case, I called Dr. C. F. Folsom in consultation. He advised giving glyco-thymoline $\frac{1}{2}$ dr. t.i.d. as an antiseptic, saying he thought antiseptics proved very beneficial in such cases. I have never ceased to be grateful to him for

¹The formula of glyco-thymoline contains: benzo-salicyl sod., eucalyptol, thymol, salicylate of methyl from betula lenta, pini pulmonis, glycerin and solvent.

²The formula of borolyptol contains: gum myrrh, benzoin and storax, eucalyptol, pinus pumilio, boric acid, glycerin and solvent.

giving me this advice. He opened my eyes, and much of my success in mental medicine I certainly owe to the advice which he gave me at that consultation. Glyco-thymoline was given and as the symptoms demanded, sulfonal in 10 gr. doses; Fowler's solution in 3 minim. doses; strychnine 1-600 gr. t.i.d.; cascara; digitalis, etc. But from my experience since then I consider the girl's life, or mental stability, at least, was saved by the general antiseptics.

She gradually improved and recovered. In October, 1901, she was able to write a very good letter to a friend. On Nov. 5, 1902, she announced her engagement to a most estimable young man, the same one whom she thought she was not good enough to marry when she was ill. On March 8, 1904, the young man wrote me, "Miss B. is so well and strong that I am eager to greet one who was the instrument of her return to life."

Feb. 1, 1906, patient remains well. Has had one child without any mental disturbance during gestation, delivery or since. Time enough, seems to me, to have elapsed to consider this case as recovered.

CASE II. Also during the summer of 1901, Mrs. W. B. S. Female. Widow. Age, sixty. Has always been in the habit of taking a great deal of medicine and drugs, and was taking a large amount of morphine when first seen. Had hallucinations of sight and hearing. Thought that Newfoundland dogs were in her room; that windows with people looking through them were in the sides of the solid wall. Constantly trying to get out of the room to go to some children whom she thought she heard playing outside. Breath very offensive. Pulse and temperature elevated. Reflexes exaggerated. Constipated. Skin sallow, dirty looking.

Treatment: Stopped morphine and all other medicines which she had been taking. Gave calomel in 1 gr. tablets. Strychnine 1-600th t.i.d.; glyco-thymoline t.i.d. Also gave, as symptoms demanded, bromide; aromatic spirits of ammonia; paraldehyde, for insomnia; guarana, for headache; tannin, for diarrhea.

Patient gradually improved, and in the fall of 1901, was able to go to drive. In the spring of 1902, went to Europe where she got on very well, and up to the last that I have heard from this patient there has been no return of hallucinations or delusions, the latter of which were mainly about her husband. At last accounts she was traveling with a companion and enjoying life. I should consider this case also as recovered.

CASE III. Jan. 29, 1902, J. B. W. Male. Age twenty-five years. Worked in wholesale millinery store. Mother fifty-two years, living. Father died at fifty-four of accident, and was always a drinking man. Sister died of nervous trouble at twenty-five. Brother died of consumption at twenty-eight and was delicate and nervous, and "things proved upon his mind." Maternal uncle and aunt and their daughters died of consumption. Patient had usual children's diseases. Never drank or smoked.

Occasionally has nightmare, but never walks in sleep. Last June while calling on friends in the evening he felt what he calls his "first spell," felt he must go out or fly, was terribly excited, felt if he did not run or jump he might faint. Later had other attacks. Woke up early in the morning and worries much about his "self." Head feels badly. Weight 141 lbs.

Treatment: Prescribed glyco-thymoline 50, t.i.d., in water with meals. 1-600 strychnine after meals. Liquid peppercorns between meals.

Feb. 15, patient says the old troubles have all left him; he has regained confidence in himself and feels well. This is certainly a case of decided improvement.

CASE IV. Sept. 5, 1902, I. B. T. Male. Age thirty-four years. Of a neurotic family. Patient has always been delicate and over-sensitive. Lost his

father two years ago, since which time he has been morose and rather avoided his friends. Has had a recent disappointment in love. Is worried about the small details of his financial affairs although he is unable to spend one tenth of his income. Was referred to me by Dr. F. I. Proctor. Has also been seen by prominent mental specialists who considered the case one of dementia precox.

I found the patient in his room, which was darkened, sitting cross-legged on the bed, partly dressed, and eating food from a plate with his fingers. Would go out of the room once a day, possibly for a little walk, behind the house and away from people; this was all the exercise he would take, and this not regularly, not wishing to leave the room even for the toilet. Does not wish to talk to anyone. Sighs deeply; scowls, and all the lines of his face are deep. Pulls hairs out of his eyebrows one by one and also from the top of his head. History indicates that he has avoided people for some time prior to his father's death.

For some years has had a good deal of stomach trouble and headache. Is a graduate of Harvard. Of late years has dressed poorly, some of his clothes being really shabby. Is self-centered and of a secretive disposition. A hard worker. Has a constant feeling that if you want a thing well done you must do it yourself. This has caused him to work more than his capacity warranted. Pupils react normally. Right knee jerk diminished. Left normal. Romberg position impossible. Coordination poor.

Clouston says, "There should be no power of the higher center compelling the lower center to do more than it is fitted for." Carlyle compelled himself to do more work than he was inclined to do. This is a dangerous thing with a neurotic temperament, or for one who is over-conscientious. This patient had suicidal tendencies once or twice. Skin is dry and cold; does not perspire. Reaction is not good. Sleep not refreshing and occupied with unpleasant dreams. There has been loss of weight.

Things he reads in the newspapers give him unpleasant and uncomfortable thoughts. Fears he may become impulsive after reading them. (I should say here that I believe 50% of the suicides and many of the crimes committed are directly due to the details of crime, etc., as published in the newspapers which offer suggestions to the unbalanced mind.)

Treatment: Started patient at once on a generous diet with egg-nogs, morning and afternoon, with hot milk at night, also antiseptics, principally glyco-thymoline, 1 dr. in water t.i.d.

Sept. 28. Patient is walking four or five miles a day, also riding a bicycle. Still sighs a good deal and seems depressed, with some headaches. Says that he had some "spells" as he calls them during which he felt he was going insane. About two weeks ago, had a crying spell, the second time that he ever cried in his life. Since this time he has seemed relaxed. His skin has looked less sallow and brown and he perspires quite freely. Gave a history of a fall on the ice some time ago at which time he was unconscious for a moment.

Oct. 8. Patient says for the first time he feels that he is really getting better.

Nov. 5. Patient calls at my office to say that he considers himself as well as ever. Tells me that this last summer before I saw him he felt, when he had an axe in his hand, that he must kill some one with it, also felt that he must choke some one. He once walked to the edge of a pond near the house to throw himself in, but that his moral strength was too strong at the last moment. He now says he is not at all choked up his work, which I have consented to after he has

taken a trip to the Pacific coast and back. Is taking only intestinal antiseptics, and these are to be gradually reduced.

Jan. 1, 1906. Patient has had no return of former symptoms. Took up his business after returning from his trip in the spring of 1903, and is now doing more business than ever. Has large interests in electric roads in the south and southwest; employs all the state convicts in one of our southern states in the manufacture of shoes; has just leased a large building in one of our southern cities, also for the manufacture of shoes; and in addition has interests in an insurance company, piano manufactory and real estate in connection with the large estate of his father. This case is plainly one of recovery.

CASE V. Oct. 5, 1903. C. F. I. Male. Fifty-five years. Bank officer and has scarcely been absent from his work a day in over thirty years. Father is said to have been insane; also a sister's child is insane. Recently patient's position was changed; the new work upset him and he became confused not only over the new work but also over matters generally. Could not sleep. Found no sympathy at home. Says for several years has had much gas and uncomfortable feeling in stomach. Now has nausea and frequent eructation of gas. Had to give up his work. Much depressed. Worries continually about different matters. Has pressure all over his head.

Two days ago felt so badly that he left his house at seven o'clock in the evening with a revolver in his hand saying he was going to shoot himself. Wandered about in the dark until eleven o'clock not having the courage to carry out his threat.

Treatment: Prescribed glyco-thymoline 2 dr. in water t.i.d. after meals. Bromide with ergot. Also high enemas of salt solution. Paraldehyde for insomnia, and a trip into the country.

This patient improved up to a certain point, and is able to lead an outdoor life in the country without mental responsibility, so may be classed among the improved cases.

Nov. 17, 1905. He writes that he has had a year of peace, that he is in pretty good condition, that he has a good mountain home and is getting on very well.

CASE VI. June, 1903. E. T. S. Female. Married. Age forty years. Several children. Born in England. Wife of a partner of a prominent publishing firm in New York. Now spending summer in New Hampshire. Cannot bear to have her husband away. Says she has a desperate feeling that her mind is unhinged and has "a horrid impulse to suicide or something worse." Has frightful dreams and a crushing pain in the back of her head. Has been taking stimulants to keep her spirits up. Has insomnia, waking about three in the morning and being unable to go to sleep again. Says "When I do sleep, I am harassed by terrible dreams. This is a beautiful country and the air is delightful, but the implacable silence of it frenzies me and I feel a maddening desire to destroy myself or something." Appetite poor. Much gas in bowels and stomach. Constipated.

Treatment: Stopped all stimulants and restricted her diet. Placed her on antiseptic tablets made by manufacturing chemists and prescribed elimination by perspiration.

Aug. 22. Writes: "I believe the tablets have been beneficial for I am feeling immensely better, and quite reconciled to this place. I am now desperately ashamed of having lost my self-control. I am trying to follow all your directions, but won't you allow me just one cup of tea a day? Have been constipated of late, but I feel extremely encouraged." This is the

last I have heard from this patient, and therefore is classed among the improved cases.

CASE VII. January, 1903. E. P. Female. Married. Age, thirty-five years. Has had periodic attacks of depression for several years. Case referred to me by Dr. V. Y. Bowditch. Patient is of nervous temperament. Is always able to entertain herself, having many accomplishments including painting, designing, leather work, etc. Clever and intelligent.

Was brought to me by her mother from New York, and had to be carried to her apartment at the hotel, not being able to stand or walk. Has delusions of self-persecution and thought she was had done wrong at different periods of her life, but could not make it plain to anyone else. Has lost much flesh. Mother says these attacks come about once a year. Head feels badly and aches a great deal of the time. Is confused and cannot bear the light. Worries a great deal because she has never had children. Dreams are unpleasant. Has been gradually running down for some time. Tongue is coated. Breath bad. No abnormal amount of gas.

Treatment: Gave liquid diet. Calomel in 1-10 gr. doses. Beta naphthol in 5 gr. doses an hour before meals. Benzoate of sodium $\frac{1}{2}$ dr. one hour after meals. High enemas of salt solution, and salt baths at night. No other drugs or medicine.

Feb. 11, no headache for some days. Sleeping very well every night. Diet now consists of Matzoon four times a day; eggnog; chicken soup; bouillon; toast; juice of an orange; Mellin's Food; lettuce; cereal milk; celery and occasionally a small piece of steak.

March 12, sat up for an hour. Is now taking a more solid diet.

March 18, saw a visitor for half an hour; slept for two hours afterwards. Is now sleeping from ten to twelve hours a day, which includes the morning and afternoon nap.

March 24, on regular diet. Eating and sleeping well. Goes to the theatre, driving, walking, etc.

Feb. 1, 1906. Patient has had no attack since she recovered from the last one in 1903. Her husband lost his position in 1905, causing the family to give up their house and the patient to support herself; this she is doing by designing silver. The change disturbed her to the extent of making her restless, but she slept and ate well and is now working for remuneration, for the first time in her life. This case has recovered and under favorable circumstances there should be no relapse.

(To be continued.)

THE SECRET OF THE MAYOS' SUCCESS.

BY WILLARD BARTLETT, A.M., M.D., ST. LOUIS.

SITUATED in Rochester, Minn., a pretty town of eight thousand inhabitants, there is a surgical clinic which is altogether unique and remarkable. It may be said to have been founded by the father of the present surgeons in charge. In 1883 a tornado swept through the fertile valley in which Rochester lies, and about eighty people were more or less seriously injured. The Sisters of St. Francis, who maintained a convent in Rochester, nursed the wounded, under the direction of the senior Mayo and, in consequence of the experience thus gained, conceived the idea of building a hospital for him. This early undertaking was a success, and from the humble

beginning has grown the beautiful and useful structure with one hundred and fifty beds which, from the outset, has been devoted to surgery exclusively.

W. W. Mayo, the father, now a hale old man of eighty-six, was aided a little later by W. J. Mayo, now forty-four, and a little later still by C. H. Mayo at present forty years of age. The father has long since retired from active practice, though his genial presence is frequently manifest at the hospital.

This perfectly equipped modern structure stands among evergreen trees on the slope of a hill overlooking the fertile valley in which the town of Rochester nestles. The building is complete in every detail, from the operating-room equipment to a clinical laboratory in which are installed all of the latest devices for emergency pathological diagnosis, as well as for permanent work of a statistical bearing.

Before entering the hospital every patient must pass through the private offices of the Mayos, where a trained corps numbering sixteen is employed to work up the various details of "up-to-date" diagnosis. Like specialists in other fields, the Mayos have a great many cases referred to them by internists and other physicians, but it is worthy of note that a far larger percentage of those who occupy beds in St. Mary's Hospital come solely on the recommendation of other patients who have been treated there. In this way the "material" differs essentially from that of most surgeons.

One knowing the vast amount of work that is done at Rochester will naturally ask the question, Where do so many people come from? A recent magazine writer, in speaking facetiously of the work, referred to the "scope of a country practice"; and it is astonishing to note that this "country practice" has embraced benign stomach cases from twenty-six states and Canada, as W. J. Mayo stated in a recent article on the subject. A wag, when asked where the Mayos got all their patients, remarked that they were not yet getting any from Mars or the other planets, for as yet they all came from this world; and indeed he was not so far wrong for they do come from almost all parts of this globe. A surgeon who was visiting the Rochester clinic in 1905 is authority for the statement that at one time there were in the hospital residents of the following American cities: New York, Chicago, St. Louis, New Orleans, Washington, Minneapolis, St. Paul and Denver, so you may estimate the scope of this country practice.

In 1904 these two men did over three thousand surgical operations, and the average daily number performed is now somewhere between twelve and fifteen. The greater number of these are major procedures, but the ease and celerity with which they are turned off will astonish the observer who is at the clinic for the first time. Naturally, an unequalled opportunity for post-graduate work in surgery is presented at Rochester, and the generosity with which explanation and descriptions are given is surprising. The

Mayos never seem to tire of answering questions, and they must be called upon to answer the same questions many times.

On Oct. 6, 1905, the Society of Clinical Surgery met in Rochester as the guests of the Mayos, and a list of the operations performed on that day will no doubt be of interest to those who are desirous of knowing what the clinic furnishes in a day:

(1) Abdominal hysterectomy; (2) pelvic tumor; (3) inguinal hernia, appendectomy and excision of the gall bladder; (4) chronic ulcer of the stomach; (5) tuberculous glands in the neck; (6) chronic ulcer of the stomach; (7) exophthalmic goiter; (8) cancer of the pylorus; (9) cystic gall bladder; (10) obstruction of the common bile duct; (11) perineorrhaphy and internal Alexander operation; (12) chronic ulcer of the stomach.

One might suppose that this was a special program in view of the fact that so many distinguished guests were present, but it is interesting to note that the next day's program was equally varied, with fourteen, instead of twelve, great operations.

To show what a wealth of statistical material is accumulated at Rochester, one has but to refer to the fact that up to 1905 some eight hundred stomach operations had been performed there, and more than eleven hundred abdominal sections for gall-stone disease. This seems almost incredible to one who has not visited Rochester, and any description which deals with cold figures alone must be utterly inadequate to do the subject justice. Those who have not seen the Mayos work are wont to ask, How is it possible for them to do so much in so limited a time? It is true they usually commence about 8:30 a.m. and are through in time for a one o'clock lunch. This facility is hard to explain, though it seems simple enough to an observer on the ground. The reason is that the utmost simplicity prevails. The Mayos' system is perfection itself. The assistants are trained to the highest degree and are permanent, while the dexterity of the surgeons themselves is marvelous. Two operating rooms are in constant use. No time is lost between operations, yet there is not the slightest evidence of nervous haste.

Surgeons flock to Rochester. If ten men were asked to tell exactly what they went for, one would reply that they went to get some of the Mayos' *tricks*. The Mayos have shown rare ability in selecting what is best in the technique of every clinic they have visited while their own ingenuity makes an indelible impression on visitors, and their methods, which are now common property, were once the astonishment of all men who saw them at work. It is common enough in any operating room to hear the surgeon say he is doing this or that by the Mayo method, but the observer has not to hear one of the brothers call an operative procedure his own.

Each may be called trope to a stream in surgery. William J. Mayo devotes almost his entire attention to intra-abdominal lesions, es-

pecially those of the stomach, duodenum and biliary passages. Charles H. Mayo does everything else, as well as those above mentioned, in his brother's absence. C. H. Mayo is thought to be most famous for his work on exophthalmic goiter, glands of the neck, inguinal hernia, senile prostate and varicose veins of the lower leg, although he operates for cataract or some other eye lesion almost every morning. Thus it will be seen that the two brothers cover an immense field and, when both are at work, divide the field between them. At the same time the work does not suffer when either is on his vacation. The work of the two is not alike, so comparisons as to their technical ability are impossible. The observer is most impressed by the fact that William J. Mayo is masterful, while Charles H. Mayo is ingenious. — if one may describe each by a single adjective. Those who know these men best recognize that their one leading motive in professional life is to do what is best for their patients, and to expose these fortunate or unfortunate ones to the minimum of danger.

What is the secret of the Mayos' success? In a word it is simply whole souled love of their work and devotion to duty, supplemented by American ambition, ingenuity and management. Many of the qualities that have made the Mayos successful and famous have made Rockefeller the richest man in America, and Edison the most noted electrician. There is no chance or accident about all this. The Mayos are striking personalities, who stand for something, and that something is success in surgery.

Clinical Department.

A FATAL CASE OF GASTRIC TETANY.

BY LINCOLN DAVIS, M.D., BOSTON.

THE following case of gastric tetany seems worthy of record, not only on account of the comparative rarity of the disease, and the obscurity which still surrounds its etiology, but also on its own account by reason of the severity of the symptoms, and the rapidity of the fatal outcome.

On July 17, 1905, at Marblehead, I was called about 10.30 P.M., to see a maid servant who was said to be having convulsions. I found a poorly developed, emaciated woman, single, forty-two years of age, lying in bed in a state of great nervous excitement, moaning with pain and declaring that she was dying. She was conscious, and able to respond to questions. It was not easy, however, to get a definite history of her ailment from her, as she could concentrate her mind on any one subject only for a moment at a time. From her, and from other servants in the house, I was able to learn that she had been in her usual health until that afternoon. She had vomited then, and shortly afterwards the pain and numbness began in her hands; this gradually increased and extended to her legs, until she finally reached the state in which I found her. She denied having taken any medicine or drug, and there had been no mental shock of any kind so far as could be learned.

Examination.—Face deeply flushed. Pupils equal. Respiration seemed normal. Pulse 100. Temperature 99. Heart sounds normal. Both arms were flexed at elbows and wrists; the fingers were flexed at the metacarpo-phalangeal joints, and extended at the phalangeal joints; the thumb was adducted and flexed on the palm of the hand. The hand was strongly pronated and held close to the chest, in the characteristic conical or obstetric position. The spasm of the left hand was more marked than in the right. Both feet were strongly plantar flexed, and the toes were likewise flexed. No spasm of other muscles was noted; the muscles of the neck were relaxed, and permitted of free flexion of the head. Great pain was complained of in the affected muscles.

Under gentle and persistent passive motion and massage, together with verbal assurance that her condition was not alarming, the spasm of the muscles of the left hand relaxed, and the fingers could be fully extended; also the wrist and elbow. The abdomen was somewhat distended, soft and not tender.

I gave her morphia, gr. $\frac{1}{4}$ subcutaneously, and directed that a dose of epsom salts be taken in the morning. When I left her that night the muscular spasms had almost wholly gone, and she was resting quietly, quite free from pain.

The correct diagnosis was not made by me at this time, nor, in fact, later, the relaxation of the spasm having led me to regard the condition as hysterical.

The next morning there was still some stiffness of the left hand, and fingers; otherwise her condition seemed normal. She had had a fairly good night; vomited once. I decided to take her to Boston to the Massachusetts General Hospital.

The patient was able to sit up in the train, and seemed quite normal during the first part of the trip. The locomotive unfortunately broke a driving rod, which necessitated a delay of about one hour. It was a very hot day, and the heat in the stalled car became intense. The patient complained greatly of this, and became quite restless, and began to have spasmodic contractions of both hands. When we finally arrived in Boston the contractions of the arms had become pronounced, and she was groaning with pain. Nevertheless she was able with slight assistance to walk from the car to a cab, and from the cab into the hospital. Having given a brief account of the case, I was obliged to leave the patient and did not see her again.

The following is an abstract of the hospital record:

East Medical Service. Dr. Minto. V. 625, p. 192.
N. McE. Maid. Single. Forty-two years of age.
July 18, 1905.

Well developed and poorly nourished. Face and hands cyanotic. Conscious. Pupils contracted, equal, and react to light. Tongue moist, slight white coat. Teeth in good condition. Throat negative. Glands in neck and groins. Heart: Impulse and dullness in 4th space inside nipple line, three and a half cm. from midsternum; action regular; first sound at apex replaced by loud, harsh systolic murmur transmitted to axilla; second sound at apex not heard. Lungs negative. Abdomen, full, soft and tympanitic; no masses. Spleen not palpable. No edema. Jaws open half way. Forearms tightly flexed on arms over chest, and wrists and fingers firmly flexed, with thumbs inside; cannot be extended. Both legs extended with toes flexed. Legs can be flexed with difficulty. Temperature 100.8; pulse 120; respiration 25. Hemoglobin, 100%; leucocytes, 18,600.

Urine: normal, acid; albumin, sugar and bile absent; Diazo reaction absent. Sediment: many squamous cells and round cells; some leucocytes; very rare hyaline cast.

Patient complained of terrible pains in the arms, and begged to be relieved. Given apomorphin, gr. 1-30 and gr. 1-16, causing slight vomiting of watery fluid with whitish particles in it. Patient later fell asleep. Muscles relaxed. One hour later patient was shaking violently all over, with indefinite movements of arms and legs. Sweating profusely. Pupils dilated. No stiffness of neck. Could not be aroused to consciousness. Given morphia, gr. 4. Coma later became profound, and no more signs of spasm were observed. Temperature 106.4 by rectum. Cheyne-Stokes respiration. Died at 7.45 p.m.

Cerebro-spinal fluid was examined by post mortem lumbar puncture. Cover glass showed no cellular elements; no bacteria. No growth on culture in forty-eight hours.

Autopsy No. 1431. Twenty-four hours post mortem, by Dr. Oscar Richardson.

"Anatomical Diagnosis.—(Tetany.) Congenital abnormal smallness of the pylorus and the upper end of the duodenum. Acute dilatation of the stomach."

"Body that of a woman forty-two years of age; 161.5 cm. long; fairly well developed; very poorly nourished. Head not examined. Incision restricted to a seven-inch cut in abdominal wall.

"Peritoneal cavity is free from fluid. Peritoneum smooth and shining. Appendix not remarkable. The lower border of the stomach as well as can be made out extends below the umbilicus, and the organ occupies a large space in the peritoneal cavity.

"Lungs, pericardium and heart on section, are not remarkable. Aorta smooth.

"Liver is of good size, and on section rather dark red in color, and somewhat soft. Spleen is small and, on section, not remarkable. No stones in gall bladder. Bile ducts free. Pancreas is rather dark and soft. Duodenum of Wirsung is free.

"The stomach is of enormous size; it measures 55 cm. in length and has an average width of 11 cm., and about 5 cm. in the other dimension. These dimensions are taken with the organ filled with just sufficient water to show its shape. On section, the organ contains a considerable amount of semi-fluid material of about the consistency of pea soup; one prune stone is also present. The mucosa presents no lesions. The pyloric opening is very small; it is about 7 mm. in diameter. The pyloric ridge is rather thin, and there is no thickening of the wall of the stomach or of the duodenum in the region of the junction of the stomach and duodenum, nor is there any fibrous thickening about them. The upper portion of the duodenum narrowed down to a circumference where it joins the pylorus which is equal to the circumference of the pylorus. The duodenum, a little below the pylorus, is of about normal size and continues so throughout its length. There are no ulcers in the lower end of the duodenum. Further examination restricted.

"Specimen preserved."

The autopsy at once cleared up the diagnosis and stimulated my interest to learn something more of the past history of the case.

Through the kindness of Dr. Samuel Richardson I was enabled to learn that the stomach's symptoms, especially the vomiting, began about three years previous to her death, and at about the same time she began to emaciate. Her appetite was ravenous, but nearly all food would be vomited sooner or later, if not on the same day, then on the following one.

In February, 1904 she was admitted to the

Boston City Hospital, where she stayed three weeks. The following abstract of her record was kindly furnished me by the hospital:

"N. McX., forty, single, Ireland, chambermaid, admitted Feb. 28, 1904, Medical Side. Diagnosis: Pyloric stenosis, malignant (?). Family history negative. Past history: Attack similar to present, one year ago. Present illness: Stomach trouble for two months. Pain and discomfort in epigastric region. Attacks of pain, sharp in character, coming on usually one hour after supper. Pain caused palpitation occasionally, but no special dyspnea, and is accompanied by nausea and vomiting every thirty-six to forty-eight hours. Vomitus consists of slimy, foul-smelling material, about three pints at a time. Blackish material once after taking black powder prescribed by a physician. Pain relieved by vomiting. Good deal of gas and cructations. For four days past, vomiting has been persistent in smaller quantities, and vomitus of same character. Feels weak. Bowels move with medicine. Best weight 122 lbs., one year ago. No cough, no headache; nothing ever noticed wrong about kidneys or bladder.

"Physical examination: Heart normal, pulses arteriosclerotic (?). Lungs: Dullness, right apex. Abdomen: Flat; tenderness in right epigastrium, accompanied by muscular spasm and sense of resistance; tympanitic throughout.

"March 3. Patient vomited twice since entrance. Less pain. Still some distress. No blood. Examination of vomitus: Amount, 1200 cc., color brownish (bismuth?); reaction, acid to litmus, odor fermentative; considerable amount mucus; food, small amount, fine particles. Free hydrochloric acid absent; lactic acid absent; total acidity, 328%; butyric acid absent; acetic acid absent; sediment, oil drops; starch granules. Considerable mucus; question of cells.

"March 7. Occasional attacks of vomiting since last note. More or less gastric distress. Stomach washed out yesterday and inflated, showing large stomach, with apparent mass at pyloric end felt, size of half dollar. Examination of contents shows hydrochloric acid present, which was absent at the last examination. Less distress since stomach so treated. Fluid diet until present, when milk toast has been added.

"March 11. Much improved. No further vomiting. Up past two days. Mass felt in right epigastrium and is now less marked. Feels stronger.

"March 15. Up every day since last note. General condition improved. Eats well, gaining flesh. No further vomiting. Now on soft solids, no gastric distress.

"March 19. Continues to improve. No gastric symptoms. Mass in pyloric region now less evident to touch. Area of stomach remains large. Advised to have exploratory operation performed, but refuses. Held as to probable nature of trouble and need of continued observation.

"Discharged fully recovered, past March 26, 1904."

After her discharge from the hospital, she was treated gastric trouble by a private physician, and professed to herself to be cured. A stomach tube was found among her effects after death. A note of the patient recalled that in the winter of 1903 the patient remarked that when sewing her hand and foot would sometimes become so stiff that she would drop her needle. This recalled her own fear or her own such an attack that of March 1st.

In considering this case it is to be regretted that the evidence to be obtained from certain internal tests, such as Treves's phenomenon

and Chvostek's, Erb's and Hofmann's signs, which are considered pathognomonic of tetany, is lacking.

In spite of the fact that none of these tests was made the diagnosis of tetany is unassailable, I think. The character of the contractures is recognized in the light of subsequent study to have been characteristic, and the whole course of the disease typical of the severe form of gastric tetany.

This case throws no light on the obscure subject of the etiology of gastric tetany. It was unfortunate that the restricted post-mortem examination allowed, did not permit of an examination of the parathyroid glands, which recent investigations would seem to show may play an important rôle in the causation of those peculiar muscular spasms which have received the name of tetany. The case does, however, very forcibly present the subject of treatment.

The treatment of this condition will necessarily remain unsatisfactory until the pathogenesis is better understood. Pursuant to the latest etiological theory the administration of parathyroid gland extract has been proposed. This is being tried at the present time, but it is as yet too early to speak of results.

Prevention is better than cure in this condition as in all others. The records of cases of dilatation of the stomach associated with tetany, which have been operated upon, gastro-enterostomy being the usual procedure, seem to show a complete immunity from subsequent attacks. Such a case was that operated upon by Watson, and recently reported by Cunningham. If this immunity from tetany is real and lasting, it is an added factor favoring the operative treatment of dilatation of the stomach.

The patient in this case was offered the benefit of an operation at the City Hospital, but refused. If the operation had been done, it seems unlikely that the case would ever have been known as one of gastric tetany.

The treatment advised for the attack itself is largely symptomatic and a long list of sedatives and even anesthetics have been proposed. It would seem rational to empty the stomach when that organ is filled with fermenting material, and yet the literature of the subject abounds with instances in which fatal attacks of tetany have been evoked by the act of vomiting, or the passage of the stomach tube.

When the spasms are severe it would seem expedient to administer ether, and under anesthesia to wash out the stomach, then, if the general condition of the patient warranted, the performance of gastro-enterostomy at the same sitting might be considered in an appropriate case.

It is questionable, I think, if any line of treatment would have saved this patient. It is generally recognized that after the spasms become severe, the condition is a very grave one. The cases of gastric tetany of all grades collected by Frankl-Hochwart, Riegel and Albu show a mortality between 70% and 80%.

Medical Progress.

RECENT PROGRESS IN GYNECOLOGY.

BY W. L. BURRAGE, M.D.

ONE DISADVANTAGE OF THE TRENDLENBURG POSITION IN ABDOMINAL OPERATIONS.

C. LAUENSTEIN¹ points out a danger which attends the elevated pelvis position, namely the entrance into the upper regions of the abdomen of infective matter from the vagina. He operated on a young woman for what he supposed to be an ovarian tumor, a prior examination having failed to reveal the presence of the gonococcus in the secretions from the vagina. At operation he found double pyosalpinx. He performed double salpingectomy with supra-vaginal amputation of the uterus, the patient being in the head down position, the vagina not having been previously sterilized. The operation lasted half an hour only and there was little shock. Death ensued in twenty-four hours and the autopsy revealed the presence of diplococci and staphylococci in the abdomen. Lauenstein thought that gravity and suction had transferred the infective organisms from the vagina to the abdomen.

[There is no doubt but that this is a real danger and that where there is special likelihood of infection, either from the vagina or from the contents of the tubes, many operators prefer to perform as much of such operations as possible with the patient flat.]

REMOVAL OF CARCINOMA OF THE POSTERIOR WALL OF THE BLADDER UNDER SCHLEICH ANESTHESIA.

J. C. Webster² reports the case of a woman of sixty-nine who had a circumscribed patch of carcinoma on the posterior wall of the bladder as diagnosed by the cystoscope. There had been hemorrhage for three months. The woman was weak and anemic. The operation was done entirely under local infiltration anesthesia with the Schleich No. 2 mixture. The bladder was filled with salt solution and a bag placed in the rectum. A wide transverse incision was made nearly an inch above the pubes, dividing the lower end of the recti and fascia down to the external peritoneal tissue. The peritoneum was dissected from the posterior wall of the bladder and the bladder was incised without any further local infiltration anesthesia, and the diseased area was removed. The aperture in the bladder was closed with formalin catgut; the ends of the divided recti and fascia were approximated by means of catgut and interrupted silk sutures which also included the skin. The wound and the bladder were drained. On removing the catheter from the bladder on the ninth day there was slight urinary leakage from the wound for three or four days, ceasing permanently on reintroducing the catheter for four days. The patient was able to hold her urine for from two to two and a half hours and was ready to leave the hospital at the time of the report.

THE BLOOD SUPPLY OF THE UTERUS.

J. H. Keiffer¹ has studied the ultimate distribution of the uterine arteries and particularly the connection between the circulating blood and the contractile substance of the organ. He employed carmine gelatin injections of the arteries in the human uterus made on the day of its removal. Such a study gives information as to the method of irrigation and nutrition of smooth muscle and allows one to appreciate the different functional conditions of the uterus.

Each artery arises directly from one of the principal uterine arteries and pursues a course of greater or less extent, usually of the helicine form, in the midst of the parenchyma. It is surrounded constantly by a layer of loose connective tissue which separates it from the uterine tissue proper and is continuous with the common interfascicular connective tissue. After giving off collateral branches, here and there, this artery diminishes insensibly in caliber, in thickness and in amount of its adventitious connective tissue coat. At a certain point the periarterial connective tissue disappears and the little arteries, progressively reduced, come in direct contact with the uterine muscular tissue and with the interfascicular tissue. Finally, the smallest arterioles lose the last muscular elements of their wall and are represented by an endothelium applied directly to the parenchyma. These capillaries form the small circulatory system of the uterus. They are irregular clefts which run in all directions, effect all the anastomoses, and develop a considerable vascular surface with a wall of a single layer of endothelium, which is in contact with all the muscular and connective tissue elements of the uterus. From the complicated plexus of these tissues very important clefts appear here and there. These clefts are quite large; they traverse muscle and connective tissue, and gradually become individualized and constitute the first canals deserving the name of veins. The veins resemble the arteries already described in their histology and course, and finally leave the organ on its lateral surface.

The physiological characteristics of the uterus explain the anatomical characteristics of its circulation. The helicine form is in direct relation with the necessities of the variations of volume produced by menstruation and pregnancy. The changes in these vascular systems depend upon considerable elongation, followed by a return to the primitive condition. The arteries preserve a decided functional interdependence on account of their surrounding loose connective tissue layer. Their walls are able to contract firmly and freely and to transmit the arterial blood wave even to the muscular masses. The intimate relation of the endothelium of the little circulation to the muscular masses gives one the idea that the capillaries and the veins possess the entire uterus as their wall, so that it may be said that the uterus is a true organ, organ.

ADVISABILITY OF OPERATING ON NEURASTHENIC PATIENTS.

In a symposium of gynecologists and neurologists, at a meeting of the Obstetrical Society of Philadelphia, in December, 1905,² Dr. R. L. Dickinson presented the paper entitled "The Uterus and Ovary of Neurasthenia," maintaining that treatment of gynecological disorders by surgical operation was to be advised in all but the congenitally delicate, the hysterical, the melancholic and all not subject to long observation.

Dr. F. X. Dercum, in the discussion, expressed the opinion that in the great majority of cases pelvic disease and neurasthenia, when coexistent, were coincident, and thought that there was no causal relation whatever between them. Neurasthenia, pure and simple, was synonymous with chronic nervous fatigue, the symptoms being characteristic and definite, all indicative of a ready exhaustion upon slight exertion. He entirely agreed with Dr. Dickinson that in the chronic and aggravated type of neurasthenia in women, pelvic symptoms were prominent. Neurasthenia, he said, may exist, independently of any pelvic disease, neurasthenia and pelvic disease may exist independently in the same patient, and, when pelvic disease and neurasthenia co-exist, the pelvic symptoms may be more readily recognized by the patient and, therefore, become more prominent because in neurasthenia the reaction of the nervous system to pathological impressions is exaggerated. Pelvic disease he thought, never caused true neurasthenia. That various signs of nervous weakness should be present in serious local or general disease, weakening the entire organism and with it the nervous system, was not surprising.

This state, he called spurious neurasthenia. The nervous symptoms directly due to pelvic disorders were exceedingly limited. The doctrine of reflex nervous disorders had been entirely dissipated by an increasing knowledge of the various functional diseases to which the nervous system was liable. A dispassionate consideration of the subject led to no other conclusion than that the surgeon should operate on surgical indications only.

Dr. Charles K. Mills thought that in a majority of cases of a neuro-gynecological type the conditions presented are dependent on neurotic or neuropathic tendencies in the individual which a study of hereditary predispositions would disclose.

Dr. J. M. Bally deprecated the undue prominence given to trivial abnormalities of the uterine organs by certain gynecologists and by pathologists. He did not believe that neurasthenia was caused by pelvic disease.

Dr. William C. Spiller did not believe that neurasthenia in most cases could be cured by treatment of the generative organs, and in cases of mild disorders he thought it better not to give any treatment to these organs. He cited Kruff's long statement that out of 2500 cases of

¹ Bulletin de l'Académie Royale de Médecine de Belgique, vol. 51, N. Y. Med. Jour., 1906, 1279.

² N. Y. Med. Jour., 1906, p. 378.

thenic females, he had been able in only nine to find a relation between the reproductive organs and the neurasthenia. Spiller thought that removal of the ovaries was one of the most serious operations from a neurological point of view, that could be performed on a neurasthenic.

Dr. John G. Clark attributed much of the meddlesome operating of the past to Charcot's teaching, Charcot having described a type of hysteria associated with so-called ovarian pain at a point where a line drawn between the anterior superior spines of the ilia intersects the outer border of the rectus muscle, the "Charcot's point." As a matter of fact the ovaries are situated much below this line and have nothing to do with the pain. He advocated turning over to the neurologist the neurasthenias of hereditary origin; those with pelvic lesions coincident he thought should be treated because the pelvic disease aggravates the nervous symptoms; in a third class of cases, the neurasthenias incident to pelvic lesions, operation should be undertaken at once.

The whole question pivoted around the history, and every phase of the patient's past life should be inspected with reference to the various possible manifestations of neurasthenia.

In the discussion of a paper on *The Border Line in Medicine and Surgery*, read by Dr. E. G. Janeway before the Practitioners' Society of New York, Feb. 9, 1906,⁵ Dr. Charles L. Dana referred to the unstable condition of the so-called neurotic persons. He said there were a large number of persons, particularly young people, who were always ripe for the development of a psychosis, and an operation appeared to be a determining factor. He could recall many cases in which an operation had produced an obsession, or neurasthenia or hypochondriasis and this had led him to the view that before an operation on a person of this temperament was advised or undertaken, the family and personal history should be very carefully gone into.

THE IMPORTANCE OF MAKING A CAREFUL EXAMINATION OF ALL MYOMATOUS TUMORS DURING HYSTERECTOMY.

T. S. Cullen⁶ reports a case of a supravaginal hysterectomy for interstitial and subperitoneal myomata in which there developed in the stump of the cervix two years after operation a sarcoma, which caused an alarming hemorrhage, and death in eight months. In this case the myomatous tumor was examined superficially at the time of operation. The uterine cavity showed nothing unusual on being laid open. After the development of the sarcoma the tumor was examined with more care and then there were found in the myoma, not only areas of hyaline degeneration, but also round and irregular areas of typical sarcoma.

Cullen urges the importance of examining at the time of operation not only the uterine mucosa but the structure of the myoma as well. He

prefers a supravaginal hysterectomy to a complete hysterectomy because the former is easier, it leaves a better support to the pelvic floor, there is less danger of tying the ureters, and, as the blood supply of the bladder is little interfered with, there is less likelihood of a post-operative cystitis.

INSANITY AS A RESULT OF OPERATIONS ON THE OVARIES AND UTERUS.

Graeme M. Hammond,⁷ in a paper read before the New York Psychiatrial Society, takes the ground that the ovaries and uterus have nothing to do with the preservation of the integrity of the brain, and that their removal alone never causes insanity; that the insanities which follow operations on these organs depend on a hereditary tendency to insanity, the psychologic causes, the physical causes, and surgical shock, but that the principal cause of all is the congenitally defective brain.

The discussion which followed the reading of the paper developed a substantial agreement among the members of the society with the views of the reader.

MECHANICAL SUCTION AND HYPEREMIA IN GYNECOLOGY.

J. Eversmann⁸ tells of his experience at the Bonn clinic with his apparatus to produce suction on the cervix uteri. It is simpler than the instrument devised by Dr. Rudolph,⁹ and consists of a large test tube with a small offset tube near the rounded bottom. A rubber tube leads from the mouth of the offset to a stopcock, and another tube from the stopcock to a suction pump. The mouth of the test tube is placed over the cervix and suction established with the pump, when the os is drawn far into the tube and can be seen to be much congested. The procedure is used for a twofold purpose, — to remove the secretions and to stimulate the circulation in the uterus. Applications are made for half an hour at a time, with intervals of several days, gradually shortening the intervals until they are made daily. After suction has been made for five minutes the stopcock is opened for one minute and then the suction again applied, this alternation of suction and normal atmospheric pressure being one of the factors in the treatment.

The author's experience has been especially favorable to this method of treatment, more particularly in cases of endometritis with considerable discharge. Exudates in Douglas' cul-de-sac were gradually softened and absorbed.

Kraemer of Giessen¹⁰ presents a similar apparatus with a mercury manometer attached to register the amount of suction. He uses the apparatus in acute inflammations to localize the infectious material as well as in passive hyperemia.

OVARIAN CYST SIZE OF A CHILD'S HEAD WHICH DEVELOPED IN OVARY LEFT BEHIND AT HYSTERECTOMY FOR FIBROMA.

A. Calmann¹¹ did a vaginal hysterectomy on a patient thirty-nine years of age for small multiple fibroids, pyosalpinx and enlarged ovary on the right side and salpingitis on the left side. The left ovary appeared to be normal and was not removed. Three years later a cyst the size of a child's head and developed in the left side of the pelvis and the patient complained of pain in the abdomen and the nervous symptoms of the menopause.

The cyst was removed by abdominal section and proved to be a corpus luteum cyst. Recovery and relief from pain followed but the nervous disturbances were as before.

A NEW OPERATION FOR COMPLETE PROLAPSE AFTER THE MENOPAUSE.

T. Landau¹² proposes the following procedure to relieve prolapse in patients who have passed the menopause, other operations having proved unsatisfactory in his experience. There are nine stages: First, the usual disinfection and drawing forward of the prolapsed uterus as far as possible. Second, a long incision in the anterior wall of the vagina beginning close under the urethra and extending to within 2 or 3 cm. of the os uteri. Third, detach the vaginal walls after incising the anterior lip of the cervix, and separate the bladder from the uterus. Fourth, open the vesico-uterine pouch of the peritoneum and antevert the uterus. Fifth, pick up a fold of the peritoneum of the posterior cul-de-sac and by means of a silkworm gut suture which is passed through the posterior surface of the uterus as well as the peritoneum of the cul-de-sac and the wound in the anterior vagina, the cul-de-sac is obliterated and the uterus is turned forward into the vagina. Tying the suture closes the peritoneal cavity and fixes the posterior wall of the uterus and the cervix. Sixth and seventh, remove the adnexa and the greater part of the body of the uterus, using a longitudinal incision and leaving behind a portion of the posterior wall of the cervix; also resect the superfluous tissue in the anterior walls of the vagina. Eighth, close the anterior vaginal wound and the remains of the uterus with sutures. Ninth, perform a high colpoperineorrhaphy. The operation lengthens the vagina, fixes the posterior portion, aided by the remains of the uterus and, with the support afforded by the strengthened pelvic floor prevents prolapse of the abdominal contents. There are no difficulties in the technique according to Landau, and he considers the operation less serious than total excision of the uterus.

REDUCTION OF CHRONIC INVERSION OF THE UTERUS BY ABDOMINAL SECTION.

L. V. Friedman¹³ discusses the different methods of reducing chronic inversion of the uterus and advocates a method employed by

him in two cases. The abdomen is opened by the usual median incision and the patient placed in the Trendelenburg position. The bowels are walled off by a plentiful supply of gauze thus diminishing the extent of peritoneal exposure and trauma. If possible the contracted ring of the cervix is dilated with the fingers, but if the constriction is so tight as to prevent this procedure the ring is dilated first with a steel dilator of the Wathen or Goodell type, then with a Reynolds' dilator, which has been found peculiarly serviceable. In inserting the steel dilator and in dilating care must be taken to avoid pressure on the tubes and round ligaments. Only moderate force should be used, and this must be regulated by the hand and not by any mechanical device on the dilator. In a few minutes it is possible to partly withdraw the round ligaments and tubes, though no force is to be employed and no attempt should be made to reinvert the uterus by traction on the ligaments or tubes. At this point an assistant places his hand in the vagina and begins to carry up that part of the uterus which descended last; as this rises it is caught and held by vulsellum forceps in the hand of the operator. The process of dilatation, reinverting and holding are repeated until the operation is completed. The procedure is a slow one and no violence should be used. A skilled vaginal assistant is necessary.

Friedman points out the following objections to Spinelli's operation, the ideal vaginal operation as advocated by R. Peterson: By the vaginal route the tubes and round ligaments are exposed to vaginal contamination and then immediately turned free into the abdomen. As both tubes, round ligaments and sometimes a loop of bowel are packed tightly into the crater formed by the inverted uterus, there is the risk of injury to these organs in making the vaginal incision. If this incision is made posteriorly there is apt to result an adherent retroversion; if made anteriorly we have the undesirable vaginal fixation. Finally, there is the possibility of a rupture of the uterine scar in a subsequent pregnancy.

Friedman's operation is similar to that done by T. G. Thomas in 1869 before the days of asepsis, and now brought into line with modern ideas.

Reports of Societies.

THE NEW YORK ACADEMY OF MEDICINE.

SECOND PAPER, FEBRUARY, MARCH 29, 1906.

SYMPOSIUM ON THE TRAINING OF NURSES.

The first paper was by GEORGE F. LADHAM, superintendent of the New York Hospital, on

THE ORGANIZATION AND CONTROL OF TRAINING SCHOOLS.

He said that the rise and development of the training school for nurses was one of the most remarkable features of the modern hospital scheme. The accommodations for the pupil nurses, while at first of extreme simplicity, were now of the most expensive and elaborate character. The curriculum had developed into a highly scientific and comprehensive

¹¹ Zentralblatt für Gyn., 1903, No. 47, 1440.

¹² Ibid., 1903, No. 43, 1321.

¹³ Medical and Surgical Reports, Boston City Hospital, 1903, 65.

system. The calling of the trained nurse had been exalted into a profession, for which laws were enacted, and in which a title was conferred after graduation. Periodicals and volumes were devoted to the subject, and national and even international associations had been organized. All this marvellous growth had occurred in little more than a quarter of a century, and the movement was recognized as one which concerned the interests of all classes of the population.

The work of the hospital medical staff and of the training school should be intimate, harmonious and complementary. As so much depended upon the principal, the importance of the selection of a proper person for this position could not be overrated. The number of assistants employed must depend on the size of the institution. It was an objection to the present system, he thought, that the advanced pupils are placed in charge of wards, and thus take part in the teaching in the nursing course. This was a defect, as there was a wide difference between a good nurse and a good ward-keeper. It was true that the patients did not suffer, but the discipline and general tone of the ward were liable to fall below the proper standard. Such a condition he believed to exist at the present time to a degree which was not formerly the case, and the remedy for it was in the appointment of permanent and well-paid head nurses. A woman in this position if thoroughly competent, would insure tidiness, ventilation, the proper preparation and distribution of food, and other matters pertaining to the welfare of the ward. Again, there should be a closer relation between the medical staff and the training school. The complete division between the two at present he thought very objectionable. It should be a part of the duty of the visiting physician to give instruction in the school.

As to the matter of control, the school should be regarded as distinctly one of the departments of the hospital's work. Unfortunately, the present tendency was towards greater independence on the part of the training school. As well might a company be independent of its regiment, or one regiment independent of the rest of the army. The special points which he would make, then, were: (1) The school should be a distinct department of the hospital, under the control of the executive authority of the institution. While allowed a certain amount of freedom in the management of its affairs its administration, should be subordinate to this central authority. (2) A closer relation between the medical staff and the school. (3) The wards to be in charge of capable, permanent head nurses.

MISS MARY A. SAMUELS, superintendent of the Roosevelt Hospital Training School for Nurses, read on a paper

WHAT NURSES SHOULD BE TAUGHT.

She took the ground that, in addition to the practical art of nursing, the pupil should receive systematic instruction in a large number of scientific subjects. The thoroughly equipped nurse, she said, should have some knowledge of anatomy, physiology, bacteriology, urinalysis, radiology, hypodermoclysis and materia medica. In bacteriology, the instruction should be elementary, but thorough as far as it went. In support of this opinion she referred to the matters of asepis, antitoxin and tuberculosis. The nurse's education, she thought, must be far more comprehensive than what was considered adequate a few years ago. It was also a fact that the average applicant for the position of trained nurse fully appreciated the necessity of a more thorough training and the advantages gained by a three years' course. The scientific branches should be taught in a preliminary

course, which should be at least six months long, and the instruction should be given by textbooks and recitations, rather than by lectures. As the pupil advanced in her course, the theoretical teaching should go hand in hand with the practical. Domestic science should always receive proper attention, and fortunate was the woman who had had some training in this before entering the school. The study of foods, in health and in disease, was of paramount importance. Having referred to massage and some details of practical nursing, she said, that a three years' course was now the rule among the training schools. While this might seem a long time to spend in the qualification for a professional career the average duration of which was comparatively short, it was to be noted that women were now entering the schools at a younger age than was formerly the case. In conclusion, Miss Samuels spoke of the necessity of taking sufficient time for ethical training. Without a proper education of the heart and character, all the rest was worthless.

DR. W. GILMAN THOMPSON read a paper on

THE OVER-TRAINED NURSE.

He said there was a feeling among a large number of physicians that the trained nurse of to-day was absurdly over-trained. The pseudo-scientific teaching prevalent in the schools was a mistake, as it left the pupil at the time of her graduation with only a smattering of knowledge on a multitude of subjects. In the instruction given there was too much of theory and too little of practice. Curiously enough, while the tendency in the medical schools was to give constantly increasing attention to clinical teaching, and to restrict the amount of didactic teaching, the reverse of this seemed to be true of the training schools for nurses.

Having referred to the enormous increase of training schools and students, he said, that among the latter we now heard much less of sentiment than formerly and much more of business. While in many schools the course was three years, in some it was three and a half years. In one it was already four years, and in one in Boston it was proposed to make it even five years. Yet all this training was for something which was in no sense a profession, but simply a calling or vocation. Moreover, it was out of all proportion for a practice the average duration of which was stated to be but ten years. This he believed to be approximately correct. Dr. Thompson quoted a number of questions given at nurses' examinations, and remarked that they would mostly be appropriate for first or even second year medical students, while some of them would puzzle the graduated M.D. Many of them also included the treatment of disease. He had known of instances where the over-trained nurses were so officious in the wards that the house-staff had taken refuge in the clinical laboratory; leaving the patients to get along as best they might.

As far as ordinary medical nursing was concerned, a two years' course was quite sufficient for the training. For those who desired to fit themselves for special work there might be an additional year, and when they had completed this course they might receive a special certificate. It had been argued that the hospitals were better served when the nurses had a long course of training, but he did not think so. The employment of third-year pupils to take charge of wards was desired by the hospitals, because it enabled them to get rid of paying for head nurses.

The enactment of legislation in behalf of the trained nurse was accompanied by many difficulties, and the nurses themselves were not agreed as to what they

wanted. The very best nurses sometimes passed the poorest written and oral examinations. The registration and licensing of the nurse might act as a boomerang, as the laws in the different states would vary, as they do in regard to divorce. There was no more necessity for legislative enactment for the nurse than there was for those engaged in any of the liberal arts. The fact was that to-day we are in the hands of the Nurses' Trust, with a trade union policy and union prices. What the community greatly needed was a body of trained workers for simple cases. For these a six months' hospital course would be sufficient, and the public could obtain their services at a much lower rate than that now paid the regularly trained nurse.

In conclusion, he expressed the opinion, that physicians connected with institutions having training schools should insist on representation in the boards of management of such schools, not merely in an advisory, but a governmental capacity and that the curriculum adopted should be approved by them. The primary responsibility for the present system of nurses' training, he said, belongs to the members of the medical profession, who, if they would devote as much time to the training school curriculum and the relationship of the nurses' work to that of the house-staff as they do to their medical duties, would soon produce ideal results in the system; which, despite its shortcomings, has been of great benefit even since it was established.

DR. A. ALEXANDER SMITH spoke on

THE TRAINED NURSE AND MEDICINE.

He said that at the outset he wished to pay a tribute to the many excellent qualities of the "sick-nurse," who preceded the trained nurse and who was still the dependence of the medical profession when he was an interne in Bellevue Hospital in 1872. It was generally supposed that the training school established at Bellevue in 1873 was the first of its kind, but he had ascertained that there were already two schools in existence at the time this was started. To-day we could not get along without the trained nurse. The personality of the nurse was a very potent factor, for good or ill, in the welfare of the patient. No matter how long or how thorough her training, it all went for naught, unless she was a true woman, with kindly feeling and possessed of tact. The management of the patient's environment (in which the patient's friends were included) was a difficult as well as important matter, and the treatment accorded the nurse often determined the results of a case. The attempt to discipline a patient might prove disastrous, and what the nurse needed above all things was tact.

DR. ROBERT ADAMS spoke on

THE TRAINED NURSE AND SURGERY.

He said that the trained nurse had come to stay, and she had almost entirely displaced the male nurse. The efficiency of the nurse depended largely on the sagacity of the superintendent of the training school. Out of a thousand applicants the principal would select perhaps a hundred for admission, and out of this hundred only twenty-five might complete the course. Those chosen were the best women for this kind of work. The proper qualities of mind and character made up four fifths of the composition of the successful nurse, and good training the remaining fifth. If selecting a nurse to take charge of a surgical case he would demand only that she should be a graduate of a reputable school at a large hospital. In surgical practice it was a fact that at the present time the tendency was for the duties of the nurse to become simpler, while those of the surgeon were becoming more complicated. Secondary hemorrhage was very rare to-day, and if it did occur, it required very little knowledge to apply the

requisite pressure until the attending surgeon could be summoned. Some knowledge of passing the stomach tube and of making saline injections was necessary for the surgical nurse, but these were procedures which were employed every day in a large hospital and with which every pupil in the training schools was perfectly familiar. In a laparotomy case the only essential was that everything which went into the wound should be rendered aseptic. In whatever emergency might arise in surgical practice an intelligent woman could be counted upon to do the right thing. Here the principal thing that the nurse needed was a well-balanced and a cool head, and a good medical nurse was as capable as a surgical one. Dr. Adams thought that a two years' course in the training school was quite sufficient for equipping the pupil with all the knowledge which was essential for her calling. Her cases ought to be her books.

DISCUSSION.

DR. A. G. GERSTER said that at the Mount Sinai Hospital, with which he was connected, the curriculum of the training school was very elaborate. Through the efforts of the medical staff, however, the requirements demanded had recently been somewhat simplified. He was entirely in accord with the opinions expressed by Dr. Thompson. It was impossible that a course of training should be thorough where there was such an overwhelming mass of material included in the instruction given. The insistence on this "pseudo-scientific" curriculum was all the more reprehensible because it was totally unnecessary for the ends in view. The pupil nurse should be taught only a few things, but in these she should be thoroughly grounded. The smattering which she received of a great variety of subjects she would very readily forget because it was impossible for her to digest such a mass of knowledge. The stand taken by Dr. Thompson was not a matter of partisanship. He did not desire a battle between the medical profession and the nurses. The only question which ought to be considered, was, What is the best thing for the patient? What was best for the patient, he thought, could be most satisfactorily learned at the bedside.

Recent Literature.

On Becoming Blind. Advice for the use of Persons Losing Their Sight. By DR. EMIL JAVAT, Honorary Director of the Ophthalmic Laboratory of the Ecole des Hautes Etudes, etc. Translated by Carroll L. Tolson, A.M., M.D. New York: The Macmillan Co. 1905.

The first paragraph of the introduction states the *raison d'être* of this book as conceived by the author. He says: "Having lost my sight suddenly at a relatively late age, I had just entered my sixty-second year, one of my first cares was to inquire what might be done to live with the least possible evil with my infirmity. Great was my surprise to find nowhere any collection of advice on this matter. In short the attention of the friends of the blind, or typhlophiles has been concentrated either on the bringing up and instruction of the blind young or upon charity organizations for the blind poor. . . . The sufferer and complete loss of sight is a relatively infrequent misfortune."

The author details his experience and researches for the benefit of those especially whom he

terms "parvenus" in blindness, and to help the family of the blind. He believes also that his confrères who are oculists may find in his pages advice which they may use to the profit of their unfortunate patients. The book is also intended to serve men of the liberal professions who have just made the "leap in the dark."

Even the general reader will find much charm in this little book. The American translator, Dr. Edson, has done his work with delicacy and discretion.

The Diseases of Infancy and Childhood. For the use of Students and Practitioners of Medicine. By L. EMMETT HOLT, M.D., Sc.D., I.L.D., Professor of Diseases of Children in the College of Physicians and Surgeons (Columbia University), New York; Attending Physician to the Babies' and Foundling Hospitals, New York, Consulting Physician to the New York Infant Asylum, Lying-In Hospital, Orthopedic, and Hospital for the Ruptured and Crippled. With two hundred and forty-one illustrations including eight colored plates. Third edition, revised and enlarged. New York and London: D. Appleton & Co. 1906.

The third edition of this well-known treatise, which occupies practically the same position among American works on the Diseases of Children that Osler's Practice of Medicine does among those on Medicine, continues to merit all the praise bestowed on the earlier editions. The book has been pretty generally revised and brought as nearly up to date as is possible in a work of this size. The illustrations have been increased in number and improved in quality. The principal alterations have been made in the articles upon the Examination of the Sick Child, Hypertrophic Stenosis of the Pylorus, Diarrheal Diseases and Dysentery, Vaginitis, Cerebrospinal Meningitis, Mental Defects, Chondro-Dystrophy, Status Lymphaticus and Diphtheria, some of which are new. While it may seem captious to criticise in any way such an admirable work, certain things do seem worthy of notice. We are surprised, for example, to see that the author still continues the irrational method of calculating the amount of the alkali added to the infant's food in relation to the total quantity of the mixture instead of to the amount of cream and milk, and that he still seems to consider the action of twenty grains of bicarbonate of soda equivalent in its effect on digestion to that of one ounce of lime water. He does not mention the new discoveries of van Slyke and Hart on the digestion of casein and does not take up the action of alkalies on digestion in this connection. Nothing is said about the operative treatment of brachial birth palsy, and acute polio-encephalitis is only referred to incidentally. We regret to see that the terms "marasmus" and "pleuro-pneumonia" are still retained, and fail to see why chondro-dystrophy and cretinism are placed among the diseases of the nervous system. These, of course, are minor matters and do not affect materially the value of the book.

THE BOSTON Medical and Surgical Journal.

THE QUESTION OF A HOSPITAL FOR CHRONIC DISEASE.

THE situation regarding the care of chronic disease in this community is such that certain measures must be taken in the near future to improve the conditions if Boston is to retain its place as a progressive medical center. We have recently had occasion to comment upon the lack of facilities for the treatment of persons in the late stages of tuberculosis. Since that editorial was written it is gratifying to observe that the trustees of the proposed tuberculosis hospital have decided that only those cases which are not incipient will be received. This is a step in progress, but in our zeal for the alleviation of the tuberculosis situation it should not be forgotten that chronic disease of other sorts is prevalent and that persons suffering from distressing maladies which are incurable have no permanent abode in this city except in the almshouse hospital at Long Island and in a few smaller special institutions. This means that the great proportion of the chronic sick and incapacitated must be declared either paupers or be forced back upon their families for such treatment as can be given in their homes. This situation demands reform, and one way at least seems open at the present time.

For some years past the suggestion has been made that the almshouse and hospital of the Long Island Institution should be separated, that the hospital should become purely an institution for the care of the sick, and that its inmates should not be subject to the declaration of pauperism as is now the case. It is true that, as the institution is now constituted, a separation of the

actually sick from those who are merely decrepit and are therefore placed in the almshouse class is difficult to make. Many of the aged and infirm through arteriosclerotic changes and other conditions due to advancing years are in one sense properly classified as sick. On the other hand, such persons require little medical care and are no doubt more economically and more satisfactorily cared for in an institution which is not strictly speaking a hospital. However difficult the matter may be, it is evident that the distinction must sooner or later be drawn and that we must have in Boston a hospital for the chronic sick in precisely the same sense as we have long had hospitals for acute disease. Alderman Curley has recently introduced a resolution in the Board of Aldermen relative to the separation of the Long Island Hospital from the almshouse department of the city. The feeling underlying this resolution coming from a lay source is no doubt the same as that which thinking physicians are everywhere recognizing.

Those who have followed the somewhat remarkable development of the Long Island institution in the past ten years realize that the most significant change which has taken place is the prominence which has been given to the hospital. It has been perfectly apparent to the great majority of those concerned in this development that hospital care in the best sense of the word was peculiarly demanded for a large number of the inmates of the institution. Recognizing this necessity, the hospital idea has steadily grown until now this department is presided over by a staff of one resident physician and six house officers, together with a visiting staff which makes visits with increasing frequency. It is quite impossible that any backward step should be taken in this beneficent charity, and it is altogether desirable that still further progress should be made. The time, therefore, seems ripe, as Mr. Curley and many others have suggested, for a legal separation between the hospital and almshouse departments, which are now conducted in conjunction in such a way that each is a certain detriment to the other. The separation practically exists at the present time, and so far as the administration is concerned the steps to make the separation complete could not be attended with great difficulty. The details, however, we have no desire to discuss at the present time. The decision to make the separation a fact is now the pressing matter.

It is hardly necessary to deduce arguments in favor of the establishment of an independent

hospital for chronic disease. It should be evident to the most casual observer that disease, whether acute or chronic, demands the best service which modern methods can give. It is hardly too much to say that the chronic sufferer often demands more care than the person ill with a self-limited disease. In the second place, it is manifestly unjust that pauperism should be a necessary accompaniment of the misfortune of illness. It is one of the great injustices of the present system that a poor man, hopelessly incapacitated, should be legally classified as a pauper. The hospital for chronic disease should stand on precisely the same footing in this respect as the hospital for acute disease. We confidently expect that the near future will see this consummation, for which the trustees of the tuberculosis hospital have in a measure paved the way. It is clear that the good work cannot stop there, and that, much as we need a hospital for the care of advanced cases of tuberculosis, none the less essential is a hospital for the care of all cases of chronic disease, absolutely irrespective of its character.

THE TRAINING OF NURSES.

It is evident that a certain reaction is taking place regarding the whole matter of the training of nurses. The development of the trained nurse has been an exceedingly rapid process and it is therefore not unnatural that mistakes have been made which are now somewhat tardily being recognized. The attempt to exalt the calling of the nurse to a profession, and the natural consequences which flow therefrom, is fraught with danger which cannot be longer overlooked.

In this connection it is interesting to call attention to a recent meeting of the New York Academy of Medicine, an abstract of which is published in this issue, at which the subject under discussion was the Training of Nurses. The entire trend of opinion of those who took part in the discussion, with the exception of Miss Mary A. Samuels, superintendent of the Roosevelt Hospital Training School, was to the effect that too much rather than too little is taught in the training schools as at present constituted. Such men as Drs. W. Gilman Thompson, A. Alexander Smith, Robert Abbe and V. G. Gerster took part in the evening's discussion. Dr. Thompson's paper was entitled, "The Overtrained Nurse," and expressed in very forcible language what many of the wisest men in the profession are rapidly coming to feel. He thought that the nurse of

to-day was absurdly overtrained, that her pseudo-scientific training was a mistake, that the time of training was too long, that legislation in behalf of the trained nurse was not desirable, that the charges for nursing are too high, and that physicians themselves should take more interest in the regulation of the curriculum. The others who spoke agreed essentially with Dr. Thompson's position. Dr. Abbe, for example, thought that two years in a training school was quite sufficient for equipping a nurse with the knowledge essential for her calling. He also was of the opinion that the proper qualities of mind and character make up four fifths of the composition of the successful nurse, and good training the remaining fifth. Dr. Gerster was equally strong in his insistence upon the mistake made in attempting to train the nurse in various so-called scientific subjects to the neglect of the essentials of nursing. At a recent meeting of the New England Association for the Education of Nurses, held in Boston, Dr. John C. Munro read a paper in which, with no mincing of words, he pointed out the errors and fallacies of our present system. That he is right in his main contention no one who has had wide dealing with nurses in private practice can for a moment question. It is to be hoped that nurses everywhere may have an opportunity to read this paper, published in *American Medicine* for March 31, in order that they may, more than they often do, see themselves as the physician sees them. "The nurse," Dr. Munro says, "should be trained to cultivate tact, humanity and the gentle art of caring for the sick. She should be less elaborately trained in the science of medicine. A few selected women should be trained for special and advanced work, but the selection should be exercised with great care and judgment."

This attitude toward the question of nursing will no doubt be accepted by a large number of physicians who have never given expression to their thoughts. It is right and proper that there should be much plain speaking now if the situation is not to become still more strained in the future. Certain matters are established. The patient's welfare is the first consideration. This must be cared for by the physician with the complete co-operation of the nurse. Anything which disturbs the relation either between patient and nurse or between nurse and physician is detrimental to the best good of the patient. Physicians are finding fault because this relationship is being disturbed, and this, in the minds of many, is due in last analysis to what may be bluntly called,

overtraining. If a nurse is obliged to devote three or four years to her training, with the prospect thereafter of approximately ten years of active life, the tendency for charges to become greater is inevitable and natural. The patient suffers inasmuch as he is paying for a sort of knowledge which is not required, and in fact which is often detrimental to the simple and conscientious performance of the disagreeable duties of the nurse. The conclusion, therefore, to which those to whom we have referred have come, and which we share, is that the over-training of nurses must stop, that the nurse's work should be looked upon as a vocation and not as a profession, and above all things that knowledge of whatsoever sort can never take the place of tact and proper feeling in the sick room. To take retrograde steps in any movement is difficult, but we are convinced that the time has come for those in charge of training schools to look the ground over carefully in view of present lay and professional opinion and to reorganize in many instances the over elaborated curriculum on a more practical basis.

DIET AS A THERAPEUTIC AGENT.

If one feature characterizes modern therapeutics more than another, it is rationality combined with, or perhaps a product of, common sense. We believe our faith is justified that therapeutic vagaries will be much less conspicuous in the future than they have been in the past. We shall either treat our patients by means for which there is adequate scientific and experimental evidence, or by methods which consider the individual as a whole whose general attitude of mind and physical condition must be regulated on the principles of ordinary common sense tempered with knowledge.

The general movement of which we speak finds expression in various ways. We are studying pharmacology as never before; body metabolism and the chemistry of physiological processes is receiving attention which cannot fail to lead to more accurate therapeutics. We are growing skeptical of drugs, and have given up the idea, still somewhat prevalent among the laity, that we habitually cure disease by their means. We are paying more attention to the mental attitude of the individual; psycho-therapeutics is gradually gaining a place which has long been denied it; attention to diet, to exercise, to general hygiene, and the use of various external means of treatment, are all being substituted for the

methods which demand that something, sanctified by precedent, must be given internally. In other words, the situation is rapidly approaching rationality. We still use drugs and no doubt will continue to use them, but our implicit faith in their efficiency is wavering in the same sense that our patients' faith is wavering. Out of all this experience is sure to come an improved therapeutics, and one which will benefit our patients because they will no longer look upon it as a mystery but as something of which they themselves can see the reasonableness.

We observe in the preliminary program of the Association of American Physicians that a group of papers is to be presented on Therapeutics Based upon Pathological Physiology. This naturally means that certain therapeutic procedures will be discussed on the basis of what we know rather than of what has been merely empirically indicated. In this connection also we note with interest that the last number of the *Practitioner* devotes its entire space, upwards of one hundred and fifty pages, to diet. In this one issue is collected a series of papers from the pens of a large number of special students on diet in connection with various recognized forms of disease, and, what is more worthy of observation, not only with those which are supposed primarily to affect the gastro-intestinal tract. For example, diet in epilepsy is discussed by W. A. Turner; diet in acute illness, by Dr. G. Newton Pitt; the effects of diet on circulatory disease by Sir Dyce Duckworth, and so on through a long list. As Dr. Robert Hutchinson remarks in his paper on the therapeutic uses of diet, the use of dietetic means of treatment has long been recognized, but in spite of this fact there is no method which we use with less confidence and precision. We cannot too warmly recommend this admirable series of articles to practitioners who fail to recognize in the proper administration of food a positive therapeutic procedure. It is of interest that Dr. Robert Hutchinson has also within the year published a second edition of his volume on "Food and the Principles of Dietetics," and that Dr. Francis Hare has likewise published in two volumes his researches and observations on the "Food Factor in Disease."

This simply points the way toward which our research is tending. We are investigating more deeply than ever before the underlying chemical problems, and perhaps even more important, we are systematizing our knowledge of agents and means of treatment long vaguely recognized but wholly unsystematized in the medical mind.

Diet, hydrotherapy, massage, medical gymnastics, electricity, psychotherapy, even fresh air, must all be studied seriously before they can be put to scientific use in treatment. This tendency is now apparent, and we have no doubt will lead to a rational therapeutics in the near future which will go far toward sapping the strength of quackery and establishing a more normal relationship between physician and patient.

THE ARMY MEDICAL BILL.

We have repeatedly commented in these columns on the need of reorganization and improvement of the medical department of the army. The bill, which is known as the Army Medical Bill and which is designed to increase the efficiency of the medical department of the army, has reached a final and critical stage in its progress toward legislative enactment. It has been passed by the Senate and reported favorably by the military committee of the house. Before it reaches the President, who has repeatedly expressed himself as in favor of its provisions, it must be brought before the House of Representatives. There is, however, no reason to think that it will be unfavorably acted upon by this body. The bill increases the officers of the medical corps by a total of 113. One object of this increase is to replace the greater number of contract surgeons, now numbering 170, by commissioned officers, thereby probably decreasing to a certain extent the total number of surgeons, but substituting for the contract surgeons men who hold regular commissions. A reserve medical corps is also proposed, the members of which will receive pay only when in actual service. In general, the design is to do away with the contract surgeon who occupies a somewhat anomalous position and raise the standing of the medical corps. Secretaries Root and Taft, the Surgeon General of the army, and many others high in authority approve the passage of the bill. From the standpoint of the medical profession at large it is clear that certain changes should be made and that the medical department of the army should forthwith receive the recognition which its importance, both in times of peace and war, deserves.

MEDICAL NOTES

NATIONAL QUARANTINE. It is reported that the House of Representatives has voted favorably upon the law which transfers provisions for the quarantine of contagious disease from individual states to the National Government. The expense

ence last year at New Orleans in relation to yellow fever is an excellent argument in favor of a more comprehensive plan of quarantine than has hitherto prevailed.

CASES OF CEREBROSPINAL MENINGITIS IN CHICAGO.—Two deaths from cerebrospinal fever (epidemic cerebrospinal meningitis) were reported in Chicago during the week ending April 7, the first since September, 1905. Investigation proved the character of the disease beyond question and revealed the existence of five other cases under treatment.

HYGIENISCHES CENTRALBLATT.—A new journal has appeared under the heading given above, published in Leipzig and designed to cover in its reviews the entire field of hygiene. The journal is represented in New York, London and Paris as well as in Leipzig, and the march of progress is further exemplified by the fact that several pages are inserted in English descriptive of the scope and general character of the journal. It is edited by Dr. Paul Sommerfeld and a number of collaborators. The journal takes up a field not hitherto covered by a periodical of this character. It will be devoted to abstracts which in this as in other departments of medicine have become essential in order to keep abreast of the literature.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, April 18, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 38, scarlatina 37, typhoid fever 4, measles 145, tuberculosis 60, smallpox 0.

The death-rate of the reported deaths for the week ending April 18, 1906, was 23.40.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending Saturday, April 14, 1906, was 234, against 235 the corresponding week of last year, showing a decrease of 1 death and making the death-rate for the week 20.50. Of this number 130 were males and 104 were females; 222 were white and 12 colored; 157 were born in the United States, 71 in foreign countries and 6 unknown; 52 were of American parentage, 156 of foreign parentage and 26 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 37 cases and 5 deaths; scarlatina, 47 cases, no deaths; typhoid fever, 4 cases and no deaths; measles, 159 cases and 2 deaths; tuberculosis, 50 cases and 29 deaths; smallpox, no cases and no

deaths. The deaths from pneumonia were 37, whooping cough 1, heart disease 24, bronchitis 6, and marasmus 2. There were 11 deaths from violent causes. The number of children who died under one year was 55; the number under five years, 75. The number of persons who died over sixty years of age was 43. The deaths in public institutions were 66.

There were 7 deaths reported from cerebrospinal meningitis during the week.

BEQUEST TO LOWELL, MASS., HOSPITAL.—It is announced that Mr. Frederick F. Ayer has given \$25,000 for the Children's Department and the Maternity Ward of the Lowell General Hospital. This is Mr. Ayer's second gift to the hospital of this amount of money.

BOSTON HOSPITAL FOR TUBERCULOSIS.—The Board of Trustees of the proposed consumptive hospital has voted that the hospital, when erected, shall be devoted to the treatment of all cases of pulmonary and laryngeal consumption other than incipient cases. This decision is based on the fact that the Rutland Sanatorium remains available for incipient cases and that the present demand of the city is for a means of taking care of the advanced cases. This opinion we expressed editorially in a recent issue.

NEW YORK.

APPROPRIATIONS FOR HEALTH DEPARTMENT.—At a meeting of the Board of Aldermen held April 3, \$20,000 was voted to the Health Department towards the establishment of the new tuberculosis sanitarium near Otisville, Orange County, and an appropriation of \$25,000 was passed for the improvement of the public baths in Rivington Street.

STATE SENATE PASSES AN OSTEOPATHY BILL.—The state senate at Albany has passed the osteopathy bill by a vote of 32 to 12. The principal provisions of the act, it is stated, are that practitioners of this sect, who are forbidden the prescribing of drugs or performance of surgical operations, are required to pass a Regent's examination and pursue a three years' course of study in a licensed school of osteopathy.

SUPPRESSION OF MEDICAL ADVERTISEMENTS.—Working in co-operation, the United States Postal authorities, the County Medical Society, and the local police have succeeded, it is believed, in practically putting out of business fifty-two so-called medical concerns which obtained their customers chiefly through advertisements in

three newspapers of the city. The newspapers in question were notified by the Post Office that these medical advertisements would have to be dropped, or the papers would not be allowed to go through the mails, and accordingly the advertisements were discontinued. Recently indictments were handed down against three of these advertisers, others left hurriedly for parts unknown, at the first rumor of trouble, and still others broke down, confessed and promised to give up their business. Without the newspaper advertisements these offenders, many of whom have been convicted in the past and nearly all of whom have been in trouble with the authorities, would be able to do but little, if any, business, and the County Medical Society considers that the withdrawal of the advertisements from the public prints is a death-blow to a fraudulent practice which has enjoyed prosperity in New York for many years.

UNDER THE TENEMENT HOUSE ACT.—Governor Higgins has signed the Prentice bill, which places tenement houses in which articles are altered, repaired or finished among those which, under certain conditions, the state Commissioner of Labor may cause to be classed as unclean, under the provisions of the Tenement House Act. The bill also provides that such goods when exposed to contagion shall be tagged accordingly.

HOSPITAL SATURDAY AND SUNDAY.—The distributing committee of the Hospital Saturday and Sunday Association met at the Mayor's office in the City Hall on April 12, and apportioned among the institutions represented in the Association the underdesignated fund of the 1905 collections. The total amount of the collections this season was \$94,000. Of this, \$9,000 was for specially designated hospitals. After deducting \$4,000 required to defray expenses, there remained \$81,000 for the general distribution. The apportionment is made on the basis of the free work done by the different hospitals during the year, qualified by the rule that no one institution shall receive more than 10% of the total fund, nor any less than the sum of \$250. The eleven hospitals leading in the amounts allotted to them were as follows: Montefiore Home and Hospital for Chronic Invalids \$8,100; Mount Sinai Hospital, \$8,100; St. Luke's Hospital, \$4,945; German Hospital and Dispensary, \$4,655; Roosevelt Hospital, \$3,919; Hospital for Ruptured and Crippled, \$3,783; Lebanon Hospital, \$3,494; Nursery and Child's Hospital, \$3,373; St. Mary's Free Hospital for Sick Children, \$3,268; Orthopedic Hospital and Dispensary

\$2,893; Home for Incurables, \$2,674. The New York Hospital, on account of its large endowment, has never asked for representation in the Association, while the Presbyterian Hospital receives the proceeds of a collection made specially for it in the Presbyterian churches; the latter not contributing to the general hospital fund.

ANNUAL MEETING OF THE AMERICAN MOSQUITO EXTERMINATION SOCIETY.—The third annual meeting of the American Mosquito Extermination Society was held at the New York Aquarium on April 11. In the course of his address, the president, Wm. J. Matheson, expressed the opinion that as soon as the public could be convinced that the extermination of the mosquito was practicable, relief from this source of danger would be afforded by National and State enactment. The secretary, H. C. Weeks, in his report stated that a bill directed against the mosquito was expected to pass the present session of the New York Legislature, and a New Jersey member announced that the Governor of that state was now considering a bill which appropriates \$75,000 for ditching certain salt marshes which have long enjoyed an unenviable reputation as breeding places for the pest. Dr. C. B. Davenport, director of the Biological Institute at Cold Spring Harbor, Long Island, read a paper in which he said that in many instances suitable measures were not undertaken on account of the lack of interest not only on the part of the public, but of the local boards of health. A statement designed for public distribution, entitled "The Mosquito Brief," which gives information regarding the various species of mosquitoes, their habits, modes of breeding and other characteristics, as well as the dangers attending their bites, was adopted by the Association.

MORTALITY RETURNS. The weekly reports of the Health Department show that the mortality in the city during the month of March represented an annual death-rate of 20.15, as against 18.81 in February and 20.08 in March, 1905. Among the diseases which showed an augmented fatality were the following: The weekly average of deaths from measles increased from 45½ in February to 51½ in March; the weekly average from whooping cough, from 3 to 4½; from diphtheria and croup, from 50½ to 5½; from cerebrospinal meningitis, from 18½ to 24; from pulmonary tuberculosis, from 171 to 194; from acute pneumonia, from 24 to 41; from pneumonia, 163½ to 170½; from broncho pneumonia,

from 120 to 140½; from diarrheal diseases, from 34½ to 42½; from diarrheals under two years, from 27½ to 35½; and from Bright's disease and nephritis, from 108 to 125. Among the few diseases in which there was a diminished mortality were the following: The weekly average of deaths from typhoid fever declined from 6¼ to 5½; from cancer, from 55¼ to 53¼; and from organic heart diseases, from 112 to 109. The mortality from epidemic cerebrospinal meningitis probably reached its maximum for the present season in the week ending March 17, when the number of deaths reported from it was 29. Since then there has been a decrease, the deaths from it in the week ending March 24 numbering 23, and in that ending March 31, 19. During the epidemic of this disease last year the number of deaths reported from it in the corresponding weeks was respectively 72, 85 and 131. Measles continues to be widely prevalent, and while the number of cases reported was progressively less each week during March, the mortality from it increased at the end of the month. The figures are as follows:

Week ending March 10, 2,384 cases reported, 55 deaths; March 17, 2,003 cases, 43 deaths; March 24, 1,952 cases, 47 deaths; March 31, 1,941 cases, 62 deaths.

Obituary.

A. C. M. MOIR, M.D. RESOLUTIONS FROM THE STAFF OF THE NEWTON HOSPITAL.

AFTER a long and trying illness, Dr. A. C. M. Moir, one of the younger members of the staff of the Newton Hospital, has died. The expectations of an ambitious life, the friendship and fellowship of years of activity with us in the hospital, the additional weight of fresh scholastic training,—all has been cut off, and we are called to record one less, present and prospective.

In view of this sad fact we are afforded easement of heart and mind in re-creating our remembrances of his interest and faithfulness in hospital work, his love of hospital associations and his frequent visits among us during the days of his health.

We sympathize in this loss with his family and relatives and wish this expression of our mind toward Dr. Moir to be spread upon the records of the meetings of the staff, that a copy be sent to Mrs. Moir, and also to the Newton papers and to the BOSTON MEDICAL AND SURGICAL JOURNAL.

FRANCIS E. PORTER, M.D.,

Chairman.

GEORGE L. WEST, M.D., Secretary.

Miscellany.

THE HARVARD MEDICAL SCHOOL AS VIEWED AT ST. PAUL.

THAT excellent medical monthly, the *St. Paul Medical Journal*, in its last issue (April) contains an interesting article by Dr. Thomas F. Harrington, of Lowell, on the Medical School of Harvard University, and an admirable editorial on the same subject. The editorial we reproduce entire below:

"The meeting of the American Medical Association in Boston, June 5 to 8, will undoubtedly attract a very large attendance from all over the country, and we hope that the Northwest will be well represented. The fact that Dr. W. J. Mayo of Rochester is president of the Association will prove a drawing card to many members from Minnesota. Boston is perhaps the most interesting city in the United States, not only from a general and historical point of view, but also from a medical standpoint. The medical traditions of Boston include some of the greatest epochs in the history of American medicine; we feel sure that every physician who visits Boston for the first time next June will desire to visit the Massachusetts General Hospital and stand upon the spot where ether was first administered in a surgical operation where, in the words of Oliver Wendell Holmes: 'The knife is searching for disease,—the pulleys are dragging back dislocated limbs,—nature herself is working out the primal curse which doomed the tenderest of her creatures to the sharpest of her trials; but the fierce extremity of suffering has been steeped in the waters of forgetfulness, and the deepest furrow in the knotted brow of agony has been smoothed forever.'

"Another institution which should be visited by every one is the Harvard Medical School. We are fortunate in having obtained from the pen of Dr. Harrington, one of the authors of the recently published 'History of the Harvard Medical School,' an article describing the beautiful new buildings of the Harvard Medical School. This article will be found on another page of this issue. When these buildings are finished the equipment for medical teaching at Harvard will be, beyond question, the first in the world, and we also believe that it would be difficult to find in any one medical school in any country a larger number of brilliant medical teachers or better clinical facilities for both under-graduate and post-graduate work than exist in Boston. Hitherto New York, Philadelphia and Chicago have attracted most of the students of medicine from this part of the country. In the future it is our belief that many of them will go to Boston. Furthermore, there is something in the atmosphere of Harvard that is lacking in the other great medical centers, and that something every man who practises medicine would do well to breathe for a while. We should hear less of medical graft and commercialism, of paying commissions for referred patients, and of contract medical prac-

tice if some of that same atmosphere could be found in the other great medical schools of this country.

"It is not enough that a medical education teaches the student how to recognize and how to treat disease; there should also be instilled into his mind, so that it becomes a part of his very being, the love of truth and of charity and of human kindness, and above all a high appreciation of the honor of his profession so that he will need no written code of ethics in order to live rightly his professional life. These things he imbibes rather by association than by the spoken word of his teachers, and these things Harvard has always stood for and always will."

MALARIA IN THE TROPICS.

COL. WM. C. GORGAS, chief sanitary officer, Isthmus of Panama, contributed a paper on this subject to a meeting of the American Society of Tropical Research held in Philadelphia, March 21. Colonel Gorgas, since 1898, has served four years in Cuba and two years at Panama, part of the time with troops, but most of the time he has been connected with municipal sanitation. At Panama, he is in charge of the yellow fever wards, and all non-immunes with fever from any cause coming into Ancon Hospital are sent to these wards. The larger proportion of such cases are malaria, about 200 malaria cases are treated per month. His experience has shown that malaria in the tropics is by far the most important disease to which tropical populations are subjected. While the percent of fatalities is not nearly so great as from some other tropical disease the amount of incapacity produced is much greater than that from all other diseases combined. At Santiago, while there were more deaths from yellow fever and typhoid fever than from malaria, it was the latter disease which prostrated the army. Even at Havana where malaria was by no means so general as would be expected, a greater number of persons died from malaria every year than from yellow fever. As a result of their mosquito work in Havana the deaths from malaria which for many years had averaged about 350 was in 1901, 351; in 1902, 77; in 1903 about 50, and has since remained at about 40. He considers Panama as favorable a place for the development of malaria as could be found. Three fourths of the disability among the laborers is due to malaria. To correct this, the greater effort was directed toward draining localities adjacent to towns and dwellings. In places that could not be drained oil was used very freely. An equally important measure is the giving of prophylactic doses of quinine. Thorough screening was also carried out. With 22,000 men on the payrolls during February, only 22 per thousand were incapacitated every day on account of sickness, three fourths of which was due to malaria. In his wards at Ancon he has personally treated 1,055 cases of malaria in the last six months. In each case blood exami-

nations were made and the character of the parasite recorded. The estivo-autumnal largely predominated, but the attacks in general were mild and yielded easily to treatment and among the 1,055 cases there were only 5 deaths. There have been 20 cases of hemoglobinuric fever in the past eight months with only 3 deaths. The treatment has been the persistent use of quinine, given for the first three or four days hypodermically, but as soon as vomiting ceases it is given by the mouth; twenty grains in the twenty-four hours hypodermically and thirty by the mouth has been the ordinary course. As sanitary conditions are improved, Colonel Gorgas believes it to be a rational hope that malaria will decrease in the same ratio.

THE HOSPITAL CONFERENCE OF THE CITY OF NEW YORK.

Dr. S. S. GOLDWATER informs us that in accordance with a resolution adopted at the meeting of hospital delegates, held on Feb. 21 in the United Charities Building, a second meeting was to be held at the Academy of Medicine, on Wednesday, April 18. Representatives of all of the hospitals of Greater New York were invited to be present.

The meeting of April 18 was called for the purpose of receiving the report of the Committee on Constitution and By-Laws appointed in February. Following the consideration and adoption of this report, a permanent organization will be completed by the election of officers and the adoption of a program for the ensuing year.

Semi-official assurance has been received that on the completion of the permanent organization of the Hospital Conference, various committees which have had under consideration problems of hospital finance and hospital economy will retire. The movement to establish and maintain a healthy state of affairs in hospital administration will therefore become concentrated and may be rendered permanently effectual by means of the Hospital Conference; and the fullest possible representation of the hospitals of New York is earnestly desired at next Wednesday's meeting.

Correspondence.

HOMOEOPATHY AND THE MASSACHUSETTS MEDICAL SOCIETY.

Boston, April 11, 1906.

MR. EDITOR: My opinion has been sought on the question of Homoeopathy, and I therefore state it as follows:

Guided by such light as the past offered, I am distinctly opposed to admitting the Homoeopathic to the Massachusetts Medical Society, while the nature of the cases and those connected with it.

This is admitting sects to part of the rights of an association which is entitled to be recognized as a medical society.

Very truly yours,

DAVID W. LEECH, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 31, 1906.

MEDICAL INTERNE.

GOVERNMENT HOSPITAL FOR THE INSANE. — The United States Civil Service Commission announces an examination on June 6, 7, 1906, to secure eligibles from which to make certification to fill at least two vacancies, at \$800 per annum each, with maintenance, in the position of medical interne, Government Hospital for the Insane, Washington, D. C., and vacancies as they may occur in any branch of the service requiring similar qualifications. Applicants should at once apply to the United States Civil Service Commission, Washington, D. C.

APPOINTMENT.

PATHOLOGIST AT THE CRAIG COLONY. — Dr. J. F. Munson, a graduate of the Literary and Medical Departments of the University of Michigan at Ann Arbor, and who has been acting as assistant to Dr. Victor C. Vaughan during the past two years, has been appointed Resident Pathologist at the Craig Colony for Epileptics, at Sonoma, N. Y.

RECENT DEATH.

DR. ROBERT C. DAVIS, of New York, died from pneumonia in the Roosevelt Hospital on April 13. He was a native of the South, and forty-seven years of age. He was graduated from the medical department of the University of the City of New York in 1880, and for twenty years had been an inspector in the Health Department service.

BOOKS AND PAMPHLETS RECEIVED.

On the Relations of Diseases of the Skin to Internal Disorders. With Observations on Diet, Hygiene and General Therapeutics. By L. Duncan Bulkley, A.M., M.D. London: Rehnman, Limited. New York: Rehnman Co. 1906.

The Influence of the Menstrual Function on Certain Diseases of the Skin. By L. Duncan Bulkley, A.M., M.D. London: Rehnman, Limited. New York: Rehnman Co. 1906.

Nasal Sinus Surgery, with Operations on Nose and Throat. By Beaman Douglass, M.D. Illustrated. Philadelphia: F. A. Davis Co. 1906.

Official Register of Harvard University. Reports of the President and the Treasurer of Harvard College. 1904-05. Cambridge.

The Diseases of Infancy and Childhood. For the Use of Students and Practitioners of Medicine. By L. Emmett Holt, M.D., Sc.D., LL.D. Third edition, revised and enlarged. Illustrated. New York and London: D. Appleton & Co. 1906.

Indigestion. An Elementary Study of its Causes and Treatment. By Fernandez Clarke, L.S.A. Lond., L.R.C.P. Lond., M.R.C.S. Eng. New York: William Wood & Co. 1906.

Department of the Interior. Bureau of Geographical Laboratories. I. Birds from Mindoro and Small Adjacent Islands. II. Notes on Three Rare Luzon Birds. By Richard C. McGregor. Manila. 1905.

The Influence of Facial Hemiatrophy on the Facial and Other Nerves. By Sir W. R. Gowers, M.D., F.R.S. Reprint.

The Practical Application and the Relative Value of the Tests used in Examining the Eye Muscles. By Alexander Duane, M.D. Reprint.

Some Unusual Fimbus Conditions. By Alexander Duane, M.D. Reprint.

Paralysis of Divergence. By Alexander Duane, M.D. Reprint.

Unilateral and Other Unusual Forms of Nystagmus. By Alexander Duane, M.D. Reprint.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology and Other Topics of Interest to Students and Practitioners. Edited by A. O. J. Kelly, A.M., M.D., Vol. IV. Fifteenth Series, 1906. Illustrated. Philadelphia and London: J. B. Lippincott Co. 1906.

University of California Publications. Physiology. Can the Cerebral Cortex be Stimulated Chemically? (Preliminary Communication.) By S. S. Maxwell.

An Analysis of 152 Cases of Hallux Valgus in 77 Patients, with a Report upon an Operation for its Relief. By H. Augustus Wilson, M.D. Reprint.

Outdoor Life Versus Confinement in the Treatment of Bone Tuberculosis. By H. Augustus Wilson, A.M., M.D. Reprint.

Mammale delle Malattie dell'Occhio. Ad uso Degli Studenti e dei Medici Pratici. Del Dr. Edmondo Trombetta. Illustrated. Torino. 1906.

The Significance of Albumin and Casts when found in the Urine of Apparently Healthy Applicants for Life Insurance. By Edwin Welles Dwight, M.D. Reprint.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING APRIL 14, 1906.

R. A. WARNER, assistant surgeon. Ordered to the Naval Academy, April 10.

W. F. SCHALLER, assistant surgeon. Appointed assistant surgeon, with rank of lieutenant, junior grade, from March 21, 1906.

J. B. KAUFMAN, A. H. ROBERT, M. H. AMES, C. K. WINN, W. S. KUDER, assistant surgeons. Appointed assistant surgeons, with rank of lieutenant junior grade, from March 24, 1906.

W. H. BUCHER, surgeon. Ordered to Washington, D. C., April 14, for duty in attendance on course of instruction at the Naval Medical School.

B. H. DORSEY, assistant surgeon. Detached from duty with Naval Recruiting Party No. 4, and ordered home to wait orders.

C. K. WINN, assistant surgeon. Ordered to duty with Naval Recruiting Party No. 4, at Des Moines, Iowa, April 30.

W. S. KUDER, assistant surgeon. Ordered to the Naval Hospital, Boston, Mass.

J. B. KAUFMAN and M. H. AMES, assistant surgeons. Ordered to the Naval Hospital, Norfolk, Va.

A. H. ROBERT, assistant surgeon. Ordered to the Naval Hospital, New York, N. Y.

A. PARENTIOL, surgeon. Detached from the "Oregon," and ordered home to wait orders.

J. P. DEBRULER, assistant surgeon. Detached from the "Oregon," and ordered home to wait orders.

SOCIETY NOTICE.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — The New England Hospital Medical Society will hold its regular meeting at Hotel Nottingham, 730 R. M., Thursday, April 26, 1906. Section of General Surgery, Dr. Elizabeth T. Gray, chairman. Dr. William P. Bolles will give a paper on Colonostomy and Similar Operations with general methods of surgical routine. Discussion and reports of cases by Dr. Emma B. Culbertson and Dr. Clara Alexander.

BLANCHE A. DENIG, M.D., Secretary.

THE SIGNIFICANCE OF JACKSONIAN EPILEPSY IN FOCAL DIAGNOSIS, WITH SOME DISCUSSION OF THE SITE AND NATURE OF THE LESIONS AND DISORDERS CAUSING THIS FORM OF SPASM.*

BY CHARLES K. MILLS, M.D., PHILADELPHIA.

Professor of Neurology in the University of Pennsylvania; Neurologist to the Philadelphia General Hospital, and Consultant to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases.

WITH the exception of monoplegia or hemiplegia, probably no single symptom or symptom complex is so often made use of by the diagnostician in his efforts to fix the site of a tumor for the purpose of operation as Jacksonian epilepsy. This term is used here in a broad sense as meaning monospasm or hemispasm due to cortical or cortico-subcortical discharge, a spasm which usually exhibits, if closely studied, an initial symptom and a serial order of phenomena. As originally and as commonly employed, the mere use of the term is supposed to predicate the existence of a focal lesion of the motor cortex, and it is sometimes defined as a spasm limited to a single group of muscles, or at least to a few muscular groups. Irritation or instability of portions of the cerebral motor area, in by far the largest number of cases of Jacksonian spasm as here defined, is a direct or indirect cause of this form of epilepsy, but it is by no means true that it is always or even nearly always due to gross lesion of the motor zone. The greatest care should, therefore, be taken not to attribute to local spasm erroneous diagnostic value. While in many cases it is a most important guide, in others it may be misleading.

A distinction needs sometimes to be made between Jacksonian epilepsy and hemi-epilepsy. Some of the cases of hemi-epilepsy belong in the Jacksonian category, but they are not all to be relegated to it. The convulsive attacks following hemiplegia are frequently unilateral, but they may begin on the paralyzed side and become general. Occasionally they are confined to a portion of one side of the body. Frequently, probably usually, they are of cortical origin. When as is so often the case, the hemiplegia, especially in childhood and youth, is due to softening from thrombosis, the convulsional areas surrounding or in the neighborhood of the parts destroyed are often the seat of deep congestion and punctiform hemorrhages. They render the cortical centers unstable and convulsive discharges ensue, which may be confined to the limbs and face of one side, may be unilateral or may become general. The monospasm or unilateral convulsions which occur in cases of this description sometimes simulate very closely those which are due to brain tumor in the motor cortex or subcortex. They have the same mechanism as the Jacksonian spasms of tumor or other lesion, namely, irritation or instability of cortical motor cells. Hemi-epilepsy may,

however, in some instances be due to an irritative lesion well removed from the cortex or to some toxic state.

It is scarcely necessary to present, as could easily be done, a large number of cases in which Jacksonian spasm has been an important or a deciding symptom in successfully fixing the site for operation in the case of a cerebral tumor. Many such cases have been recorded, and not a few by the writer. I shall refer only, and that briefly, to the histories of a few such cases.

Dr. C. H. Frazier, May 2, 1903, operated successfully for tumor of the motor region in a case under the care of Dr. Wm. G. Spiller,¹ which was seen by me in consultation. This case had the typical features of a neoplasm of the motor region, including Jacksonian spasm. The patient was a motor aphasic and agraphic with paresis of the right side of the face, right arm and right leg, exaggerated reflexes, and most of the general symptoms of brain tumor. Sensory symptoms were absent. He had had frequent attacks of spasm confined to the right side of the body, chiefly to the face and arm. According to the notes of the case, he always knew when these attacks of spasm were coming on by a twitching in the right eye for about five minutes before the spasms developed. The attack began by a peculiar sound in the throat, the eyeballs then rolled about, and the right arm and hand became implicated in the convulsive movements. Sometimes the right lower limb was affected, but never the left side. Consciousness was not lost, and the man did not fall into sleep after the convulsions. The attacks occurred usually when the man was awake, but several times when he was asleep. The convulsions lasted about three minutes, sometimes longer.

I have had under observation a number of cases of cyst of the motor region in some of which unilateral convulsions or monospasms have been present, these being evidently due to the unstable condition of the cortex surrounding the cyst. In several such cases Dr. C. H. Frazier has operated, exposing the cyst, and in some instances cutting away its roof with some benefit in the direction of lowering the frequency and severity of the attacks.

A tumor largely limited to the motor region was removed by Dr. W. W. Keen from a patient seen by me in consultation with Dr. M. Bland and Dr. Keen. This patient's symptoms began with weakness in the left upper extremity about eight months before the operation. She had an attack of vertigo with monospasm about six or even weeks before operation. She gradually developed almost complete paralysis of the left upper extremity. She had about twelve to twenty attacks of the hand below the elbow. The left lower extremity was also almost completely paralyzed. The knee jerk and the deep reflexes on the left side were all exaggerated. Ankle clonus was persistent. The same reflexes on the other

¹Spiller, Wm. A. Personal History of a Case of Tumor of the Brain, with Operation. *American Journal of Medical Sciences*, February, 1904.

* Read before the New York Academy of Medicine, April 19, 1906. From the Department of Neurology, University of Pennsylvania.

side were prompt, but not abnormal. The Babinski response was present on the left; on the right the plantar response was prompt, but not abnormal. Examination made for sensation showed no sensory loss or impairment.

The Jacksonian spasm from which this patient suffered was observed in one attack by a trained nurse who reported that the spasm began in the arm by a lifting movement of the entire limb, and quickly extended to the hand and leg, and sometimes to the left side of the face. The operation was osteoplastic and was so planned that the opening included an exposure of the brain two thirds in front and one third behind the central fissure. A large sarcomatous tumor was successfully removed, the patient making a good recovery. This case, which I give only in its broad outlines, although reported to one or two societies, has not been hitherto published.

In one case of tumor of the motor region seen by me in consultation with Dr. T. C. Potter and Dr. Wharton Sinkler, the growth after accurate localization, was removed by Dr. Wm. J. Taylor.

The patient had no objective sensory symptoms although she at times complained of a numb feeling in the left side of the face, left arm and left leg, which were paretic, the loss of power being marked in the lower extremity. She had several convulsive seizures, chiefly affecting the limbs of the partially paralyzed half of the body. All the deep reflexes on the left side were increased, persistent ankle clonus being present. The Babinski phenomenon was elicited on the left side. Headache was not conspicuous, but vomiting occurred, and double optic neuritis was present.

One of the most interesting of my motor region cases was that in which successful operation was performed by Dr. W. J. Hearn at the Philadelphia Hospital, Oct. 21, 1902. This was a case of localized pachymeningitis and gumma of the cortex. The patient was a man twenty-seven years old, who had been struck in the left parietal region eleven years previously and who also probably had syphilis. Vertigo, headache, vomiting and optic neuritis were all marked symptoms during the development and progress of the case. His chief symptoms just before the operation were, extreme pain in the left parietal region, frequent spasmodic seizures beginning in the right hand and arm, and later involving the right leg and right side of the face, with temporary loss of power in the right arm and leg after the seizure. Tenderness was extreme over the left parietal scar and over the surrounding region for a distance of three inches or more. Grip in the right hand was slightly impaired. Sometimes immediately after a spasm loss of power in the right arm and forearm was marked. Biceps jerk in both arms was slightly increased, but triceps jerk was normal in both. Tactile, pain, and thermal senses and stereognostic conception were normal. Voluntary and resisted movements in the right leg and foot were slightly impaired. Knee jerks were exaggerated on both sides, more markedly on the right. Ankle clonus was present

on both sides. The Babinski response could not be obtained on either side.

In connection with these cases on which operation was performed, and several of which have been published in detail, I am able through the courtesy of Dr. C. W. Burr and Dr. R. L. Lavenson, to present the notes of an unusual case of Jacksonian epilepsy due to small cortical lesion. It will be seen that this patient had for a long time a continuing clonic spasm of the upper extremity, preceded by a marked Jacksonian spasm with unconsciousness. For a time the clonic spasm was intermittent. A few similar cases have been reported under the title of *epilepsia continua*. This interesting case will later be published in full. The following are notes furnished by Dr. Burr:

"The patient was a woman, fifty-five years of age, who, four years after amputation of the breast for carcinoma, began to have convulsive twitings in the left arm. At first the spasm continued for a few minutes to a half hour and would recur from ten to twenty times a day. About a week later quite violent convulsive movements commenced and were persistent. They decreased but did not cease during sleep. There were flexion and extension of the fingers, and flexion and pronation of the forearm. If the muscles were tapped the spasm increased greatly. Voluntary movement in the arm also increased the spasm. There was only slight loss of power. The patient did not complain of the left leg at all. On examination, however, there was seen a coarse, persistent, clonic, spasmodic tremor. She was able to walk and there was no palsy of the leg. The left knee jerk was increased, the right normal. There was no ankle clonus, no Babinski sign. She had no headache or vomiting. Once, before the spasm became persistent, the patient had a localized fit with unconsciousness, following which there was loss of power and sensation in the arm for a few minutes. This was the only time in which the sensation or consciousness was affected.

"The brain showed the following: The whole organ was somewhat atrophied. In the ascending frontal convolution of the right side, at about the hand center, was a spheroidal tumor about one third of an inch in diameter, arising from the pia and deeply compressing the cortex so that the tumor was buried in a socket. On microscopic examination it proved to be a carcinoma. There was another small tumor about the same size in the pia on the inferior surface of the left lobe of the cerebellum. I do not think that the latter had anything to do with the symptoms."

These cases have been given, omitting many details, to show the importance of Jacksonian spasm in gross lesions of the cortex, especially in tumor and localized meningitis. In such cases a few features would seem to point with comparative certainty to gross lesion. In these and in a large number of similar cases, other evidences of gross lesion in addition to the spasm were present. They were chiefly monoplegia

or hemiparesis with exaggerated reflexes on the side of the body in which the localized spasm occurred. In most cases close investigation of the conditions of motility and of the reflexes shows this persisting impairment of power and abnormality of reflexes.

So important is this question of Jacksonian epilepsy in the focal diagnosis of brain tumors, that it will be advisable to consider at length the seat and nature of various lesions and conditions producing this symptom. The diagnostician must bear in mind (1) that tumors situated in other parts of the brain than the motor cortex may cause Jacksonian epilepsy; (2) that other lesions besides tumors situated in the motor cortex may cause this form of spasm; (3) that it may occur in toxic and other disease in which no demonstrable focal lesions are present; (4) that a spasm closely counterparting the Jacksonian type may be observed as a reflex or a hysterical disorder; and (5) that Jacksonian epilepsy may be simply an integral part or the entire expression of a case of idiopathic epilepsy.

Jacksonian epilepsy due to cortical discharge may occur as the result of tumors in other parts of the brain than the motor zone. The irritation owing to its intensity, spreads to the motor cortex. It is probable also that in some of these cases unusual instability of the motor cells plays some part. Cases of this kind, in which the lesion is in the cerebrum proper, and absolutely outside of the motor zone are comparatively rare, and the focal diagnosis can only be made in them by a full consideration of the non-motor symptomatology.

These cases in which Jacksonian epilepsy is a so-called distant symptom are not to be confounded with the comparatively common cases in which the spasm is an invasion symptom. A midfrontal or even a prefrontal tumor not infrequently invades caudally until the motor region is grazed or implicated. Jacksonian spasm of typical form showing itself after psychic, graphic and speech disorders have become prominent. In these cases, if the tumor be meningeocortical in position, spasm may precede paresis or paralysis, although sooner or later, in accordance with the amount of pressure or destruction of the motor region the patient will become monoplegic or hemiplegic. Tumors invading backwards from the prefrontal towards the motor region are, in my experience, much more likely to cause Jacksonian epilepsy than those which originate in the parietal lobe and advance forwards. I have recorded several cases of parietal tumor in which the motor cortex and subcortex were invaded and in which Jacksonian epilepsy was not present even at a late stage of the disease. Destruction of the sensor, cortex and subcortex, before involvement of the motor projection fibers or cortex, would seem to give a certain immunity from such spasm. A case beginning and continuing for some time with such symptoms as cutaneous hypesthesia, ataxia of the upper extremity and loss or impairment of the muscular sense and of stereognosis

conception, frequently has paresis and then profound paralysis among its later or terminal symptoms, but this is not often accompanied by Jacksonian spasm.

In some instances, Jacksonian epilepsy, apparently of the usual motor area type, is observed in tumors of the cerebellopontile angle or of the cerebellum. In two cases which have come under the writer's observation, cerebellopontile tumors caused Jacksonian epilepsy or what appeared to be this affection. The first of these cases has been reported in detail by Dr. T. H. Weisenburg.² The tumor sprang from the eighth nerve, and the chief focal symptoms were one-sided deafness, tinnitus, facial monospasm, hypesthesia of one side of the face, nystagmoid movements, slight paresis of the right abductens, and vasomotor and cardiac disturbances. Severe headache, nausea, vomiting and optic neuritis were also present. I examined this patient many times and on several occasions witnessed the facial monospasm which usually showed the same features. In this spasm the mouth was drawn as far as possible to the left and the eyelids were brought together. Only the left side of the face was involved in the seizure. On one occasion it was thought that the facial spasm was accompanied by some spasmodic movements of the left hand, but this was doubtful, and even the observer thought it may have been a voluntary movement.

In a second case seen by me recently,³ one in which a tumor was successfully removed by Dr. John H. Gibbon from the cerebellopontile recess, Jacksonian epilepsy, or at least facial or facio-brachial spasm, was one of the most striking features in the symptom complex. In this case the general symptoms of brain tumor, including headache, vertigo, nausea and vomiting, and optic neuritis with atrophy were present, the chief focal symptoms being deafness in one ear, and on the same side facial and abductens paresis with nystagmoid movements and the spasm above described. In the convulsive seizure the face was markedly drawn to the left, and the spasm in some instances passed to the arm and hand of the same side. Spasmodic attacks occurred at intervals for several months. In at least one or two of them observed before the operation tonic spasm involved both sides of the body.

Some discussion was had as to whether this case could be a prefrontal one involving the face and arm areas, or as it proved to be a cerebellopontile growth. The diagnosis was not as easy as might at first sight appear, as abductens paralysis occurs in tumors variously situated, and at first there was some question as to the central origin of the deafness. Decision was finally given, however, in favor of the cerebellopontile angle, and the operation was the result.

²Weisenburg, T. H. New York Medical Journal, as quoted in The Medical Record, Oct. 1, Feb. 15, 1907. The case is also described in the Medical Record, Dec. 15, 1907. Dr. M. J. Longueville, who saw the patient, reports that the case is a typical one.

³This case was later published in detail by Dr. John H. Gibbon and the writer.

successful which has as yet been performed for a tumor situated in this locality.

Collier⁴ calls attention to two cases in which a tumor of the cerebellum caused Jacksonian attacks. Local convulsion of slow spread and confined to the arm and face was repeatedly observed. Some bilateral spasticity was present in these cases. No lesions except the cerebellar tumors were present, but the ventricles were considerably distended. Hemi-epilepsy is noted by Collier as having occurred in one case of tumor of the pons and in one case of tumor of the cerebellum. General convulsions occurred in other cases. Collier is inclined to attribute the local spasms, in some cases at least, to hydrocephalus. He warns against confounding Jacksonian spasms of ordinary type with Hughlings Jackson's lower level fits. Grainger Stewart and Gordon Holmes⁵ direct attention to this point in the same number of *Brain* as that in which the article by Collier appears.

In considering Jacksonian epilepsy in its relations to the focal diagnosis of a cerebral tumor, the question of spasm due to dural irritation must not be overlooked, especially as certain forms of neoplasm commonly grow from the inner surface of the dura. Convulsion, local or general, due to intense dural irritation may occur as one of the symptoms of a brain tumor situated anywhere within the cranial cavity as has been demonstrated by clinicopathological observation corroborated by physiological experiment. Galvanization or faradization of the dura sometimes causes intense and generalized convulsive attacks. On two occasions I have seen such spasms produced by faradic applications to the dura while tests were being made during operation. The experimental investigations in this field are well known. One point of distinction between cortical Jacksonian spasm and the convulsive affection due to dural irritation is that in the latter the spasm, if observed at the start, will be found usually to begin in the face or limbs of the side of the irritation, spreading however rapidly to both sides of the body; so rapidly that the initial spasmodic phenomena may pass unobserved. The spasms almost always become generalized, and tonic spasticity is prominent. Such spasms are really reflex in character, the irritation being transmitted to the bulbar centers of the same side, and thence to those of the opposite side. In addition to the peculiarities of the spasm just noted, the diagnosis from cortical Jacksonian epilepsy will, of course, have to be made by the other focal symptoms present, as by those indicating parietal, occipital, temporal or midfrontal disease.

In some cases in which tumors grow from the agglutinated dura and pia in the motor region, a confusing picture of more or less generalized convulsions is presented. I have seen such cases in which it was possible, especially

with after-knowledge, to pick out that part of the spasmodic outbreak which was due to irritation of the motor cortex, and that which was dependent on dural irritation.

The nature of the lesion of the motor area causing localized spasm next requires attention. That other lesions situated in the motor cortex besides tumors may cause Jacksonian epilepsy is, of course, well understood, but the fact is not always given as full consideration as its importance demands when the question of operation is under discussion. Decision as to the nature of the irritative lesion is particularly difficult in those cases, not inconsiderable in number, in which such general symptoms of brain tumor as persistent headache and optic neuritis are absent. I have known both of these to be absent in tumors of considerable size, while vertigo and nausea and vomiting have been so little marked as not to direct decided attention to their probable cerebral origin.

The gross lesions of the motor area which cause monospasm or hemispasm, counterparting that produced by neoplasm, are, (1) depressed fractures; (2) localized meningitis; (3) meningeal or cortical hemorrhage; (4) focal hemorrhagic encephalitis or cortical polio-encephalitis; (5) focal necrosis occurring from embolism or thrombosis, including cases associated with generalized arteriosclerosis.

It would, of course, only be in the case of an old fracture of the inner table with slight or no outward evidences of the traumatism, that the mistake would be likely to be made of holding that Jacksonian spasm was due to a tumor. It occasionally happens that an injury to the head which leaves only a small scar in its wake results after a considerable time in the development of Jacksonian spasm. Usually in such cases both headache and vertigo, more or less severe and persisting, are present and a tumor may at first be inferred. Close investigation into the history of the case and as to evidences of injury will usually clear up the diagnosis. A mistake is not necessarily of serious import in such a case, as tumors sometimes develop at the site of old injuries, and in any case operation is indicated for the relief of the lesion causing the irritation. Localized meningitis with adhesions or even an abscess may, of course, occur at the site of such a traumatism.

With regard to localized meningitis not of traumatic origin, and not connected with neoplasm, this is usually of syphilitic origin. The case referred to in which Dr. Hearn operated successfully was one of localized pachymeningitis, or rather of conjoint gummatous inflammation, of the dura and pia arachnoid with exudate of sufficient extent and consistence to constitute a tumor mass. It is in this form of gummatous meningitis, more or less amenable to active specific treatment with mercury and the iodides, that too hasty decision in favor of operation is occasionally given. On the other hand, operation is undoubtedly indicated in some cases with a syphilitic history and with

⁴Collier, James: The False Localizing Signs of Intracranial Tumor. *Brain*, part iv, 1904.

⁵Stewart, T., Grainger and Holmes, Gordon: Symptomatology of Cerebellar Tumors, A Study of Forty Cases. *Brain*, vol. xxvii, 1904.

clear evidences of vascular and meningeal specific disease, but in which the case does not respond even to the most energetic medicinal treatment. In some of these cases occlusion of vessels takes place and deposits become organized so that they cannot be influenced by absorbent remedies, and the lesion, although at first simply an active localized meningitis, becomes an inert and irritating mass which should be dealt with by the surgeon.

Little needs to be said about Jacksonian spasm due to meningeal or cortical hemorrhage in connection with our study of the focal diagnosis of brain tumors. Supradural and subdural hemorrhages are so constantly due to traumatism, and their symptoms so frequently acute in onset, that the spasm which is sometimes present in the subdural variety, and may be largely confined to one half of the body, is not likely to be confounded with the spasm of a brain tumor. The diagnosis will be decided by the history of the case and by the well-known phenomena of dural hemorrhage, such as contralateral paralysis, dilated pupil on the side of the lesion, varying conditions of consciousness, and peculiar changes in pulse, temperature and respiration.

Cortical hemorrhage of slight depth and irregularly distributed sometimes occurs in cases of sinus and venous thrombosis. Horsley* has reported a case of this sort in which Jacksonian spasm clearly defining certain subareas of the motor zone was the most characteristic symptom. In such a case the history of acute or subacute onset, and the symptoms of sinus and venous thrombosis would guide. A hemorrhage or a cyst remaining after a hemorrhage from one of the branches of the medullary artery may give rise to Jacksonian epilepsy and other symptoms simulating somewhat those of a tumor. The diagnostician is usually not called upon to differentiate in such a case until weeks, months or years have elapsed after the original lesion, and as the history is sometimes imperfect or confusing, and as the patients who suffer from such attacks are usually victims of arteriosclerosis, they may have some headache and vertigo, which may be regarded as general symptoms of a neoplasm. Associated with the paresis or paralysis commonly present in such cases, may be recurring Jacksonian seizures. Close study of the clinical phenomena will, as a rule, be sufficient to throw the weight of opinion in such cases against tumor or localized meningitis.

A rare form of cortical disease which causes Jacksonian epilepsy and may be regarded as a tumor of the motor zone in an early stage of its development is focal hemorrhagic encephalitis. Such cases are now and then observed, both in children and in adults. Recently a case of this kind died in my wards in the Philadelphia General Hospital. The patient was an aged woman, who had a number of carefully observed Jacksonian spasms involving the arm and face. Consciousness was retained in the convulsive

attacks. The different parts of the arm and face were usually involved in about the same order. The hand, for instance, was drawn somewhat to the left, and the angle of the mouth was drawn outwards and upwards; the eye was closed and the brow wrinkled, but without any frowning movement or movements of the eyeballs or jaws. Dilatation of the left nostril and movement of the platysma took place. In the spasm the movement was confined to the deep extensors of the fingers and thumb and group of ulnar extensors, there being no movement of the upper arm and shoulder muscles. Examination showed that the patient was distinctly parietic in the left side of the face and arm, but not in the leg. She had no affection of sensibility and the reflexes were not altered to any marked extent. She was probably hemianopsia, although this was not clearly determined owing to the mental condition of the patient.

The necropsy showed many interesting pathological conditions in various parts of the body, including a circumscribed area of hemorrhagic encephalitis in the motor cortex, this evidently having been the cause of the Jacksonian spasm.⁷

One of the forms of focal cerebral disease which must be taken into full consideration when the question of operation, and especially for operation for brain tumor in the motor region, is presented is that of arteriosclerosis which has caused either local instability or local softening with symptoms which simulate those which are exhibited by neoplasms. The cases of this kind most difficult of decision are those in which Jacksonian epilepsy is present. In such a case the history will be that of gradual cerebral failure dependent usually upon generalized arteriosclerosis with its renal and cardiac accompaniments, and a record of seizures and of progressive loss of power of the limbs, or the limbs and face of one side. Instead of the motor manifestations, or in addition to them, the symptoms may be loss or impairment of different forms of sensibility or of stereognostic conception or some disturbance of speech and writing, according to the parts involved outside of the motor region. The patient may have an attack of transient dazing or of vertigo at one time, and at another, with this or independently of it, some form of localized tonic or clonic spasm; the face may twitch on one side or the fingers and hand may be clenched, or the arm may lift or the toe may be extended. Still later this ill-defined Jacksonian attack may merge into a facial, brachial, brachio-facial or hemi-spasm. In brief, the record is one of Jacksonian attacks slowly and irregularly developed to their full stature, usually with late coming on one-sided paresis or paralysis.

Such a case is to be differentiated from one of brain tumor by a close study of the manner in which the symptomatology has developed, by the exclusion of the general symptoms of brain tumor and by taking into consideration the evidences of renal, cardiac and general

⁷ This case will be reported in full in a paper which will be presented at the meeting of the American Neurological Association, to be held in Boston, June 4 and 5, 1906.

*Horsley, Victor. *Ibid.*, April, 1888.

arterial disease. Optic neuritis is practically always absent, and a very skillful ophthalmoscopic examination will often show evidences of sclerotic disease of the vessels and of some grade of optic nerve atrophy. Headache if present is not that which is often characteristic of brain tumor. Nausea and vomiting are generally absent. Examination of the urine may show albumin or casts or both. Dilatation with hypertrophy of the heart is present, and arterial tension is nearly always high. The possibility of the co-existence of arteriosclerosis and brain tumor must not be overlooked.

As in this connection I am chiefly concerned with the discussion of Jacksonian epilepsy, the interesting general subject of arteriosclerosis and focal cerebral lesions will not here be discussed in detail. I have had under observation several cases of necrotic lesion in which the diagnosis of brain tumor was made at some period in the history of the case, and in which operation was performed.

In one of my cases in which the localizing symptoms were astereognosis, diminution in pain and temperature senses, word deafness and word blindness, amnesic aphasia, paraphasia, lateral homonymous hemianopsia and late hemiparesis, operation was performed and revealed an area of necrotic tissue. A study of the history of this case shows how mistakes may be made with regard to what appear to be the general symptoms of brain tumor. At one period a most skillful ophthalmologist reported in effect that while optic neuritis was absent, the conditions present might indicate that it was imminent. Demonstrable neuritis was never present, neither before nor during the several years which intervened before death and after the operation. The patient complained at times of headache, but this was not severe. His first marked symptoms were initiated with an attack of dizziness and numbness, but this dizziness proved not to be the vertigo of brain tumor, but that which is associated with arteriosclerosis and spreading vascular lesions. Nausea and vomiting were not present.

In another case which I saw in consultation with Dr. J. H. W. Rhein, and in which an osteoplastic operation was performed by Dr. A. C. Wood, an area, probably of necrosis, was found situated largely in the motor zone. The patient was a woman fifty-seven years old, whose train of serious symptoms was ushered in by a convulsion. Later she developed recurring aphasic attacks preceded by incoherence, excitement and fright; still later paralysis of the arm and leg and paresis of the face appeared. The reflexes were increased on the paralyzed side, including slight ankle clonus and the Babinski response. Sensation was everywhere preserved. Ophthalmoscopic examination showed moderate pressure signs where the arteries crossed the veins; otherwise the eye grounds were entirely normal. Some albumin was found in the urine, and at one examination one granular cast.

While true Jacksonian epilepsy was not a

manifestation in either of these cases, they belong to the class of cases in which vascular lesions give a symptomatology somewhat closely simulating that of brain tumor. Cases with similar general symptoms and Jacksonian epilepsy are occasionally regarded as tumors of the motor region.

The diagnostician must not lose sight of another class of cases in which vascular lesions occur with brain tumor, but in other locations than that of the tumor.

The occurrence of hemorrhage or necrosis due to thrombosis or embolism, and especially the former, with brain tumor may, as Collier points out, give false localizing signs. He records one case in which operation revealed an area of necrosis which had evidently caused the localizing symptoms which guided in the choice of a site for operation, and in which subsequent necropsy showed the presence in addition of a large tumor. Hemorrhage is not very uncommon in the progress of a case of brain tumor, and may be in, around or at a distance from the site of the growth. The concurrence of vascular lesions with neoplasms is what might be expected when it is considered that tumors are so frequently observed after middle life, and in those who exhibit senile or presenile arteriosclerosis.

Hemi-epilepsy, or Jacksonian epilepsy of smaller range, is sometimes observed as a toxic or diathetic affection. One of the most striking cases of Jacksonian spasm ever seen by me was in a patient suffering from diabetes who had an attack of spasm while consulting me in my office. He remained conscious during the attack and even succeeded in talking a little about his feelings, although he did this with difficulty. The arm and face were the parts affected, the spasm beginning in the distal portion of the limb and extending to the other parts. It is now well known that monoplegias and hemiplegias sometimes occur in the course of nephritis, and in some of these cases necropsy has shown that all forms of gross lesion were absent. A few such cases have fallen under my own observation, necropsy showing no gross lesion. In other cases, however, where the toxic form of uremic monoplegia or hemiplegia was diagnosed, necropsy has shown a hemorrhagic or embolic lesion or local cerebral edema. Uremic convulsions occasionally are of Jacksonian type, and more frequently begin in the limbs or face of one side, the attack later becoming general. Jacksonian epilepsy is also sometimes observed in Korsakoff's disease or as an acute alcoholic manifestation, and may indeed be present in any form of toxic or infectious disease. These toxic spasms need only passing reference in the discussion of tumors of the cerebral motor zone. It is only in extremely rare cases that the diagnosis is not evident, — cases in which the vertigo and headache are present, or in which an optic neuritis of toxic origin is regarded as due to cerebral neoplasm. The diagnosis is, of course, to be made by a study of the history of the case, by examinations of the urine and

blood and by the absence of the typical general and focal symptoms of a brain tumor.

The dural epilepsies which have been considered on the previous pages are reflex epilepsies; in fact, they probably afford the best possible illustration of a severe convulsive attack due clearly to reflex causes. A tumor situated in the dura, or a galvanic or faradic current applied to this membrane, stimulates the sensory branches of the fifth nerve distributed towards its inner surface, and this excitation conveyed to the bulb produces the severe and characteristic spasmodic symptoms to which reference has been made. The broad assertion may be made that peripheral irritation almost anywhere in the body may cause, in rare cases, a convulsive attack, and that this may in still rarer instances assume the Jacksonian type. In such a case, as in the toxic convulsive disorders, the spasm indicates cortical discharge, and it is probable that the occurrence of the attacks is conditioned by unusual inherited or acquired instability of the motor cortex. It is only in a very unusual case that the diagnosis of brain tumor would be considered in such reflex spasms. Some years ago I reported a case of this kind in which the spasm, typically Jacksonian in its initiation and spread, was due to a fibroma of the palmar surface of the hand. The attacks became frequent and severe. They continued for some time after the operation for removal of the palmar growth, but eventually disappeared entirely. The patient was of a neurotic constitution and the intense peripheral irritation in this case undoubtedly affected the unstable cortex. The history of the case and the discovery of the source of peripheral irritation are sufficient to guide the diagnostician.

Some hystero-epileptic attacks bear a close resemblance to Jacksonian epilepsy. The presence of hysterical stigmata and the absence of the symptoms, general and focal, indicative of organic brain disease are sufficient to prevent error in diagnosis.

The question of the differential diagnosis of Jacksonian epilepsy due to tumor or other gross, and possibly operable, lesions of the motor zone from idiopathic epilepsy is one of great moment. Collier goes so far as to say that the commonest cause of Jacksonian spasm is idiopathic epilepsy. In several cases in recent years I have known operations to be done without revealing any tangible lesion, the diagnosis of the nature and site of the lesion having been chiefly made because of the characteristics exhibited by the Jacksonian spasm which was the chief feature of the symptomatology of the case. In some of these cases a small undetectable growth was present in the subcortex or just outside of the limits of the cerebral surface exposed, this being demonstrated by subsequent developments of a second operation or by necropsy. In other cases observation of the patient over a considerable time, as well as a more thorough consideration of all the features of the symptomatology of the case, have made it clear that the Jacksonian

spasm, although apparently typical, was in reality simply an integral part of the attack of true idiopathic epilepsy. In rare instances the idiopathic case shows almost restricted Jacksonian manifestations, at least the spasm continues to be largely a hemi-epilepsy. It is extremely rare in an idiopathic case for the spasm to remain limited to one limb, or to one side of the face, although this is not unknown and patients, as is well known, may have abortive attacks of epilepsy with a sensory or sensorimotor manifestation of a very transient character in a part to which the aura of a completed attack is commonly referred. In some cases in which Jacksonian spasm occurs as a part of the manifestation of an idiopathic epileptic attack, the Jacksonian spasm occurs, so to speak, inside the general convulsion; in other words, the patient during the seizure has clonic and tonic spasm which involves more or less irregularly all parts of the body, but in which the spasm shows itself most pronouncedly in the limbs or in the face and limb or limbs of one side of the body.

Every neurologist has had frequent occasion to confirm the truth of Dr. Hughlings Jackson's well-known opinion that almost every case of idiopathic epilepsy, if studied carefully enough, will be found to have had local spasm as the initiating phenomenon of the general attack. It is true that it is almost impossible in many cases to get a clear record of the initial local spasmodic phenomenon by questioning those who observe the attacks, and even the trained physician or nurse may fail to make this observation largely because of the speedy manner in which the spasm radiates to many parts of the musculature.

In a case recently observed, a convulsive attack began with a somewhat suffused appearance of the face, the head and eyes turning to the left conjointly with a spasmodic movement not very pronounced in the right upper extremity, chiefly affecting the forearm, hand and fingers, which were held in a partially flexed position. The spasm did not, in the attack observed, become entirely generalized, but the left lower extremity was spasmodically extended. It was reported to me that in other seizures the spasms were or became general. In a second case spasm began with a movement performed by the pterygoid and masseter muscles of one side, and facial twitching, the patient becoming unconscious, with generalized tonic spasticity. In a third case the spasm, which soon became general, was in its earliest stage confined to tonic spasticity of the extremities of one side. An opinion in favor of operation was refused in these cases, the evidence pointing to idiopathic epilepsy. With the exception of the localized spasms, other signs of a growth or of localized meningitis were absent. These cases could be easily multiplied, and probably more striking illustrations of initial Jacksonian spasm in cases of idiopathic epilepsy, furnished. I refer to them simply because of their recently having come under notice and because they were under observation for the purpose of a decision with

regard to surgical procedure. Among the operative cases of which I have notes are two in which osteoplastic operations were made by Dr. C. H. Frazier, and to which brief reference might be made. In the first of these cases it is probable that the true solution of the case is that it is one of the idiopathic epilepsy very closely simulating a case of brain tumor with Jacksonian signs. In the other it is probable that sooner or later a subcortical neoplasm, at present small, will appear on the surface or in some position close to the limits of the exposed portion of the cerebrum.

The first of these cases was a man thirty-four years old, many of whose spasmodic seizures were carefully studied in the hospital of the University of Pennsylvania. These attacks usually began with a frequently repeated trisyllabic sound, the patient's head was turned somewhat to the right, his face drawn on this side and the right arm flexed at the elbow. During four or five months before the patient came under observation, he had had a series of attacks, about half a dozen in all, some of which were mild and others severe. The patient knew when the attacks were coming on by a feeling of confusion and dizziness and by a movement of the right forearm, which flexed and extended on the arm. He remained conscious long enough to experience and observe these phenomena. The light attacks passed off without the spasm becoming general. He had on one or two occasions what appeared to be the epileptic status, or at least a series of spasmodic attacks extending over three or four hours, and after one of these periods he remained unconscious for two days. In the severe and recurring attacks the spasm became general, although almost invariably beginning in the same way and always being more marked on the right side of the body.

Examination for all forms of sensation was negative; the grip of the right hand was not quite as good as that of the left, but no other evidences of paresis of the limb were present. Voluntary movement of the right side of the face was weaker than that of the left. The right knee jerk was exaggerated, but ankle clonus and the Babinski reflex were absent. Optic neuritis was also absent, and the patient did not suffer much from headache.

Operation was performed in this case, an osteoplastic flap being made over the midfrontal and the lower two thirds of the motor region. No lesion was discovered except that the dura seemed unusually thick and dense. This patient had a specific history, and the question of a gumma or gummatous meningitis was considered, but in the light of the operation and with the history which has only been briefly sketched, the case may have been one of idiopathic epilepsy. Of course it is possible that a subcortical prefrontal growth developing backwards may later be revealed.

The second case was that of a man thirty-two years old, of healthy appearance, without any history of specific disease or alcoholism. He said that he had been perfectly well until four weeks before he came to the hospital, to which he was referred by Dr. M. H. Fussell, under whose care he had been as a private patient. Some three months before his admission he had given himself a sudden strain in attempting to get on a moving car, but otherwise had no history of injury. Four weeks before admission he noticed for the first time feelings of numbness in the thumb and finger of the left hand immediately followed by twitches of the left eyelid. Later he began to have frequent attacks of localized spasm which affected the left upper extremity alone, the left side of the face alone

and both the left side of the face and the left upper limb. These were observed by various members of the neurological staff. The patient kept an account of his attacks which became very frequent before the operation. He remained conscious in them and described the peculiar sensations felt by him and would often detail the manner in which the attack was progressing, saying, for instance, "Now it is in the fingers, now in the arm, now in the eyes, now in the face," etc. The spasm was distinctly Jacksonian, being either brachial, facial or faciobrachial in form. In one of his seizures the patient first complained of numbness of the thumb and index finger of his left hand. In a few seconds a distinct twitching of the left side of the occipito-frontal muscle was noticed, followed quickly by movements of the orbicular and levator palpebrae, and next by movements of the left side of the mouth and face. Finally the right occipito-frontalis took part in the spasm. The patient remained conscious, and in this spasm no part but the face was affected.

In another seizure first a fine clonic spasm of the thumb and forefinger was observed, quickly followed by supination of the hand and forearm, flexion of the hand on the forearm, then by biceps, anconeus and deltoid spasm. When the spasm began to affect the flexors of the forearm, the left occipito-frontal and the left side of the face became involved also after the manner described in the previous notes. At the close of the main attack movement of the subscapular muscle could be distinctly felt, although not observed during the main attack. No movement of the eyeballs was observed. At no time during the attack was the patient unconscious. Many other attacks were observed, these recurring with great frequency, even as often as twelve or thirteen times in one day. In all either facial or brachial spasm or both were present, the details of the twitching differing considerably as regards the movement of the musculature involved, especially in the upper extremity. I had the opportunity of showing a portion of one of these attacks at one of my clinical lectures, the patient walking into the arena during the seizure. The occipitofrontal, orbicular and facial movements were still evident as he entered. The spasm in the arm was passing off, but the hands still slowly flexed and extended, the forearm being held semi-flexed on the arm.

Examination showed some slight general weakness of the left upper extremity, and in the thumb and fingers marked impairment of power. Weakness was marked in pronation and supination and in flexion and extension of the hand and fingers. Extension of the second and third phalanges and flexion of the first phalanx of the index finger were almost lost. He was unable to oppose the thumb to any of the fingers or to abduct the thumb. The musculature of the left arm was distinctly flabby as compared with that of the right, and slight wasting of the muscles of the left forearm was evident. Movements of the fingers and hand were awkward, and attempts to make the finger to nose test caused some coarse tremor of the hand. The muscles affected by the spasm in the left side of the face, like those of the upper extremity, showed some impairment of power, but this was not marked. The deep reflexes in the left upper extremity were exaggerated.

Other parts of the body than the left side of the face and left upper limb showed no abnormal conditions although the knee jerks and deep reflexes generally were rather over-prompt. No loss of cutaneous sensation was anywhere present, and the patient was not astereognostic. Hemianopsia was absent, as were also all disorders of ocular movements. Repeated

examinations of the fundus showed no optic neuritis, although some blurring of the disk was present. The patient complained at times of dull headache, but pain in the head was not that characteristic of a brain tumor. It was decided, however, that the symptoms probably pointed to a small growth in the cortex or subcortex of the arm and face areas.

Dr. Frazier performed an osteoplastic operation, uncovering the arm and face areas in the usual manner. No tumor was found. At one spot the coloration of the surface seemed somewhat lighter in appearance but incision here revealed nothing, and it was decided not to explore the subcortex any further. The patient made a good surgical recovery. He had a few left-sided spasms during a day or two after the operation, but these ceased, and at the time of writing, between six and seven weeks after the operation, he had had no recurrence of them. The arm is, however, considerably more paretic, but it has improved in this respect since the first few days.

This case seemed to present in almost every respect the characteristics of a small gross lesion, and it is not improbable that a subcortical tumor will eventually make its appearance on the surface. The case is similar to one which came under my notice at the Philadelphia General Hospital in the service of my colleague, Dr. Win. G. Spiller, and which will later be published in full by Dr. Spiller and Dr. Edward Martin who operated. This patient was a man sixty years of age who had had convulsions confined to the left side for eight years. The spasm implicated the left upper and lower limbs and left side of the face, and the face and eyeballs were drawn to the left. The attacks had become more severe during the past four or five years, and five were observed by Dr. Spiller within an hour. An operation was performed and a peculiar appearing area was uncovered, but it was not distinctly pathological. The patient died two days after the operation. A very small sarcoma was found in the right second frontal convolution, just in front of the pre-central convolution and immediately beneath the cortex.

Just as this paper was approaching completion an article by A. Playce on minor (smaller) motor epilepsy appeared in the *Neurol. Centralbl.*, Nos. 3, 4 and 5, Feb. 1, Feb. 15 and March 1, 1906. The author contributes the history of a case of a boy eleven years old at the time of the first observation. At this time the diagnosis of facial tic was made. Some years later the patient again fell under the attention of Playce when the diagnosis of abortive epilepsy was made, and still later it became clear that the case was one of ordinary idiopathic epilepsy with the minor or local seizures being similar in character to the Jacksonian attacks which are observed to occur during the progress of a true idiopathic convulsion. The not very extensive continental literature of the subject of Jacksonian epilepsy is reviewed by Playce, especial attention being given to articles by Léré,* Binswanger†

Burnhardt,¹⁰ Sarraillhe,¹¹ Liebert¹² and Kjelmann.¹³

He defines smaller motor epilepsy as that form of attack in which a local spasm occurs without disturbance of consciousness and without an aura. The differential diagnosis of hysterical attacks, reflex spasms, seizures due to cortical lesions and idiopathic epilepsy is considered at some length in the light especially of the valuable contributions of Binswanger and Léré. In connection with what has been said in this paper, the conclusions of Léré, that cases of so-called tic are often in reality of epileptic nature, are of interest. Cases are cited to demonstrate the truth of this position. So-called attacks of myoclonus probably occur in about 5% of the cases of idiopathic epilepsy. The reader is referred to the paper of Playce and also to the contributions of Binswanger, Léré and others for some interesting points in the diagnosis of Jacksonian epilepsy and its counterfeits.

A few of the differential points brought out by these writers might be presented here in addition to those to which attention has been called in previous pages.

The aura in idiopathic epilepsy is not as common as that occurring in organic epilepsy and in those cases of epilepsy due to reflex causes. Idiopathic epilepsy is liable to occur at night; true tics and hysterical attacks scarcely ever at night, although one or two cases are noted in the literature in which severe cases of tic were said to have occurred at night. Reflex epilepsy and true Jacksonian attacks may occur at night. Léré and Binswanger believe that idiopathic epilepsy may be of organic origin and that Jacksonian attacks may be only part of the idiopathic attacks, a point which I have already somewhat fully considered. Jacksonian attacks do not come on as often at night as do the idiopathic attacks.

Léré states that in Jacksonian or cortical epilepsy the patient is always awakened from sleep so that he is compelled to be awake during the whole attack; in idiopathic epilepsy the patient is only awakened from sleep in those attacks which, during the day, would not cause him to lose consciousness.

An important symptom of minor motor epilepsy is more or less paralysis of the part after an attack. This occurs most often after cortical or organic epilepsy, but cases are on record in which after a reflex or idiopathic attack this has been present. The paresis may be overlooked, as it may last only a few minutes after the attack. At times instead of the convulsion the epileptic attack may be manifested by weakness, temporary in character, and this may occur without loss of consciousness. Instead of paresis there may be sensory changes as diminution of the visual fields and distortions of cutaneous sensation.

AN OPERATION FOR CYSTOCELE.

BY W. P. GRAVES, W.D., BOSTON.

OF all the plastic operations on the vagina, the most difficult in which to attain a permanently successful result is that for cystocele. Numerous ingenious operations have been devised and exploited, but after all has been said, the perfect operation which in all cases can be relied upon has not yet been invented. However, many of the difficulties and disheartening results which attend the treatment of cystocele can be avoided

exist above it, as it is sure in time to stretch out the external portion of the repaired perineum.

No particular originality is claimed in this operation, as it combines and modifies principles long ago described by Dr. Emmet.

The steps of the operation are as follows: Two points are selected on each side of the cystocele, about one-half inch from the lateral creases, which, when drawn together (A to B and C to D), sufficiently reduce the cystocele and at the same time do not exert undue tension on the lateral flaps. With these four points as corners a rectangle

repaired perineum, and, secondly, as starting points for a new cystocele, according to the principles of any beginning hernia. The most important protrusion to reduce is the somewhat loosely-called urethrocele. This consists usually of an hypertrophied tab of vaginal tissue, and in operations for perineorrhaphy should always be reduced even in cases where cystocele does not

backward a cervix which has a tendency to prolapse.

Great care should be exercised in making the denuded figure symmetrical, so as to gain perfect approximation of the edges, for in all vaginal work it is the perfect approximation of the edges of the wound which avoids sepsis and secures union by first intention.

The wound should be closed with silkworm gut or chromicized catgut sutures, excepting at the point where A, B and E meet. This is a crucial point for the avoidance of sepsis and non-union, and for that reason a silver wire suture is used. By placing it as depicted in Fig. 1, the corners can be fitted to a nicety without cutting off their circulation.

After finishing the operation for cystocele, a *perineorrhaphy* should always be done, even in cases of recurrent cystocele where the perineum has been previously repaired. A firm perineum should be done and one which will hug closely the anterior wall. Stitches from the cystocele operation may be removed as soon as the perineum is strong enough to stand the traction of a speculum, usually about the third or fourth week. Daily corrosive douches should be administered, great care being exercised not to allow the corrosive solution to enter the urethra. The patient should be encouraged to pass her water as soon as possible, in order to avoid the continued use of the catheter.

SOME INFLUENCE IN FAVOR OF BETTER MARKET MILK.*

BY R. A. FARMON, ITHACA, N. Y.,
Professor of Dairy Industry, Cornell University.

IN dairying, as in many other lines of industry, there is to-day a decided movement for improvement. This improvement is chiefly in the direction of more sanitary methods of producing and handling milk. Several different influences are responsible and I propose to mention and briefly discuss some of the chief ones.

I. Laws and ordinances. Most states have laws relating to milk and most cities have ordinances on this subject. These legal regulations usually prescribe standard or minimum amounts of fat and total solids. Three 3 per cent fat and 12 per cent total solids is the most common standard, but in Massachusetts the standard is a little higher. So far as this milk standard is concerned, the laws and ordinances are generally well enforced. It is easy to enforce such provisions because they are definitely stated and failure to comply with them may be easily traced. Legal regulations usually apply also to the sanitary conditions under which milk is produced and handled; these include the health of the cows, manner of stabling, character of feed, handling of the milk, etc. Obviously it is difficult to state requirements relating to these subjects as exactly as those relating to composition of milk, hence such requirements are not as well enforced. In fact, in many cases no attempt is made to enforce regulations other than those having to do with the composition of milk unless the most serious conditions exist. The great majority of dairies sending milk into our cities are not regularly inspected and conditions must become exceedingly bad before they are noticed.

It should be understood that well-meaning

dairymen do not object to but rather favor the enforcement of reasonable milk laws and ordinances as they see the advantage of preventing dishonest practices. Official records show that where reasonable regulations are enforced, the amount of milk used is large as compared with the amounts used in places having poor or poorly enforced laws. But the best dairymen would like to see milk regulations clearly stated and dignified by being separated from other municipal regulations relating to garbage, cemeteries, and like subjects and, more important, they would like to see these regulations enforced by men who have been trained to do such work and not those who are appointed merely because it is the wish of some politician. A dairy inspector who has been well-trained for such work may often accomplish more good by giving advice where it will be useful than by his detective and police work.

Furthermore, dairymen would heartily approve enactment of new laws that would relieve them of much trouble and loss and of much blame, now unjustly heaped upon them. These would include laws relating to the care of milk bottles and, more important, the condition of milk cans when returned by dealers to dairymen. And dairymen would welcome laws that would prevent dishonest competition, such as is seen when one dealer having poor milk succeeds in getting trade by making grossly inaccurate claims.

II. The second influence is public demand for purer milk. This is increasing slowly. If the public were anxious to get better milk than they are now getting they could have it very soon, but the fact is that the great majority is satisfied with the present milk supply. If the milk going into most houses contains a fair proportion of cream and will not sour in twenty-four hours it is quite certain to give satisfaction. The purchaser gives little or no thought to its condition otherwise than stated. Perhaps the average householder can be excused for this neglect on the grounds that she innocently believes the milk inspectors will protect her from unwholesome milk. But can we excuse the hospitals and other large institutions on the same grounds? Their position seems remarkable to say the least. These establishments are managed by men who know the real conditions, yet most of them buy their milk on contract with no stipulation whatever as to quality. It is of course understood that the milk shall be sweet and contain at least the legal standard of fat. Most consumers and dairymen will say if the ordinary milk is good enough for the patients in hospitals where there seems to be no lack of funds for expert treatment and wholesome food, then that same milk must be good enough for well people.

III. The milk commissions constitute the third important influence. These commissions have received much credit but not as much as they deserve. I believe the value of the commissions should be extended and they should receive support for the work from the public treasury. In the end they accomplish much that the regularly

* Paper read before the Suffolk County Medical Society, Boston, Mass., Dec. 20, 1905.

organized officers of milk inspection are expected to do and on these grounds alone it seems they should not have to rely upon private support. The benefits of milk commissions could be easily increased at least by a little dignified advertising among physicians and perhaps among the public. It is strange that even now many physicians who claim to be interested in better milk and who reside in cities where milk commission are doing good work, do not know about these commissions.

IV. There are several other influences in favor of better market milk, but the last to be named, and perhaps the most important, is the example of well-conducted dairies. By contrast with poorly-conducted dairies, these places have emphasized the value and the attractiveness of pure milk as nothing else could do. They have often been run at a loss because of the extreme measures taken to prevent contamination of milk, but they have succeeded in reducing some of these extreme measures to practical methods that can now be followed in all dairies and thus they have rendered valuable service to the dairy industry. If one doubts the power of example in this case he should visit almost any high-class dairy of to-day and he will be likely to find that some person or persons connected with that dairy have visited and obtained valuable help from other high-class dairies previously established. And a good feature is that proprietors of these places like to be visited and have their successful methods copied because every new dairy of this class does more to advertise their kind of milk and increase general demand for it.

Thus we have considered, briefly, four of the chief influences in favor of better milk. It seems to many persons that these should operate more rapidly but there is a serious drawback. It is the unwillingness of the majority of people to pay even a small advance for improvement in the quality of their milk. The dairyman is a business man. He may be compared with the manufacturer. He will not willingly increase the cost or labor of producing milk so long as he can receive no more for it. If milk consumers could be made to appreciate the hard work which is done on the average dairy farm, and the heavy cost for feed and the small returns now being received, then it might be easier to increase prices.

Most dairies should have considerable money expended upon them for better equipment, but great improvement in quality of milk could be brought about by the adoption of more careful methods of work. This, however, means a higher class of help or closer supervision which amounts to the same as cash outlay.

One who has not been engaged in the production of sanitary milk nor given close attention to it can hardly appreciate the high degree of intelligence required for this work. It is a battle with bacteria and this means the utmost care at every step. Carelessness at one point will cause bad results. Sometimes experts have to be called to assist in finding mysterious sources of contamination. The man possessing skill sufficient to

produce clean milk can usually find more profitable employment in some other line of work, than in making milk at present prices. If the public wants clean milk he will gladly produce it for a fair price.

[The above paper was followed by an exhibition of lantern slides showing the extreme care required in the production of sanitary milk and arguing for higher prices which will encourage producers to follow better methods.]

A CONSIDERATION OF THE TREATMENT OF AUTO-INTOXICATION OR AUTO-INFECTION WHERE THEY ARE THE CAUSE OF MENTAL DISTURBANCE.

BY L. VERNON BRIGGS, M.D.,

Physician to the Mental Department of the Boston Dispensary.

(Continued from No. 16, p. 434.)

CASE VIII. April 7, 1904. F. B. A. Male. Single. Age, thirty years. Patient as a boy was subject to severe pains in abdomen. Has had more or less dyspepsia all his life. Is nervous and irritable. When he feels well is careful about his dress but says he does not "care a rap" about it when he is not feeling well. Has been under Dr. Pfaff and Dr. Gannett for stomach. Much depressed at the present time. Does not care whether he lives or dies, but acknowledges that he would struggle against death.

Sentences rather slow and retarded. Pulse 58 and sluggish. Belches gas frequently. Much gas in bowels and stomach enlarged. Knee jerks exaggerated. No ankle clonus. Plantar and abdominal reflexes diminished. Pupils equal and react to light and accommodation. Romberg position and co-ordination, fair. Has smoked and used coffee in excess. Family history negative.

Treatment: Prescribed nux vomica before meals. Glyco-thymoline after meals. Restricted diet.

June 1, has improved but condition not satisfactory. Advised his going on a ranch, since which time I have heard only once from him. He had not then improved.

CASE IX. June 6, 1904. M. E. P. Female. Single. Age, forty years. Referred by Dr. Mary Hobart, who has had charge of the case for several years. Mother died of heart and stomach trouble. Father had shock many years ago. Sisters delicate and subject to headaches. Brother committed suicide.

Patient has pains all over her body. Is unable to ride in electric cars because they "affect her so." Comes to my office in a carriage from D — and says she will have to go to bed for several days after taking such a trip. Pulse 152; temperature 101.

Gives her history as follows: "First they say I was not born with strength enough. That my mother really ate nothing to speak of before I was born. Next, I had bronchitis as a baby and was seriously ill. Then lung fever; after that whooping cough. Then I fell down a long flight of stairs and struck my nose. My stomach was always delicate. Then I was sick with the measles and was kept in a dark room for my eyes which were weakened. Always read books that few children would care for. Next I fell from a barn loft and had constant backache, headache and sideache, which started in immediately afterwards so that I had to give up my music. The doctor thought there was some local trouble.

"At school took seven subjects when the course was four; also lectures by the best foreign lecturers and

Harvard professors. Went to all the dancing school parties and everything worth while at Harvard. Was very sick every time I was unwell which only came once in months for many years. When I walked or danced the pain was intense. Kept running down but never went to bed until finally I vomited everything I put in my stomach without nausea.

"First, I had chronic diarrhea and constant trouble with the bladder, getting up some nights thirty times. Finally I had paralysis of the muscle of the bladder and my urine passed all the time for three months. Then I had hemorrhoids. When I dropped into bed, I vomited fifteen weeks steady, and most of the time for two years. The doctor gave me up when I threw up blood and the lining of my stomach. They kept me alive with brandy and oil on the outside of my stomach. I had nervous prostration.

"They made a local examination and said I must wear a support, and that every time I was sick the suffering must be as bad as an obstetric case. I have had Dr. Doe for prolapsed ovary and electricity, and Dr. Strong has operated on me. Have had Dr. F. H. Harrington, Dr. Mary Hobart, Dr. Holmes who operated on my nose, Dr. Samuel Hopkins for my jaw, Drs. E. G. Cutler and Fred Shattuck for my stomach and Dr. C. F. Folsom for my nerves, besides other physicians; in all I have had fifty-two."

Treatment: March 21, 1905. I had patient come in and take a room near my office, as treatment could not be carried out at her home. I gave her glycyrrhizine two teaspoonfuls t.i.d. with meals. Beta naphthol 5 gr. twice daily two hours after meals. Colonic flushings of saline solution daily. Colomet at night. Generous diet. Salt baths of from twenty minutes to half an hour before retiring. Pulse varied during the day from 96 to 140. Temperature 99.8 to 101.

March 28, patient went out for a walk for the first time; complained much.

March 30, out for two hours, one spent at a picture gallery. Is now taking beside her three regular meals, 3 eggs, 3 cups of soup and 3 glasses of milk.

April 4, was out for a walk in the morning of two hours, visiting the Art Museum, and in the afternoon for one hour, during which time she made her first call for several years.

April 7, Goes out daily visiting the art galleries, calling, etc. Is eating and sleeping fairly well. At this time as I was going away I was obliged to send patient home with directions as to her treatment, which included the antiseptics. Those directions she followed until June, when she said she was unable to continue them.

Feb. 1, 1906. Is now in very much the same condition as when I first saw her, having had no treatment by any physician since last spring. This case improved while under treatment.

CASE X. Jan. 15, 1905. W. R. L. Male. Age twenty-six. Single. Mother died of paralysis at forty-one years of age, when patient was six years old. At thirty-nine she had hemiplegia. Was at time out of her head, especially during menstruation. Father clergyman, strong physically but sensitive to outside suggestion and environment. Paternal grandfather died of general debility at sixty-seven. Paternal grandmother of consumption at twenty-five years. Maternal grandfather died at eighty of old age. Grandmother also died of old age. One paternal uncle's "mind was clouded for a time." One great aunt was peculiar. An uncle drowned himself after a long period of insomnia. Patient had violent crying and screaming spells as a child which came on with no apparent cause, but was quoted by his father's de-

him in his arms. At seven he had gastric fever. At eight, scarlatina. At ten, while jumping on the bed, fell on the floor striking on his head; there was no loss of consciousness, but a queer feeling which lasted for some time. At fifteen he had a mild attack of typhoid fever. The same year he entered a school at G— where he did very well and took a Latin prize. At nineteen, he entered Harvard, and while there was substitute on the eleven and class crew. He was fond of bicycling.

He worked very hard and completed the course for an A.B. in three years. He failed the following year to get his A.M. and it was then noticed that he had become somewhat "scatter-brained." He also became unmethodical and careless about his clothes. This condition however did not prevent his taking the position of instructor in languages at the G— school in the fall of 1901. The head master of the school wrote his father that he had a wonderful gift in managing boys. At the end of six months he again wrote patient's father that he was not up to his work. Patient said at this time that his head felt badly, and it was noticed by those out late at night that he was apparently asleep at his desk with the light burning at three and four o'clock in the morning.

His appetite increased and he became critical. In January, 1902, it was noticed that he was unusually emotional at the marriage of a friend. He seemed unable to concentrate for any length of time or to satisfactorily accomplish his work. It was therefore suggested that he should go abroad with a tutor.

Accordingly, in August, 1902, he went to Germany. He did not appear able to apply himself but he picked up a good deal of German. His letters at from this time became erratic and somewhat confused. When the time came for him to return he for some reason did not do so, and it was necessary to send a relative to bring him home; he would not consent to return until after a trip to Italy. Before leaving Germany he had some operation performed on his nose which he says the doctors told him was to get the blood from the brain.

He returned to this country in September, 1903, and was met by his father who found him very morbid and over-conscientious and worrying over something he did in college, saying he never should have been allowed to graduate. Said he had let someone look over his paper and use some of his work and he so exaggerated this fact in his mind that he refused to matriculate in the University in Iowa because he said he had not earned his degree honorably.

In January, 1904, he was taken to Dr. McParney who referred him to Dr. Dana, who after seeing patient for two months gave a bad prognosis and advised an asylum in England. The patient was then taken to Dr. Bangs, who was associated with Dr. Peterson in New York, who advised patient to live an out-of-door life with a companion and away from his family. About this time he was very slow mentally and had a nervous smile which had developed abroad, and his judgment was impaired.

A little later he was taken to Dr. Wheeler, an Osteopath, where he apparently improved for a time, but in May the osteopath considered him a case for a mental specialist.

On May 24, 1904 at the suggestion of Dr. Joel E. Goldthwaite, patient was referred to me. At the time of my examination I found no dizziness, no insomnia, appetite normal, eating hearty meals and also between meals. Little tremor of the hands and tongue. Bowel position good. Keen, gets along well. Pulse 104, temperature 99.6, healthy strong, good. Delusions of self accusation and possibly some latent delusions. Several times during the examination

tion he went to the front door, which was some distance from the examining room, saying he wanted to get some fresh air. No loss of weight; rather gain. Speech and ideas retarded. Memory for names and events good; not so for dates. Laughs at times, not out loud, but something more than a smile. Considerable negativism. Patient says he had dull sounds in his ears in January. That his occupation should be manual because his head leads his hands. That things come to him in an abnormal way which causes feelings of mirth, and that he laughs because he cannot see the logical proportion of things. At later examination he showed unmistakable symptoms of dementia praecox.

Gave glyco-thymoline, 1 dr. t.i.d., regulating his diet and exercises. I was unable to go far in the treatment as in June 1904, he developed a dislike for me, caused by opposition, and Dr. C. F. Folsom was called in consultation.

He thought it useless at that time to continue treatment where the opposition was so strong and the case was placed in the care of Dr. G. F. Jelly, for the balance of the year, the patient living an outdoor life in the mountains.

In the fall of 1904, patient attacked his cousin on the street and also interfered with people whom he heard swearing or doing things he thought they should not do. At Christmas time, he was allowed to go home but he did not do especially well. He took twenty-five minutes at the station to transfer a few articles from his trunk to a bag. Requested his companion to walk at a certain distance from him and no further; not to sing or hum and to pass on a certain side of the trees and pillars. Made such remarks as "S. is full of subtle influence—keep walking—when you see people rubbing things walk." Was very forgetful, undecided and self-willed by turns. His friends considered his character as passing away and said it was like watching a soul die.

About this time, Dr. Weir Mitchell was consulted and advised placing the patient in a sanitarium as he considered the case virtually hopeless.

About Jan. 1st, 1905, patient was sent south with a graduate physician as companion. On the way patient lost his money belt and contents. Later while at the hotel in Asheville, N. C., patient locked the door, having accused his physician of taking the money, and proposed to settle the matter by boxing, which the physician refused to accede to. Patient then caught him by the throat and being the larger and stronger was choking him when his cries brought assistance.

Dr. S. Westray Battle, of Asheville, was called in and advised the patient to put himself under the immediate charge of Dr. Robert S. Carroll at his home in Asheville, where patient could have the benefit of a hydrotherapeutic treatment and sanitarium care without the objections of a sanitarium. Patient acceded to this proposition and entered the family of Dr. Carroll.

Dr. Jelly at this time being away for his health, I was asked to again resume the case which I did on Jan. 20, 1905. Dr. Carroll agreeing to co-operate in carrying out my prescribed treatment, which consisted of eliminating baths, including turkish and cabinet baths and spinal douches, colonic flushing with salt solution daily, salt baths of thirty minutes each at bed time. Beta naphthol 5 grs. after meals and restricted diet with long walks, sloyd, etc. For the first ten days patient was violently excited and as Dr. Carroll writes, "thoroughly insane, savagely attacking his physician and attendant and having to be fed by tube." At the end of the ten days he cleared up mentally and on the 20th of February, was taking long walks out of doors with his attendant, which he seemed to enjoy.

During March, glyco-thymoline, 2 dr. before meals,

was given and mainly liquid diet. Patient had some hallucinations of sight and smell; said his food was dirty; was also very decided in his statement that other people were crazy and must be taken care of. Also had delusions against women in general, which were so strong that he would try to get out of the window when the female nurse came around in the morning to make up his bed. Also thought his physicians were not honest, or that they were immoral or insane.

In April phosphate of sodium after meals was given to replace the beta naphthol, and from time to time since then his treatment has only varied in the kind of antiseptic given, no one kind being given over three or four weeks without changing. Twice he has received iodide of potassium for limited periods.

During the spring he had expressed delusions against his aunt and also as to horses and other things. In spite of this he apparently improved in many ways being able to accomplish work begun, such as making book shelves, and the drawing of landscapes. He played a good game of ball; bowled a good string and enjoyed services in churches, amusements and lectures.

In April, I visited him and was cordially received. Patient voluntarily consented to continue under my care for an indefinite period, invited me to lunch, etc. He did not wish to go to walk with me, the reason he gave was that he feared my professional zeal would lead me to attempt some method which would cause trouble between us. There was much mental deterioration and impairment and undoubted damage to the brain.

His idea of Russian and Japanese war consisted mainly of a lot of proper names which he repeated in a slow, dragging way. He confused "law" with "lawn" and other words in the same manner. Also in speaking of some one falling he said, "Niagara Falls," "Bellows Falls," and named over other falls ending up with "That's what you mean, isn't it?"

Treatment was continued during the summer and many trips taken through the mountains with attendant, patient walking fifteen and twenty miles a day for a week or more at a time; building their own camp fires, stopping at farm houses, fishing, etc., but at no time during those trips was the antiseptic treatment, including the colonic flushing, interrupted, except the latter, when camping out of doors. The violent outbreaks which occurred periodically disappeared, and he has had but one slight one since last summer.

In March and April the improvement was slow, but noticeable. In May, when several of his relatives visited him, his delusions were still prominent.

By August, his delusions had faded so that he did not express or give evidence of them. His complexion which was muddy and full of pimples had cleared, blood pressure was diminished, and the indician, which was quite in excess at the beginning of the treatment, was normal. The antagonism and negativism were slight, and Dr. Carroll reported, on the whole, general improvement.

On June 30, his father after a ten days' visit with patient, during which time they took a mountain tramp of several days, writes, "I was most agreeably surprised at my son's condition. He is very natural, reasonable, and said nothing whatever against any one; was affectionate toward me, and his mind seemed stronger and less clouded; also he manifested fewer delusions."

On October 8, his father after another visit in which they were again off together, part of the time alone, writes, "I am glad to say I have not seen him so well, so reasonable and so gentle as he is for years, and I think there is real improvement."

My opinion was that the progress of the disease had

been stayed, but considering the fact that we have no way of replacing damaged brains, this perhaps is all that could be accomplished. I therefore wished a consultation to decide whether the elaborate and rather expensive treatment was warranted in view of the slight improvement which might occur. I suggested to the father a consultation with Dr. Edward N. Brush, of Baltimore, which was assented to. Desiring Dr. Brush to have every opportunity to observe the case, I asked him to take the patient into the Sheppard and Enoch Pratt Hospital temporarily, which he kindly agreed to.

On Nov. 10, 1905, patient was brought to Baltimore and placed in Dr. Brush's charge. During his stay at the hospital he was very quiet, tidy in his habits and acted in a gentlemanly way toward all, with whom he came in contact. He was slow in his actions and speech and frequently in conversation would stop for a few moments before finishing a sentence. He was very prompt in asking for his medicines and treatment, if he thought they were neglected in any way. Was amenable to discipline. Liked to go for long walks. Ate slowly, but a great deal. Was fond of using big words and would put several words in a sentence with a sort of rhythmic ending; frequently used wrong words.

Since returning to A. — the treatment has been kept up. On December 30, Dr. Carroll reports that the patient seems much improved. That he was very active in Christmas preparations, getting holly trees and evergreens and making many presents.

Jan. 26, 1906, Dr. Brush writes: "I am fully of the opinion, based upon the history of the case and our observations here that your patient is one of those unfortunate cases of early mental breakdown, to which the term has recently been applied, 'dementia precox.' There is certainly, as I think would be generally admitted by those who know him and see him now, a large degree of mental reduction. He is somewhat over impulsive as is rather characteristic of those cases and his outbreaks of excitement and violence are of a purposeless and childish kind, characteristic of this type of mental disturbance. I do not think we have far to go in seeking for the cause, even leaving out any prenatal elements. Overwork at an important period of his life associated with undoubted auto-toxic processes, would, I believe, tell the story. I feel that the course which you have pursued in the case since he has come under your direction is by far the most judicious that could be suggested. If there is any hope in his case at all, and it strikes me that there is very little to be expected in this line, it is in preventing further mental deterioration and this would only be done in getting him interested in manual rather than mental occupation."

All I claim in this case is that the energetic antiseptic treatment which has been so faithfully carried out by Dr. Carroll has stayed the progress of the disease, and has enabled the patient to enjoy a simple and quiet life.

I will add an extract from Dr. Carroll's last letter dated Jan. 27, 1906: "Patient is very genial and kindly. We all hear Sousa's band to-night, to which he looks forward with great interest. His physical condition is as good as I have ever seen and I think he is now free from any tendency to small obstacles that at any time."

In the treatment of these cases we must remember that much of the repair of the system takes place during the hours of sleep and it is therefore

necessary that at no period of our life, should we neglect our hours of sleep. No one has gone into this subject so thoroughly, or is doing more good to-day for the young minds and bodies that have neglected the hours of rest than has T. D. Acland, M.A., M.D., Oxon., F.R.C.P., Physician to St. Thomas' Hospital, London, etc. On May 11, 1905, he read a paper before the medical officers of Schools Association on the hours of sleep at public schools, in which he says, "It is generally held that an average of about eight hours' sleep is right for adults after they have obtained their full development and during the best years of their active work. Some, of course require less, and a few, more." He gives most interesting tables showing the approximate hours of undisturbed rest in forty English public schools, and quotes Prof. J. G. McKendrick, M.D., F.R.S., Professor of Physiology in the University of Glasgow, etc., and writer of the article on "Sleep" in the *Encyclopædia Britannica*, as saying that "a young growing lad should have ten hours of sleep, both summer and winter," and that he had known men who needed nine hours' sleep if they were to do effective work. Prof. C. S. Sherrington, chairman of the British Association on School Hygiene, says: "During sleep the chemical changes of the body are reduced in the case of CO_2 output to one fifth so that the organism during sleep may be said to have its fires banked instead of being run under forced draught. Sleep is not only a respite from chemical change, it is a mechanical rest as well. By insufficient rest the growth can be stunted and development retarded. That most of the boy's growth in stature is done in bed; that without plenty of sleep the activity of the waking day is like a house built on sand, in constant danger of breaking down and giving way."

Dr. Acland further says: "The number of hours in bed often does not represent the hours of sleep, especially in dormitories. We all must be acquainted with the fact that the quality of sleep is influenced by darkness, and to insure the most complete rest to the nervous system, it is necessary that sleep should not only be uninterrupted by noise, but also by the exclusion of sunlight from the room. In few schools would it appear that any attempt is made to encourage the habit of getting proper sleep, and the head masters should offer prizes to the best sleepers. That boys do want more sleep is clear from the fact that they often have to be roused out of a deep sleep in the morning and dress half asleep in silence and weariness instead of being filled with the confidence of spirit which is natural to the healthy boy."

On Nov. 19, 1905, Dr. Acland writes me: "The subject has been warmly taken up by the medical officers of the School Association which is a society which includes amongst its members the medical officers of a large number of schools in England. It was also taken up by the Congress of School Hygiene held in London in June, and the Parents' National Educational Union. All these bodies have sent official communications

on the subject to the head masters of all the principal schools in this country [Great Britain] and two of them have sent copies of my paper so that the authorities can hardly remain in ignorance of what our profession thinks about the matter in this country."

On Dec. 31, 1905, the London *Times* in a long editorial gives an interesting account of what is being done in Great Britain, and publishes communications from a large number of medical authorities concerning the inadequacy of the time allotted to sleep by many schools for boys, and in this editorial the *Times* quotes Dr. Acland largely.

Frederick Peterson, M.D., President of State Commission in Lunacy, New York, and who has a clinic of nervous and mental diseases in the Columbia University says, "When auto-intoxication is suspected as a causative factor in any nervous disorder, it is essential to regulate the diet which should consist mainly of milk. There are at our disposal a number of antiseptics, which though not always efficient are yet often of great benefit. I have found in my own practice that beta naphthol is one of the best intestinal antiseptics. I give it in capsules of 5 gr. each, two hours after eating, with water. In several cases of epilepsy and melancholia, it has acted extremely well. In many cases of epilepsy salicylate of soda has proved itself of great value, and salol, too, as an intestinal antiseptic. Sometimes I have made excellent use of peppermint for the same purpose. I think the abundant use of water a necessary adjunct to the treatment. I usually advise the drinking of hot water several times daily on an empty stomach; sometimes adding thereto frequent flushing of the large intestines with warm water."

Dr. Charles E. Quimby, of New York (the first to bring to my attention the Quimby syringe, so-called, and which I use for colonic flushing in most of my cases), in a paper read in Buffalo, May 31, 1901, on "The Relation of Intestinal Toxemia to Arterio-renal Disease," gives a history of several interesting cases. One, a man of forty-three, a contractor, complains of nervousness which prevents application increased by attempts to apply himself, insomnia and anxiety and undefined discomfort. Tongue coated. Pulse, full and hard. Urine shows excess of urates, etc. Diagnosis: Intestinal toxemia. Treatment, lavage of the colon every day until free, then twice a week. Laxative t.i.d. Vegetarian diet. Relieved within a week. Cessation of all symptoms within a month.

Dr. Allan McLean Hamilton, of New York, in a paper on "The Connection of Auto-Toxins with Certain Forms of Insanity," read before the Medical Society of London, some time ago, sums up his treatment as follows:

"The most successful treatment consists of lavage, intestinal antiseptics by means of hydrochloric acid, borax, salicylate of soda, charcoal, guaiacol, or naphtholine in small repeated doses, and the administration of the combination of

the red marrow from the small bones, blood and glycerin."

In another paper written by him and printed in the *Medical Record* later, on "Insanity in Connection with Diseases of the Ductless Glands," he refers to the enlargement of the thyroid as an immediate pathological condition in melancholic patients and strongly advises the administration of the organic extracts in this condition. In insanity coming from disturbance of the other glands he gives thyroid or powdered pituitary gland. In hysterical mania he says he has used the splenic glyceride in divided doses of from 5 to 20 gr. which promptly reduced excitement and produced sleep.

Dr. Maurice S. Guth, superintendent of the State Hospital at Warren, Pa., writes me as follows: "Our treatment of cases of insanity due to auto-intoxication consists of stimulants, nourishment and hypnotics, milk, whiskey, amylene hydrate, prolonged hot baths and careful nursing."

Auto-intoxication is only mentioned as the cause of death in two state reports of the insane in 1902. Louisiana gives one death and Alabama four deaths from auto-intoxication.

Dr. Marcello Hutchinson, superintendent of the Vermont State Hospital at Waterbury, Vt., says that in the care of such cases of mental disturbance as are manifestly due to the action primarily and secondarily of bacterial toxins, the treatment, aside from the routine hospital confinement, has been symptomatic, but not particularly antiseptic in character.

Dr. J. W. Gray, Jr., in an article on "Auto-Intoxication," in the *Journal of the Mississippi State Medical Association* for September, 1905, says that "auto-intoxication as defined by most authors is a condition of self-poisoning produced by the absorption of ptomaines or the products of fermentation and decomposition in the stomach or intestines, or both; but I think the term should have a much wider significance and should embrace the defective elimination of all end products of metabolism." For treatment, he gives calomel in small doses every three hours with some saline in hot solution and strychnine hypodermically. Hot salt solution by hypodermoclysis and irrigation of the bowels with hot salt solution through the return flow rectal tube.

Dr. J. T. Mitchell, superintendent of the State Hospital at Jackson, Miss., in an article read in Montreal, June, 1902, on "Instinct an Important Factor in the Diagnosis and Treatment of Diseases," in speaking of purgation says, "One of its good properties is to evacuate the ptomaines and impure secretions remaining in the bowels; even in dysentery, it is the instinct of the patient and thus gives a valuable hint to the physician to save him from an auto-toxic death."

D. L. Field, M.D., of Jeffersonville, Ind., in an article on auto-intoxication, says: "Among the poisons which rank first are the toxic substances resulting from intestinal putrefaction.

It is strange to find so many poisons in the intestinal canal, and yet so few toxic accidents; and we must never neglect, in auto-intoxication, to keep up the strength of the patient so that he may have time to eliminate the poison. If we keep him alive, we may save him. The therapeutic treatment is effected to a certain extent by nature. Poisoning from substances in the alimentary organs may be diminished. Patients must not take broths that contain the mineral elements of meat, and diet should be restricted." Hydrotherapy, cathartics, enemata of turpentine and the yolk of egg in warm water, are some of the things he recommends.

Dr. H. E. Allison, superintendent of the Mattewan State Hospital, Fishkill Landing, N. Y., writes me: "We have no doubt that there are many cases of mental disease caused by derangement of the metabolism. Many manifestations of mental disease depend upon auto-infection not only from the intestinal tract, but upon disorders of other excretory channels. Derangements of the digestive organs and consequent evils are, in our opinion, responsible for many conditions of ill health and for various forms of insanity. Personally we have felt that it is responsible for many maniacal outbreaks, for many states of mental depression, and have always directed our attention in a therapeutic way to such conditions, often with satisfactory results."

Dr. Moses J. White, superintendent of the Milwaukee Hospital for the Insane, writes: "We do not ignore the element of auto-intoxication. In almost every case on the assumption that that element is present in a greater or less degree we have had very gratifying results by the pursuit of this theory, and treatment adapted thereto. The measures chiefly used to relieve this condition consist in increasing the action of the skin and bowels by turkish baths, massage and the administration of saline cathartics, and the employment of high enemata, and we find that these methods prove to be very efficacious."

Drs. Brackett, Stone and Low, writing in the BOSTON MEDICAL AND SURGICAL JOURNAL, July, 1904, give for the treatment of acid intoxication the administration of sodium bicarbonate by mouth or in enemata and infusion of large amounts of saline solution.

The cause of acid intoxication they state is some derangement of the metabolism.

Dr. F. Ferschheimer, of Cincinnati, Ohio, writes as follows: "In regard to your own subject, the relation of auto-intoxication to psychoses, I am sure that it exists. We all recognize the psychoses of Graves' Disease, for instance, and in a number of cases I am able to give complete relief by the administration internally of large doses of quinine. Again, the psychoses characterized by depression have been absolutely relieved in a large number of cases by the treatment of intestinal auto-intoxication. Another class that I might mention that have been relieved on the principle of auto-intoxication are some of the menopause psychoses."

Dr. E. C. Dent, superintendent of the Manhattan State Hospital, Ward's Island, writes me as follows: "There is no question in my mind that a number of our psychoses have as their basis an auto-intoxication. It is quite probable that in course of time dementia paralytica, dementia precox and the insanities occurring in epilepsy will be traced to auto-intoxication. We have for some time been making careful studies in this direction, but as yet feel the results we have obtained have not been sufficiently established to justify me in bringing the matter before the profession. It is conceded that the most prominent physical disturbance we find in insanity is that of disturbance of nutrition due to the derangement of the gastrointestinal tract. Our principal aim is to restore as quickly as possible the normal functions of the body, and our treatment can be summed up in two words, *eliminate* and *supportive*. I feel that this is an important field that has not been given the consideration it should."

In November, 1905, I visited the Manhattan State Hospital and spent some time with Dr. Adolph Meyer. He said to me, "Why should we use the term 'auto-intoxication'? Why not say 'habit-disturbance' and correct the habits of the glands, secretions and organs, and life of the patient—the same as our mothers would have done if we had contracted bad habits?" The result of his analysis of urine shows him that indican varies in normal individuals, so he thinks it is not to be depended upon. For melancholies and excited patients, especially, he gives calomel, prolonged baths of from twenty-four hours to a week, sometimes, at temperature from normal to 105°. No restraint is used; if one nurse is not sufficient then two are assigned. Then the hot or cold pack. Two pictures are taken of each patient on entering.

(To be continued.)

Reports of Societies.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

PROCEEDINGS OF THE FIFTIETH ANNUAL MEETING, HELD IN KANSAS CITY, MO., DEC. 28 AND 29, 1905.

TODD PROSSER, DR. H. D. NILES, SALT LAKE CITY, LEAD, to the chair.

THE customary Address of Welcome and Response to the same were omitted, and after a brief speech by the Chairman of the Committee of Arrangements, the reading of reports was begun.

THE TRANSVAGINAL OPERATION FOR THE TUBES IN UTERINE AND ADnexAL DISEASE.

DR. CHARLES A. BOWERS, Wichita, Kan., read three more conservative and rational operations on these patients would yield better results and lower the mortality per cent. An exact diagnosis of many cases can only be made upon suprapubic exposure of the vesical outlet. The suprapubic operation can be done

with greater exactness and will yield better results than the infrapubic in morbid conditions in the male, as has been the case in the female pelvis. The suprapubic route is as rationally indicated for the relief of prostatic obstruction at the urinary outlet as it is in vesical calculus. The perineal operation offers only 30% of cures, with a mortality of 7%, and a 50% chance of having exchanged one urinary difficulty for another, and not infrequently a lesser for a greater one. The transvesical operation entirely relieves all who survive it of their urinary trouble, if it is due to obstruction in and about the vesical outlet, except when they are carcinomatous in character, without sequelae; and with the improved operative technique of to-day no greater mortality.

The controversy that is now going on relative to perineal and suprapubic prostatectomy is only a repetition of the one waged when lithotomy was undergoing its evolution. Who-to-day cuts for stone in the male bladder via the perineum? The most essential thing to-day is to bring home the facts to the profession in general. First, that prostatism is due to other causes than hypertrophy of the prostate gland. Second, that the transvesical operation for the relief of prostatism has attained a sufficient degree of perfection to be recommended to this class of pitiable sufferers, with the assurance of a cure if undertaken before the inflammatory process has reached the kidney and arrested its functional activity. Third, patients should not be submitted to catheterism in the future as they have been in the past until it is hopeless to interfere surgically.

DISCUSSION.

DR. HENRY T. BYFORD, Chicago, thinks hypertrophy of the prostate is due to some irritation; that it cannot come entirely from age alone, or from the sclerotic changes which occur with age. In some cases of enlarged prostate he thinks there is a gouty diathesis, and that perhaps the treatment recommended by Fletcher of reducing the calories from 3,000 to 1,500, and dieting the patient a little, might obviate the necessity of suprapubic cystotomy in some cases.

DR. JAMES E. MOORE, Minneapolis, Minn., did his first prostatectomy suprapubically twenty years ago, and as it was done at that time it was a bloody, blind and unsatisfactory operation. When perineal prostatectomy was suggested and practised so successfully a few years ago, he took it up and has been advocating it ever since. He maintains that there are certain cases that can be operated better by the suprapubic route as it is done at the present time. However, in his judgment, a surgeon is not broad-gauged, he does not do the best work he can do until he performs both operations. He believes the perineal route is the choice in the vast majority of cases.

DR. J. W. GRANT, Denver, Col., maintains that in the average case the perineal operation is the more desirable one. In cases in which there is pus, hyaline and granular casts, the perineal route is indicated. The dirty cases can be better and more safely operated through the perineum; the clean cases by suprapubic cystotomy by modern methods.

DR. J. W. ANDREWS, of Mankato, Minn., believes there are selected cases which should be operated by the transvesical route, but in the majority of instances he thinks the perineal route is the better. He has operated eleven times, with one death. One of the operations was done suprapubically. He found it difficult, unclean, and was unable to get good drainage. Lack of drainage is one objection to the suprapubic route, as it is not and could not be as good as it is through the perineum.

DR. M. L. HARRIS, Chicago, says that when one attempts to generalize from a few cases in surgery, the generalizations are always wrong. The essayist, he said, had generalized from 12 cases that the suprapubic route is the only one to adopt; consequently, he thinks he is wrong. There are many cases in which a good and thorough operation cannot be done suprapubically. There are also many cases in which the best operation can only be done suprapubically; consequently, the surgeon must select the best operation for the particular case.

Every case of prostatism should be diagnosed accurately before an attempt is made to select the method of operation, and the surgeon can only make such a diagnosis when he employs all the means at his command, and one of these is a thorough cystoscopic examination.

SOME OBSERVATIONS ON RENAL SURGERY.

DR. D. W. BASHAM, of Wichita, Kan., deals with certain questions with reference to nephropoies and suppurative diseases of the kidney. He points out the reasons why nephrorrhaphy sometimes fails to relieve the symptoms. He discusses the desiderata necessary to make the operation a curative one. He criticises the methods in vogue, and refers to the modifications necessary to make the operation curative by fixing the kidney in a natural position, and of obliterating the enormous pouch resulting from the mobility of the kidney.

He refers to the methods of Jacobson and Edebohl and says that they give permanent results, so far as anchoring the kidney is concerned, but he thinks the kidney is fixed too low in the loin, too far from the center of the vertebral column, and too near the anterior wall of the abdomen. There are many operations which anchor the kidney permanently, but which are open to objection from the standpoint that the organ is not held in the natural position. Surgeons do too many nephropexies without making a thorough and painstaking effort to ascertain the conditions of the kidney, its pelvis and the upper part of the ureter.

DISCUSSION.

DR. WILLIAM JEPSON, Sioux City, Ia., believes there exists a range of mobility of nearly an inch to every kidney that is normally placed. Each case of movable kidney has to be considered by itself. A certain number of them have to be fixed. He is not a firm believer in decapsulation of the kidney, for the reason that it has been demonstrated experimentally that if a kidney is decapsulated, in the course of three or four months a new capsule is formed, and the amount of blood supply the kidney receives from the new source during the time it exists is not sufficient, probably, to maintain vitality.

DR. A. W. ABBOTT, Minneapolis, Minn., says that in a series of over two thousand examinations, only a very small number of kidneys were felt beyond the limits described in text-books, but this is not in accord with clinical experience. There are very few of these patients who present any symptoms referable to the position of their kidneys, largely due to the fact, he believes, that the upper part of the ureter falls with the falling of the kidney.

DR. C. W. OVIATT, Oshkosh, Wis., said occasionally it is necessary to operate on cases of movable kidney. If an operation is undertaken, surgeons should profit by the teaching of Harris, which was promulgated several years ago, of obliterating the space beneath the kidney rather than trying to suspend the organ alone either by the fibrous or fatty capsule. If one simply suspends it, undoubtedly there will be a re-

currence of the displacement. The space beneath the organ should be obliterated by the Harris method, making a new pocket of peritoneum, using a purse-string, as Harris did.

DR. A. E. BENJAMIN, Minneapolis, Minn., lays down three or four rules for fixing the kidney. One is when it shows evidence of hydronephrosis due to a faulty position of the kidney, or to a faulty position of kinking of the ureter, not allowing free drainage. Another is where there is enlarged kidney, congested or dilated, and where it is tender. On examining such patients, one can elicit pain by palpating the kidney. Another condition is where the kidney seems to produce obstruction of the alimentary canal, either of the colon or duodenum, and accessory organs, such as the gall-bladder apparatus, the common bile duct, etc. In such cases the kidney is prolapsed, adherent down in the pelvis, and the patients are troubled with obstipation, and by putting the kidney in position and relieving the adhesions the symptoms will partially or entirely disappear. Patients with a dilated condition of the stomach and a diseased condition of the gall-bladder, when apparently due to loose kidney, are sometimes benefited if their cases are taken early.

CARCINOMA OF THE DESCENDING COLON.

DR. W. W. GRANT, Denver, Col., said that the rectum is the most frequent seat of intestinal cancer. The descending colon is next in order. Cancer of the stomach is more common than that of the intestines, and its progress is more rapid. Cancer of the colon is more common in men; it is not common under thirty years of age. It is primary and circumscribed. Metastasis and constriction are late occurrences. Chronic indigestion, both occasional diarrhea and mucous discharges, are suspicious symptoms. Ulceration is a late occurrence. Floating kidney and membranous colitis may exist a long time without producing marked symptoms or seriously disturbing the health. It is less malignant than the same disease of the stomach or rectum. It is not painful until late. Stenosis is not attended with striking symptoms until obstruction is complete. Mild malignancy and late infection demand radical operation. More care is necessary in examination at an early period, in order to detect disease. He reported a case of long duration. Typhlotomy was followed by radical operation later. He considered the methods of procedure, intestinal anastomosis and results.

DISCUSSION.

DR. I. R. PERKINS, Denver, Col., narrated the case of a woman, sixty-two years of age, whom he saw three weeks ago, in whom there was a tumor in the groin in the region of the cecum. It was supposed by the physician who had charge of the case to be an appendiceal abscess. It was very hard. There was vomiting of fecal matter, and had been for twenty-four hours. He made a long incision in the right rectus and on examination found a hard tumor, but no pus. The appendix was caught in the mass, also the ileocecal valve and a portion of the cecum. He resected the intestine and closed the end of the colon by the use of the Connell suture, then implanted the ileum into the upper portion of the wound. The patient did well except there was a slight leakage at the outer and upper portion of the anastomosis, and a great deal of very small fecal fistula which he thinks will soon close. Another time he believes, he would close the ends of both guts and make a lateral anastomosis.

DR. A. W. ANTONI, Minneapolis, calls attention to one feature connected with cancer. It has been his fortune to see two cases of intussusception in his own practice, and one in the practice of the late Dr. Dugan.

He thinks intussusception occurs in cancer of the large intestine oftener than in the small. He has never seen a case in the small intestine, but has no doubt it may occur. He thinks it is wrong to make an immediate anastomosis in these cases, because they are the ones in which a colostomy should first be made, because the condition about the cancerous area is so extreme that the parts will not unite if one attempts to sew them.

DR. J. L. STUMMES, Omaha, in referring to the location of carcinoma, said that he had found it everywhere in the large intestine, except at the hepatic flexure. In dealing with carcinoma of the transverse colon it is necessary to manipulate the gastrocolic omentum, and unless this is done with the greatest gentleness, one is apt to have a complication following the operation which may be serious, namely, hemorrhage into the stomach. A week ago he removed the transverse colon, for carcinoma, and as a result of manipulation there was a serious hemorrhage for days from the stomach. The speaker's attention was first directed to this complication some years ago following an operation for incarcerated umbilical hernia, in which it was necessary to remove considerable portions of the omentum, and the manipulations were rather rough. The operation was proceeded with without any special difficulty, but it was followed in two hours by profuse hemorrhage from the stomach, from which the patient died.

DR. GRANT, in closing, said he wanted to urge one point, namely, the symptoms of this disease are not pronounced at an early period; but when there are suspicious indications it is very important to use more care in examining these patients than the surgeon is accustomed to do. Under favorable conditions, when the bowels are thoroughly evacuated, the surgeon may discover the presence of a growth in the colon, and this is the time when operation brings about such satisfactory results, and also it is the period when operation can be done at one sitting.

THE CHOICE OF LIGATURE AND SUTURE MATERIAL IN THE SURGERY OF THE PERITONEUM.

DR. H. G. WEATHERS, Denver, Col., said that he no longer uses non-absorbable ligature or suture material for purely serous surfaces. The absolute sterilization of catgut is no longer difficult, and it is now realized that so-called catgut infections usually have their origin in a contamination of the gut through handling or in allowing it to come in contact with unclean surfaces or substances in or about the wound. The chromizing process prolongs the life of even the smaller strands to any desired time, providing the mucous surfaces or serotons are not in contact with it. These features make of catgut an ideal suture and ligature material for intraperitoneal use, and all that becomes necessary is the exercise of due care and skill in the selection of the catgut and the application of sutures and ligatures, and the making of knots. So far, he has had the good fortune never to have had a secondary hemorrhage or other accident from the use of catgut, either in the way of a slipping knot or a too rapid absorption, and he believes this immunity from accident to have been due to the exercise of extreme care in its application.

For about three years he has had great satisfaction in using the Dukes electrolytic catgut suture, a suture in selected cases, then doing away with all catgut and suture material, and using pedicles. For a year he has been using a catgut suture in cancer of the stomach, and finds it ideal. It is easily rapidly and effectively absorbed, and gives the greater security and safety in the management of recurrent early cases. Therefore, he is convinced, one and payment to double that patient operated

upon with the Downes clamp by either the vaginal or abdominal route have smoother and more rapid recoveries, and above all a very noticeable freedom from the intense pain and backache so common after all pelvic operations when the terminal nerves of this region are tied for days or weeks in the bight of a securely lifted ligature or closely applied suture.

He has had one or two experiences with the Downes clamp, however, which lead him to believe that there is increased danger from thrombosis and embolism after its use, occurring occasionally several weeks after operation, and until this doubt is settled he would exercise great care in the selection of the cases upon which it is to be used.

A NEW TECHNIQUE FOR BREAST AMPUTATION.

DR. JABEZ N. JACKSON, Kansas City, Mo., described a new technique for use in radical operation for carcinoma of the breast. The method of operation was devised by him about eight months ago, and has once been used exclusively by him in all cases of the character with which he has had to deal. His experience is limited to 8 cases. He believes that the method has certain elements of advantage, as well as originality, which justify him in presenting it for a wider field of service.

After describing the technique at considerable length, he emphasizes the following advantages: (1) The flap forms a covering for the chest defect, as a rule, without any tension, and thus almost entirely obviates the necessity of grafting, which is so frequent in other methods. He has not found any case operated on by his method that requires grafting. This is not intended to cover cases where there has been extensive previous ulceration, or where one cannot get healthy tissue for a flap of any character. (2) The drawing of the skin up to the arm does away with the fossa axillaris, and thus with the large space which nature would have to obliterate by the formation of scar tissue, with the resultant pressure upon the axillary vessels and nerves. (3) The ligation of all vessels at their nearest point of origin does away with the use of a large number of hemostatic forceps, which cause loss of time, to say nothing of the inconvenience of having a large number of instruments in one's way. He has in no instance used more than one dozen forceps in this operation, and says he can usually do the work with about six. The operation is thus shortened, so that, as a rule, he finds that to complete it requires from forty minutes to one hour or thereabouts. In fact, personally he has never run beyond an hour, even doing the operation slowly, as he has in most cases, for the purpose of demonstrating this new technique, and he has done the operation in a period of time as short as forty minutes. (4) The most noticeable feature to the onlooker, when the operation is done, is the marked absence of hemorrhage, so that it can almost be called a bloodless operation. (5) The entire technical portion of the operation is completed before the chest is exposed by the removal of the breast; therefore, long exposure of an enormous area of raw chest surface, with the attendant shock, is done away with. As soon as the breast is removed, the surgeon is ready to close the wound.

DISCUSSION.

DR. CHARLES A. POWERS, Denver, Col., said the key to the operation described by the essayist lies in the flap which covers the large skin defect. This feature appealed to him. He asked Dr. Jackson whether in any of the cases there has been any sloughing at the corners of the quadrilateral flap. Personally he has been very much pleased with the procedure of Dr. J.

Collins Warren, of bringing up a flap from the arm. The technique of Dr. Jackson's operation is easier he thinks, and said he is going to employ it in the future.

DR. JACKSON, in rebuttal, said that in some instances there has been slight sloughing at the corners of the flap. In recent cases, by using a wide Halsted mattress suture for tension, union was secured without sloughing.

FRACTURES ABOUT THE ELBOW JOINT.

DR. W. D. HAINES, Cincinnati, Ohio, said that the open method of treatment is to be commended in all cases of extensive joint involvement. After freely exploring the joint cavity, freeing it from clot, removing detached spicula, and fixing the fractured fragments, a strip of fascial from the arm may be inserted between the joint surfaces after the method of Murphy in excision or the Mosetig bone filling may be used, with a view to preventing adhesions until sufficient repair has taken place to permit of passive motion. The operation is completed by suturing the capsule, fascia, nerves and skin with ample provision for drainage. The arm should be dressed in the fully extended position, placed on an incline, and a light weight applied. This position and dressing should be changed at the end of one week. After light massage the arm is redressed at a slight angle, and permitted to remain for four or five days, when it is changed to as nearly a right angle as possible without pain to the patient too severely. Subsequent treatment consists of massage and passive motion every third day for a period of three weeks. Local pain and tenderness are given precedence over crepitus by the author in diagnosis. The use of weights to overcome muscular rigidity permits of infiltration, diminished elasticity, interfering rather than assisting in the reduction of these fractures. The proper treatment of pain and swelling accompanying fracture is early reduction and the application of extension, ice, or other adjuvants being deemed advisable. Immediate amputation is reserved for those extensive crushing injuries, such as bumper wounds, in which the circulation and joint are so badly damaged as to be beyond all hope of repair. The author expressed the opinion that fractures about the elbow joint have been over-treated in the past.

TALIPES CALCANEUS.

DR. A. F. JONAS, Omaha, Neb., described a plastic operation for the permanent relief of *ciatricial talipes calcaneus*.

TUBERCULAR PERITONITIS.

DR. T. E. POTTER, St. Joseph, Mo., referred to the etiology of tubercular peritonitis, to the symptoms and diagnosis, giving the more modern views on the subject. An early diagnosis is highly recommended and the physician is urged to be on the alert when there are any symptoms pointing toward tubercular peritonitis. The success in treatment at any age is much greater when the disease is recognized before it has made too extensive progress. In the treatment, the writer gives preference to surgical methods, showing that at least 66½% or more recover in the hands of surgeons, while not more than 33½% recover after medical treatment, by the latest and most approved methods of hygiene and the administration of medicine.

A discussion of the theories as to the benefit of surgical interference was taken up in the paper.

THE TREATMENT OF VARICOSE VEINS.

DR. C. H. MAYO, Rochester, Minn., said that the various operations in use at the present time are necessary from the diverse conditions and symptoms mani-

fested by the disease. The condition is probably from a defect in the vein walls, valves, or enervation. The Trendelenburg operation is deservedly popular, especially for cases of vicious venous circle of the deep and superficial veins of the thigh. Enucleation of the veins in a subcutaneous manner through several short incisions is a satisfactory treatment for the majority of cases. The subcutaneous removal of the internal saphenous from above, at the side of and below the knee, by destroying the main superficial channel and deep communicating branches, is the best method, accomplishing in one operation all that can be obtained by either the Trendelenburg above or the Schede below. Goerlich's report shows 81% of operations as satisfactory, and 16% failures. From experience in 184 cases this seemed a fair statement of the late results from the various methods employed at present, except in the percentage of failures. Dr. Mayo thinks 16% is too high, as many of those not satisfactory are much improved over their former condition.

UNDESCENDED TESTICLE.

DR. A. E. BENJAMIN, Minneapolis, Minn., said that the causes of undescended testicle may be due to improper development of the organ, to a rudimentary vaginal process, to peritoneal adhesions between the testicle and bladder or intestine, and to obstruction of the canal. The testicle may be found anywhere along its course of descent to a point just outside the external ring. Hernia is a common complication of this condition. The organ will not develop as well when located at any point above the scrotum. The possible sterility of the cryptorchid, and the frequency of malignant, tubercular and traumatic disturbances, complicating this condition, all argue for an early operation to place the gland in its proper location. The operation for undescended testicle has been perfected in the last few years. It has been demonstrated that by careful dissection and an occasional sacrifice of the spermatic vessels, the organ will remain in the scrotum.

THE FREE INTERVAL IN MENINGEAL HEMORRHAGE.

DR. F. GREGORY CONNELL, Sahda, Col., reported two cases, one of which he said was quite usual, with an interval of two hours, in which recovery followed operation. The other was one in which the patient retired for the night, five hours after a slight trauma, and was found dead in the morning. Autopsy revealed a fracture, with a large extradural clot from the lateral sinus. This second case was not very rare; but in 80 cases collected by the writer only 2 similar instances were encountered.

The free interval is defined as a practically symptomless period of consciousness, which follows a primary, transitory unconsciousness, and precedes a secondary, increasing and permanent loss of consciousness. This condition is usually found in association with a head injury. The cause of the bleeding is usually traumatism, with or without fracture. Various causes of the free interval are considered, with preference given to Kocher's explanation. The length of the free interval is studied, in an analysis of the 80 cases, the average length being thirty-five hours. The difference between extra and intra-dural hemorrhages is noted, and the long free interval in this series of cases is found to accompany the intradural hemorrhage. But it is stated that much stress cannot be placed upon the length of the interval as a guide to the location of the hemorrhage.

The typical train of events in a meningeal hemorrhage is: (1) trauma; (2) concussion, unconsciousness; (3)

consciousness, free interval; (4) compression, unconsciousness; but this may be variously modified.

In the diagnosis the focal signs are of more value than evidence of injury.

The occurrence of collateral hemiplegia must be remembered. Fractures of limbs, previous paralysis, or congenital attachment of the iris has caused confusion in diagnosis. Contusion, or laceration of the brain, abscess, fat embolism, and other conditions may closely resemble meningeal hemorrhage.

In the 80 cases collected, 52 were operated upon, and 28 were not. After operation there were 39 recoveries, and 13 deaths. Without operative interference, 4 recovered and 24 died.

THE EFFECTS OF OSMIC ACID INJECTIONS.

DR. JOSEPH RILEY EASTMAN, Indianapolis, Ind., said the injection of ten drops of osmic acid in a two per cent. solution into sensory nerve trunks is safe. The likelihood of irritation of the kidney, however, should not be forgotten in cases exhibiting kidney lesions.

Injections into the inferior dental or other nerves should not be made through the mouth since infection of the wound and necrosis may result, with consequent failure in the action of the acid. Immediate relief should not always be expected, notwithstanding the cases of Bennett and Murphy were all immediately relieved. No one of the writer's cases, even those in which the acid was accurately injected into the nerve trunks and into the perineural fat, was promptly relieved, relief coming in from one to two weeks. The observations of Wright on this point, who has had a large experience with osmic acid injections, correspond to those of the writer.

There is very little doubt but that the stretching of the nerve trunk necessarily incident to the injection is productive of good, supplementing, as it does, the action of the acid. There is no good reason why the stretching should intentionally be avoided, except perhaps for experimentation. In the case of small nerves, it will be found exceedingly difficult to inject directly into the nerve trunk, that is, the needle eye will pass to the distal side of the thread-like nerve, or perhaps not enter the nerve substance at all, or, notwithstanding the utmost care be used, the fibers may be so teased apart by the needle point that the fluid will simply be spilt about the nerve. In such a case, in order to bring the acid in contact with all of the fibers, it is wise to clip the nerve so that the end may be bathed in the fluids. The effect of manipulation of the nerve, as by stretching, has not as yet been eliminated as a possible aid to the chemical action of osmic acid; therefore, a general anesthetic should be administered so that neurotomy or section of the nerve may be practised, if desired.

The writer's experiments have shown no other changes in the nerve tissues as the result of injections of osmic acid than the disintegration of fat and oil globules in the perineural space and in the white matter of Schwann, such white matter of Schwann being simply fatty matter in a fluid state, insulating and protecting the essential part of the nerve. The degenerations appearing in the nerve itself are only such as may be attributed to nutritional changes and exposure to the indirect result of the selective action of osmic acid of destroying fat. There is no reason why the fat should not be restored, and the nerve again be once capable of transmitting sensation, that is, the neuritis and the neuralgia may return after injection of osmic acid. Osmic acid injections are uncertain in effect as to the cure or relief of neuralgia. A large percentage of cases of neuralgia may be relieved for months by osmic acid injections. The injection of osmic acid for the relief

of the douloureux is quite justifiable, even if it should become necessary to repeat the injections at intervals of a few months, particularly in view of the unfavorable results of the so-called radical operation. The local irritation produced by the acid and the remote toxic and irritant effects are not serious in their consequences and have no meaning as to the effect of the osmic acid in relieving neuralgia. The solution of osmic acid should be made fresh for each operation, as deterioration is rapid.

(To be continued.)

Recent Literature.

A Manual of Bacteriology. By HUBERT J. WILLIAMS, M.D., Professor of Pathology and Bacteriology, Medical Department, University of Buffalo. Revised by B. MEADE BOLTON, M.D., Expert, Bureau of Animal Industry, Washington, D. C. With 108 illustrations. Fourth edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co., 1012 Walnut Street. 1905.

That a new edition of Williams's well-known textbook was demanded only two years after the appearance of the third edition clearly indicates the favor the book has found. It is well adapted to the needs of the medical student. The section on immunity has been amplified, and records the recent advances made in this subject. There is a good presentation of the theories of Bordet and Arrhenius as well as the better known side-chain theory of Ehrlich. The original photomicrographs of bacteria are excellent. The book contains much information not found in larger and more pretentious works. It is to be hoped that in the next revision *Micrococcus catarrhalis* will be noted and the paratyphoid bacilli more adequately described.

Operative Surgery for Students and Practitioners.

By JOHN J. McGRATH, M.D., Professor of Anatomy and Operative Surgery at the New York Post-Graduate Medical School; Surgeon to the Harlem Hospital, etc. Second edition, thoroughly revised. Illustrated. F. A. Davis Co., publishers. Philadelphia. 1906.

The author claims that this edition was published after a thorough and careful revision. He believes that the new features introduced will greatly enhance the value and usefulness of the work which is intended to combine in a practical manner surgical anatomy and operative surgery, "a knowledge of one being essential for the intelligent study of the other." At the same time he has tried to avoid the introduction of anatomical data which would have no practical surgical value from an operative standpoint.

The book is a royal octavo volume of 628 pages, supplemented by 265 illustrations, many in color and half-tone. The classification of operations is that of the regional anatomist. After a short introductory chapter in which anesthesia, the technic of incisions and sutures and control of hemorrhage are quite concisely discussed, the descriptions of special operations are grouped

under the regions of head, face, neck, tongue, thorax, abdomen and back, rectum, hernia, spermatic cord, testis, etc., urinary system, upper extremity and lower extremity. Under this arrangement operations on blood vessels, nerves, and such widely distributed organs are described when the region in which each specific structure is located is under consideration.

The operative list is a full one and includes many so-called atypical procedures in addition to the operations usually found in the customary school courses in operative surgery. In the section on the abdomen, gastro-enterostomy, the operative technic required by pathological changes in the stomach and intestine, as well as the pancreas and spleen, is described in some detail. Diagrammatic drawings are used for purposes of illustration. Much new and interesting material has been added to the subject matter of this edition. The illustrations assist in a clear understanding of the meaning of the text. Some are excellent and very accurately depict operative detail. By the aid of the appended index and by a system of paragraphing of the text, any particular operation can readily be found. In some operations the final details of operative technic are omitted, as, for example, intravenous infusion, but, as a whole, the book is an excellent one and well worth inspection. To the operative surgeon it is an excellent review of the subject.

The Practice of Medicine. A Textbook for Practitioners and Students with Special Reference to Diagnosis and Treatment. By JAMES TYSON, M.D., Professor of Medicine in the University of Pennsylvania and Physician to the Hospital of the University; Physician to the Pennsylvania Hospital; Fellow of the College of Physicians of Philadelphia; Member of the Association of American Physicians. Fourth edition, revised and enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1906.

This excellent textbook on the Practice of Medicine has reached its fourth edition. In preparing this edition for the press Dr. Tyson has made those alterations in the text which the progress of knowledge demands. The most significant change is a revision of the section on animal parasites by Dr. Allen J. Smith. The illustrations have been improved and amplified, and various minor changes have also been made. The book in general maintains the standard of excellence with which we have become familiar, and will continue to hold its place as one of the recognized best textbooks on general medicine. The section on diseases of the nervous system has been edited by Dr. W. G. Spiller, which is a guaranty of the correctness of its statements. It is, however, becoming increasingly unsatisfactory to include in the limited space permitted so large a subject as the disorders of the nervous system. The typography of the volume is admirable, and the illustrations, although not so numerous as in certain allied books, are adequate and extremely well executed.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, APRIL 26, 1906.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$5.50 per year for all foreign countries (belonging to the Postal Union).

All communications for the Editor and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 207, Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE, Incorporated,
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE DEATH OF PROFESSOR PIERRE
CURIE.

IN view of the recent events which have been happening in the natural world, there is danger that the full significance of the death of Professor Curie to the world of science may be overlooked. His death occurred last week under perfectly avoidable circumstances. Deeply preoccupied, as was his usual habit, he was thrown down and killed by a passing vehicle on a Paris street, which, had he been on his guard, might easily have been escaped. Professor Curie's laboratory assistant on learning the news is said to have remarked, "I knew my dear master would be killed some day. He was very imprudent, and was constantly dreaming when walking the streets."

It is quite impossible to speculate intelligently as to what this extraordinary man would have accomplished had he lived, but in view of what he and his talented wife had already done, it is not hazardous to say that much in the way of scientific discovery was still in store for him. The very great prominence which his researches on radium have given him, within the last few years had not in the least detracted from his scientific ardor nor from the complete simplicity of his life. His career up to his untimely death had been so remarkable and so measureless, unexpected, that much future discovery might well have been predicted.

As a boy he had the reputation of being a prodigy and for this reason was early placed under the care of a private tutor. The preparatory studies leading up to the degree in arts were wholly congenial, and he gave no promise until his mind

was allowed to enter upon the subject of abstract science. His devotion to the scientific exploitation of radium has made one of the most romantic chapters in the history of modern science. To it he has given all his time and energy, and has not been tempted or distracted by the offers which have been made him to better his social or financial position. For example, he declined the decoration of the Legion of Honor and rejected an offer of five hundred thousand francs for a small quantity of radium which he had laboriously gathered together. The Nobel prize he accepted merely that the money it brought might be devoted to further research. He finally, in 1905, accepted a chair at the Sorbonne, but only on condition that a laboratory should be there furnished where he, together with his wife, might continue their investigation. The documents relative to this laboratory were issued on the very day upon which he was killed.

In Professor Curie's death the world loses a man whose achievements already had placed him in the forefront of the discoverers in science, and also one who will stand as the best type of a disinterested man of science. It is to be expected that Madame Curie is conversant with the work in which he was engaged at the time of his death and that she will not only carry this to a conclusion, but also inaugurate further researches in the line in which both were masters.

THE DANGER OF EPIDEMIC DISEASE IN SAN
FRANCISCO.

NOW that the first shock attending the disaster at San Francisco has passed, many interesting and important problems will present themselves regarding the immediate future. That the city will be rebuilt there seems to be no question, but the situation presenting itself before active operations in this direction can be begun will no doubt prove even more difficult of solution than actual reconstruction. The practical destruction of the entire San Francisco waterfront, apart from the larger section to be repaired and exposed, is a serious and unique emergency. It means the possibility of epidemic disease and, therefore, the most urgent measures to prevent the outbreak of such a disease among the people from the great concentration of bodies of the thousands of the homeless and the great numbers of the homeless who are now crowded into the few remaining habitable structures. The health authorities have been very busy in the past few days in the preparation of plans for the disposal of the bodies of the victims of the disaster. These measures are being carried out with the utmost efficiency and the health authorities are doing all that is possible to prevent the outbreak of epidemic disease. The health authorities are also doing all that is possible to prevent the outbreak of epidemic disease. The health authorities are also doing all that is possible to prevent the outbreak of epidemic disease.

averted, but only through the most vigilant care, and co-operation on the part of the people who remain in the city or its neighborhood during the coming months.

It has long been recognized that plague has had a definite, though often extremely insecure, foothold in the Chinese quarter of the city. Revelations regarding the extent and character of the dwellings of these people have come to light as a result of the fire and general destruction. No doubt, from a sanitary standpoint, the city ultimately will be greatly benefited by the annihilation of the Chinese quarter. The possibility also exists that the infection of plague, now generally recognized to be conveyed by rats, might, under favorable circumstances, be disseminated beyond the region in which it has hitherto found a foothold. Although we have not the slightest idea that this is a real menace, it is no doubt desirable to be forearmed against it, should it by chance occur. In general, the developments of the next few weeks will be regarded with interest by the medical profession at large, and particularly by those especially concerned with the large problems of sanitation and prophylactic medicine. The relative order which has already been developed out of chaos through the efforts of General Funston and his assistants is sufficient evidence that no stone will be left unturned to prevent the avoidable consequences of the far-reaching disaster.

HUNTING AS A MEDICAL SIDE ISSUE.

In view of the forthcoming meeting of the American Medical Association and the means under consideration for the entertainment of the members, it is interesting to call attention to plans being made for the meeting of the British Medical Association, which this year is to be held in Toronto, Canada, from August 21 to August 25.

The *British Medical Journal*, in its issue of April 14, publishes a communication from its special correspondent on "Sport in Canada," under the general heading of the "British Medical Association." The opening sentence of this readable article is somewhat characteristic of the British mind: "The following notes on shooting and fishing in Canada have been compiled for the information of those who have it in mind to end off the scientific work of the meeting at Toronto by a sporting holiday. The temptations to do so are very great for the facilities for shooting and fishing in Canada are unrivalled." Following this tempting introduction is a series of brief

statements regarding the possibilities of the various portions of Canada as regards game, both large and small. As stated in another place, "the shooting possibilities of Canada cover anything from a snipe to a wild turkey and from a hare to a moose or a bear."

The efforts which this city is making toward the entertainment of its guests in June, so far as we know, do not include the possibility of hunting or fishing, except, possibly, on an extremely small scale. We suspect, in fact, that such entertainment has rarely been offered before in connection with a medical meeting. It goes far toward showing how diversified a function one of these great medical gatherings has become. The scientific pabulum is still served, but its importance is certainly being encroached upon in divers ways. We are inclined to think that the attendance at the British Medical Association meeting will be increased by the possibilities which this correspondent suggests. We have also no doubt that the coming meeting of the American Medical Association in Boston will find its attendance swelled by the fact that other meat than pure science is to be offered for its entertainment.

MEDICAL NOTES.

PATHOLOGIST AT THE CRAIG COLONY FOR EPILEPTICS. — It is announced that Dr. J. F. Munson of the University of Michigan has received the appointment of resident pathologist at the Craig Colony for Epileptics at Sonoma, N. Y. This position was formerly held by Dr. Onuf, who did much to develop the pathological work in epilepsy.

ANNUAL REPORT OF THE OHIO HOSPITAL FOR EPILEPTICS. This report states that on Nov. 16, 1904, there were 982 inmates in the institution and that during the year recently ended this number had increased to 1,328 under care during some period of the year. It is expected that this number will be still further increased in the future and that the next two years will see a demand for accommodations for 1,400 patients. These statistics are further evidence of the widespread interest in the treatment of this disease at special hospitals.

YELLOW FEVER INVESTIGATION. — The report of Working Party No. 3, on attempts to grow the yellow fever parasite and the hereditary transmission of the yellow fever parasite in the mosquito, has been published. The work was done by Dr. M. J. Rosenau and Joseph Goldberger.

The attempt to grow the yellow fever parasite was not successful, nor were the authors able to confirm the results of Marchoux and Simond regarding the hereditary transmission of the virus of yellow fever in the *Stegomyia fasciata*, who claimed to have shown that the progeny of a mother directly infected by a case of yellow fever are themselves infected hereditarily.

EXPLOSION OF A RADIUM TUBE.—In the current number of the *Medical Record* Dr. Robert Abbe of New York gives an interesting experience regarding the explosion of a radium tube. Since December, 1905, he had had fifty milligrams of pure radium bromide in a small glass tube hermetically sealed. On March 20, on attempting to remove the tube from its receptacle, the glass was pressed in such a way that it exploded with a loud report and a large proportion of the radium fell to the floor. By means of Röntgen photography it was possible to localize the exact position of the radium on the carpet. A portion of the carpet was carefully beaten out and further photographic tests showed that all the radium had been recovered. Dr. Abbe will hereafter keep his specimen sealed in a tube into the end of which is fused a fine platinum wire to permit the discharge of the stored up positive electricity. The danger of explosion in the careless handling of radium tubes has before been observed. The extraordinary value of the element renders precautions of every sort desirable. It is, however, gratifying to know that should such an accident happen, the radium may again be recovered and is not likely to be widely disseminated on account of its high specific gravity.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, April 25, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 36, scarlatina 50, typhoid fever 7, measles 120, tuberculosis 38, smallpox 0.

The death-rate of the reported deaths for the week ending April 25, 1906, was 20.42.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending Saturday, April 21, 1906 was 246, against 214 the corresponding week of last year, showing an increase of 32 deaths and making the death-rate for the week 21.56. Of this number 120 were males and 126 were females; 239 were white and 7 colored; 156 were born in the United States, 86 in foreign countries and 1

unknown; 49 were of American parentage, 172 of foreign parentage and 25 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 33 cases and 2 deaths; scarlatina, 39 cases, 2 deaths; typhoid fever, 6 cases and 1 death; measles, 156 cases and 3 deaths; tuberculosis, 48 cases and 29 deaths; smallpox, no cases and no deaths. The deaths from pneumonia were 41, whooping cough 3, heart disease 17, bronchitis 5, and marasmus 7. There were 13 deaths from violent causes. The number of children who died under one year was 48; the number under five years, 70. The number of persons who died over sixty years of age was 52. The deaths in public institutions were 64.

There were 1 case and 2 deaths reported from cerebrospinal meningitis during the week.

A POSSIBLE DANGER TO THE BOSTON CITY HOSPITAL RELIEF STATION. There is under discussion the question of running the extension of the Washington Street Subway under part of the Boston City Hospital Relief Station in Haymarket Square. The present subway runs under a corner of this building and causes a very perceptible vibration.

PREVENTION OF CONSUMPTION IN NEW HAMPSHIRE. The current number of the *New Hampshire Sanitary Bulletin*, which is published quarterly by the State Board of Health, is devoted to a popular consideration of the prevalence, cause, restriction and prevention of consumption. The object of this type of publication is that through general distribution among the people of New Hampshire a knowledge of the measures necessary to the restriction and prevention of consumption may be widely disseminated. The publication should certainly accomplish this end through its general arrangement and the easily understandable character of its subject matter.

NEW YORK.

HOSPITAL CONFERENCE OF THE CITY OF NEW YORK. Representatives of thirty-eight hospitals, at a meeting held at the New York Academy of Medicine on April 18, adopted a permanent organization for what is to be known as the Hospital Conference of the City of New York. Its purpose is the promotion of economy and efficiency in hospital management by the comparison of methods and results, and to this end the various institutions were notified to send in to the secretary detailed statements of their work and ex-

penditures. All the principal private hospitals, with the exception of the Presbyterian, have already joined the Conference, and it is stated that the public hospitals of the city will shortly be invited to obtain representation in it. Any hospital with not less than thirty free beds is eligible to membership on payment of the annual dues, \$5.00, and this entitles it to two representatives in the Conference. The following officers were elected: President, Rev. George F. Clover, St. Luke's; vice-presidents, R. H. Townley, J. Hood Wright Hospital, and Mrs. A. M. Lawson, General Memorial; secretary, Dr. S. S. Goldwater, Mount Sinai; treasurer, Dr. A. H. Harrington, New York Eye and Ear Infirmary. There is also an executive committee composed of seven members.

FRESH AIR WORK.—A conference of fifty organizations interested in fresh-air work was held at the United Charities Building on April 18. Addresses were made by President Darlington of the Health Department, Dr. John J. Cronin, chief inspector of schools for the department, and others, and the following resolution was adopted:

"Resolved, That this Conference considers it desirable to establish a bureau of application, to be composed of representatives of fresh-air agencies and of public schools, and to establish and maintain a card catalogue to be open to the use of all those interested in fresh-air work; secondly, that the fresh-air agencies communicate with the public school principals in the months of May and June, to discover children truly deserving but otherwise not reached."

Another resolution was adopted calling on the mayor to give his sanction to the Saxe bill, now pending at Albany, under the provisions of which the city would be empowered to appropriate \$2,500,000 for the purchase and establishment of a seaside park and home for convalescents.

A HEAVY VERDICT FOR PERSONAL INJURIES.—Capt. Alexander De Noyelles, of Watervliet, N. Y., obtained a verdict in the United States Circuit Court at Syracuse, N. Y., on April 11, against the New York, New Haven & Hartford Railroad Company for \$20,000 damages on account of personal injuries resulting from the company's negligence. The action was brought in a Federal Court for the reason that the railway company is incorporated in another state. The case is of unusual interest for two reasons: First, because the verdict is believed to be the largest of the kind ever awarded in a Federal

Court in New York State; second, because of the differing views of contributory negligence held by the Federal and State courts. At the time of the accident by which he was injured Captain De Noyelles was in command of the steamship "Winnie" of the Williams Line. He had just discharged a cargo of lumber on the New Haven docks on the Bronx side of the Harlem River, and was easting off a hawser preparatory to leaving when a tugboat belonging to the railroad company rammed a boat lying outside the "Winnie." By the shock he was thrown between his vessel and the dock and crushed, sustaining injuries which resulted in his total and permanent disability. The defendant road contended that the striking of the outside boat was not the proximate cause of the accident, and that the plaintiff was guilty of contributory negligence. On this point the difference between the Federal and State laws was brought out. It was shown that in the State courts, in a negligence action, the plaintiff must show that he is free from contributory negligence in order to recover damages, while in the Federal courts the defendant, in order to prevent recovery, must prove that the plaintiff is guilty of negligence.

Miscellaneous.

THE INTERNATIONAL CONGRESS AT LISBON.

The program of the entertainments held in connection with the International Congress of Medicine at Lisbon was as follows: On April 19 the inaugural meeting took place at 2 P.M. in the rooms of the Geographical Society, and in the evening the president of the Congress held a reception at the School of Medicine. On April 20 a garden party was given by Sir Francis L. Cook, Visconde de Monserrate. On April 21 the king entertained the principal delegates of the various governments at dinner. On April 22 there was bullock racing at Villa Franca, the journey there and back being made by water. On April 23 there was a *soirée* held by the Geographical Society. On April 24 the king's garden party took place at Necessidades, and in the evening there was a reception held on behalf of the government, to which the delegates sent by the various governments, as well as by schools of medicine and scientific societies, were invited. On April 25 there was a reception of the members of the Congress on behalf of the city. As above indicated, only a minority of the visitors attended the king's garden party and the government reception, but the other entertainments were open to all the members of the Congress. The sittings of the sections of the Congress took place in the School of Medicine from 8.30 A.M. to 2 or

3 p.m. on April 20, 21, 23, 24 and 25. The general meetings were held on the afternoon when no entertainment was provided.

Correspondence.

A SYSTEM OF CLINICAL RESEARCH DIRECTED PURELY TOWARDS THERAPEUTIC ENDS.

CAMBRIDGE, April 19, 1906.

Mr. Editor: Since the mention of my name in your editorial of April 5 counts me among those who "stand out on the basis of a single therapeutic principle," to whose sectarian perverseness you attribute the difficulties in the way of a solid front on the part of legitimate medicine "against the encroachments of manifest quackery," perhaps you will allow me the needless space to define my position, and that of some who unite with me, on the special points to which you refer so discouragingly. On these points I trust there may be reasonable discussion without reopening the old homoeopathic controversy.

The points referred to are those touching the feasibility of instituting a system of clinical research directed purely towards therapeutic ends. Hitherto, as you may be willing to admit, all clinical research has concerned itself mainly with questions of pathology, from which it is held that therapeutic measures flow by *a priori* reasoning. Within limits this is true, but beyond the province of surgery in its widest sense, these limits are—as the present state of therapeutics abundantly shows—exceedingly encircled. You will hardly deny that a very large proportion of all therapeutic measures, as applied to internal diseases, are purely empirical, or that within the field of pharmacotherapy the number of remedial agents other than those of empirical origin and application is deplorably small. In fact, there is no exaggeration in declaring the thought of the helplessness of the profession with no other aids at its command, save those derived from scientific knowledge, to be fairly appalling.* And here it cannot be out of place to remind you that empirical remedies in no wise change their character from the fact of their being prescribed by scientific men. On this point there exists, both within and without the profession, a very widespread and most pernicious error which it is one of the numerous functions of homoeopathy to aid in correcting.

Since you are clearly unfamiliar with the principles, history, literature and aims of homoeopathy, you must allow me to point out to you that this method of treatment deals with drug effects, the mode of action of which is for the most part unknown. These drug effects are those, both objective and subjective, produced in the healthy organism by drug poisons, and those found by experience to follow remedially in abnormal states on the exhibition of drugs under certain conditions. Here you will observe it to be a grave mistake to declare, as you do, for example, in the Address in Medicine before the Congress of Arts and Sciences at St. Louis in 1904, that homoeopathy had its origin like some other therapeutic medical systems, in speculative philosophy. Homoeopathy, in point of fact, had its origin purely in experience, partly in the experience of the profession, where Hahnemann's rare condition enabled him to trace at thought, at all available medical literature, and partly in the experience of the people from which some of the better therapeutics have sprung. If you will visit the truly excellent first edition of the *Organon*, you will find some twenty pages of such evidence, and a very useful introduction upon which to rest, without need of speculation or hypothesis, the case against the *a priori* reasoning for the elimination of error, and the establishment of a firm and positive foundation for a system of research in determining the effects of drugs on the healthy organism.

Here was the first, as it has remained the last, step in the * This may be safely said despite the fact that the present representation of the Relation of Therapeutics to other Sciences in the Nineteenth Century, by Prof. Laessle, in the *Scientia Medica et Pharmaceutica*, Internat. Congress of Arts and Sciences, St. Louis, 1904.

tion of the scientific method to pharmacotherapy, the same method which, in that field, you so persistently reject, although you so fully appreciate its value in all other departments of medical research.

You must pardon the mention of these points here despite the fact that they touch so closely on matters in controversy. As they are matters of fact, however, they call for no further discussion. Beyond them it is needless to go, for therein lies the region of theory and hypothesis on which it is idle to venture. If you will accept the scientific method as a legitimate means of building up therapeutic knowledge, we shall be on common ground from which to proceed towards further understanding. We do not declare it to be the only method of reaching therapeutic knowledge, but we do hold it of the first importance in dealing with all those countless instances of prompt and unexplained recovery, improvement and relief which have followed, and may still be seen by conscientious observers to follow, the exhibition of such remedies, the effects of which bear a close resemblance to the objective and subjective phenomena occurring in the great majority of such maladies as are capable of being favorably influenced by treatment.

Here is the fundamental point on which all other issues turn, including those of our reluctance to abandon our "separate school of practice with separate medical foundations and hospitals and all the appurtenances which go therewith." In the last analysis they are all reducible to the question of correct or faulty observations, and here alone can the test of soundness be applied. We fully agree with the distinguished author of the Address in Medicine above referred to, that all sound medical philosophy must rest on science, but science must rest primarily on facts. Generalizations and theories must follow later. They are indispensable, but may be disregarded here. What we ask first and foremost is that the facts, or, if you prefer, the observations, on which we found our law shall be subjected to well conducted clinical research before the majority of your "thinking men" shall be justified in their "attitude towards homoeopathy that its law has not been proved." Is anything in medicine, more particularly in therapeutics, proved or disproved without the scrutiny of facts? You do not believe in homoeopathy. We believe in it. Is it not fair to ask whether your skepticism has more sound to value than our credulity, despite your majority of "thinking men"? In fact, may we not claim to hold the stronger ground since we are able to marshal a large array of facts out of your own most modern literature bearing the contradiction we put upon them and thus showing the best evidence possible against your belief, while you have nothing to add your bald denial?

But neither believe nor disbelieve on of value in questions of science, however much they may influence practice. They are in point of fact, worth only so much as now, in this twenty-first century, when so often we are found to escape from the old certainties of our fathers, there are some efforts to be made to get the most trustworthy conditions to determine the objective or subjective effects of certain declared therapeutic measures, and our expectations.

We have no quarrel with the importance of looking at the great picture of the human organism as a whole, but we hold that the most intelligent method of doing so is not to regard the organism as a whole, but to regard it as a series of parts, each of which has partaken of the general picture, and for the purpose of which a very complete organization of the parts must be maintained. We hold that the only way to get the most trustworthy results is to get the most trustworthy facts, and that the only way to get the most trustworthy facts is to get the most trustworthy observations, and that the only way to get the most trustworthy observations is to get the most trustworthy clinical research.

With very truly yours,
W. W. WESSCHOTT, M.D.

CHANGES IN THE MEDICAL CORPS U. S. NAVY
FOR THE WEEK ENDING APRIL 21, 1906.

C. D. LANGHORNE, surgeon. Ordered to Washington, D. C., for duty in attendance on course of instruction at the Naval Medical School.

E. L. WOODS, assistant surgeon. Ordered to the Naval Academy.

H. T. NELSON, JR., assistant surgeon. Detached from the Naval Academy and resignation accepted to take effect April 14, 1906.

T. N. PRASE, assistant surgeon. Detached from the "Columbia" and ordered home to wait orders.

F. H. BROOKS, assistant surgeon. Ordered to the "Columbia."

W. F. SCHALLER, assistant surgeon. Ordered to the Naval Hospital, Mare Island, California.

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The annual meeting of the Suffolk District Medical Society will be held at the Boston Medical Library, Saturday evening, April 28, at 8.15 P. M. Dr. Walter E. Fernald, Superintendent of the Massachusetts School for Feeble-Minded, will read a paper on "The Feeble-Minded in Massachusetts," with stereopticon illustrations. Light refreshments after the meeting.

L. R. G. CRANDON, M.D., Secretary.

APPOINTMENT.

MR. E. D. COOMAN has been reappointed a trustee of the Boston City Hospital for a term of five years.

RECENT DEATHS.

DR. MATTHEW T. GAFFNEY, of Newark, N. J., died on April 16. He was thirty-six years of age, and was graduated from the College of Physicians and Surgeons, New York, in 1897.

DR. JOSEPH HEDGES, a retired physician of Newton, Essex County, N. J., died on April 14 at the age of seventy-eight years.

DR. CHARLES FISK died at Greenfield, Mass., April 21, aged seventy-five years. He graduated at the College of Physicians and Surgeons in New York and had been in practice in Greenfield for fifty years. He had been a vice-president of the Franklin District Medical Society, and at one time was chairman of the Board of Health.

BENJAMIN HENRY BURRELL, M.D., M.M.S.S., of Roxbury, died in Denver, Colo., April 23, 1906.

BOOKS AND PAMPHLETS RECEIVED.

Studies from the Rockefeller Institute for Medical Research. Reprints. Vol. IV. 1905.

Diseases of Metabolism and of the Blood. Animal Parasites. Toxicology. Edited by Richard C. Cabot, M.D. An authorized translation from "Die Deutsche Klinik" under the general editorial supervision of Julius L. Salinger, M.D. Illustrated. New York and London: D. Appleton & Co. 1906.

Address.

THE PHYSICIAN'S DUTY TO HIS FELLOW-PRACTITIONER AND TO HIMSELF.*

BY WALTER LINDLEY, M.D., LL.D., LOS ANGELES.

The physician's duty to his fellow-practitioner and to himself makes the complex subject of my talk to-day.

The physician should be an educated gentleman. It is too late to talk to you of the Senior Class in regard to your own preliminary education. The die is cast as far as that is concerned, yet you will have your influence on many young men who are to follow in your footsteps. Urge all to secure a well-founded general education before beginning their professional course. The medical student who has the education that is represented by the degree of A.B. or B.S. is to be congratulated. The time will soon come when at least an experience of two years in a college of liberal arts will be required to gain matriculation in any reputable medical college. Speed the day.

Mathematics, English, Latin, Greek and chemistry are the foundation branches. Botany and zoology are both important. If any of you are unfortunate enough not to have had a well-rounded preliminary education, then you should take up at least two of these studies with a tutor or a correspondence school and keep on until you have secured that education that is expected from a gentleman in one of the learned professions.

Become thorough in the metric system of weights and measures. Learn to write your prescriptions in that system. This is very difficult for the elderly physician who was not taught this system, but you young men must learn it. Try to get to thinking in the metric system. The metric system has come into my life so recently that I have to translate kilogram into pounds and ounces and meter into inches before I have a real conception of how much they mean.

The metric system originated in France in 1790, and has been adopted by forty-two other countries, i. e., by all civilized and semi-civilized countries, excepting Great Britain, the United States and Russia. It was adopted by the United States Pharmacopoeia of 1890, and is largely used in many sections of the United States. It is generally conceded that the system, while simple and uniform, affords a facility of computation which renders it superior to all other systems of weights and measures.

1. It is orderly, clear and logical.
2. There are no specific trade tables, such as avoirdupois, wine measure, grain measure, etc.

3. The single ratio of ten is involved, thus making calculations extremely simple.

In order to minimize difficulties in writing prescriptions, as far as possible it has become the custom in things medical to use only two metrical terms, the gram (gm.) and the cubic centimeter (cc.).

Every first-class pharmacist thoroughly understands the metric system. It would pay you well to practice writing prescriptions in the metric system ten or fifteen minutes every evening. You do not need a teacher for this; you can teach yourselves.

Take advantage of every opportunity to learn the Spanish language. Mexico invites us, Panama will be the great avenue that we will travel. The South American republics will be brought nearer and nearer to us. The Philippine Islands and Porto Rico are part of the United States, while our relations with Cuba are bound to always be intimate. It is a beautiful, musical language. Learn it and there will be opened to you many doors to success that would otherwise be sealed.

If you have limited means, begin now and select book by book a general library. Spend an hour now and then in a second-hand book store, and get your Hugo and Goldsmith, your Eliot and Johnson, your Macaulay and Tennyson, your Dickens and Tolstoi, your Poe and Swinburne, and your books of reference. Buying your library this way, you will love each book as it comes to your grand salon where the old masters are your guests.

In regard to your medical library: Do not spend much money on it. Do not buy any systems of medicine to be paid for on the installment plan. Those installments will be sure to come due just when you are in the greatest financial stress. Systems of medicine are generally a delusion and a snare. Buy one good book now and then, not too often. Study what you do buy. Take at least two medical journals, one weekly and one monthly. Then, if you can afford it, take one special journal on surgery, obstetrics, nervous diseases, or whatever line you are most interested in. Keep ample notes of all your cases. These notes will make your most valuable library.

Whenever you have an interesting case, write it up for your medical society. Read and speak before your society whenever you can. Take occasion to speak briefly and concisely in public as often as possible. Practice public speaking on every possible audience. Naturally you may be ever so diffident, but you can soon educate yourself to think on your feet and to express yourself in a clear and interesting style. Speak slowly, enunciate distinctly, and pitch your voice according to the hall in which you may be speaking are the three cardinal points in delivery.

Financially you must have a little money, not too much, and then invest your savings judiciously. Do not be miserly, but live according to your station in life, even though it may be some time before you can save anything. Never keep over \$1000 in a savings bank. Savings banks are good for old women and children. Never invest your money in outside enterprises, like mercantile or manufacturing companies. Do not buy a farm. Do not invest in mining stock, oil stock, rubber plantations, or any of these big enterprises, the end of which no person can foresee. The best investments are town or

* Lecture delivered to the senior class of the College of Medicine of the University of Southern California.

city real estate, bank stock, township, city, state or national bonds. Go in debt for a lot. Study the location of the lot and be sure that you invest in the line of growth.

Very few men make money without going in debt. Do not go in debt for more than you know you can pay, and, when you do go in debt, pay, if it takes you years. Never speculate. Never invest in anything that is going to pay "big." Such propositions are invariably a gamble. Never go security for any man.

Do not be in a hurry to marry. The medical student, the interne, the young practitioner is very likely to be, to use the language of Balzac, "Like all unprotected boys, he loves the first woman who throws him a kind look." Wait until you have settled into a substantial practice, until your judgment is mature, until your tastes have become discriminating. Let me urge you to summon all of your will power to resist that youthful tide of passion that sweeps so many young men off their feet and results so frequently in an unfortunate *mésalliance*. The professional man has no time for marriage before he is thirty. If he graduates young, there is all the more reason that he should devote himself to post-graduate study instead of occupying his time with the anxieties, cares and affections of his wife and his offspring. It is due those who employ you in your sacred calling that you give these early years to professional preparation and that you, for the time being, sacrifice your personal desires for the felicities of domestic life. Marry, by all means; marry some good, pure woman, loyal and true, but do not marry until your education is somewhat rounded in practical experience, and you are thoroughly established professionally.

Attend to your patients carefully, thoroughly, conscientiously; charge reasonably; save and invest conservatively. By so doing, if you have health, you will accumulate a competence and may eventually become financially independent.

Your duty to your fellow-practitioner? Act as one gentleman naturally would to another. Rules and codes of ethics are only necessary for those who have not the instincts of gentlemen. Never envy another physician. There is just one way that you are justified in taking patients from another doctor, and that is by being better qualified than he. Yes, there is an additional thing you may do, and that is to be faithful in your office hours.

You should get the good will of the community in which you live. Become a part of that community. Attend the club, the church, the lodge. In other words do your part in carrying the burdens of your community. Take some part in the political party whose tenets come the nearest meeting your approval. All of these things you should do through patriotism and not through policy.

Take an active part in the medical societies. If you will attend regularly, read a paper whenever called upon, report cases, take part in discussions whenever opportunity offers, you will

find that your society is really a post-graduate school.

Help make your medical society; help build it up.

In your society, in your town and in your state be history makers. The intelligent physician is always expected to be a leader. Let your leadership be for the best interest of your profession and for the best interest of the community in which you live.

Do not be narrow and hide-bound in regard to the medicines you prescribe or the men with whom you consult. Take the homeopathist, eclectic, or masseur on his merit. Some of the best ideas a young practitioner will get come from some good old lady who has raised a family of children. Do not despise the fruits of experience. Sometimes these old ladies may puzzle you with questions. Just be deliberate about answering and they will answer their own questions. This method never fails.

There is a great deal being said now about not prescribing so-called proprietary medicines. You simply prescribe what is best for your patient, regardless of the preaching of the zealot who proposes that every person else must follow in his own narrow, contracted path.

In entering a new town you had better call on all of the physicians, if it is a small town, but if it is a city, call on the officers of the medical society and a few of the leading men.

Be ready to call in a consultant in every serious case, and in all cases where the patient or his friends show the least desire for additional advice. It is dangerous to tell a patient that you are willing to call in any person he wants. Tactfully endeavor to have some person called who is able and honorable. Do not start into a consultation determined that it shall be a mere form and with your mind irrevocably made up. Put yourself in a receptive state. Try to avoid discussing the case before the patient. After your consultant has examined your patient, you should both retire and privately decide the course of treatment to be pursued. In regard to the fee: It is very nice for the attending physician to collect the consultant's fee.

Do not be jealous and suspicious of older practitioners. Maeterlinck says: "A man who is good attracts with irresistible force events as good as he." If you are suspicious and envious of your fellow-practitioners, your own course will make them suspicious of you, and soon you will be working at cross purposes, and men who should be your friends will become your enemies.

In a recent address on "The Ideal Doctor,"¹ Dr. David W. Cheever, the Boston surgeon, who is really himself America's ideal doctor, said: "Altruism is sacrificing self to others, and egoism is sacrificing others to self. The relations between doctor and patient are so peculiar as to require a blending of altruism and egoism, of self-denial and self-assertion. . . . The ideal doctor looks after the interests of his brother physicians: he says no evil. . . . He who has a

¹BOSTON MEDICAL AND SURGICAL JOURNAL, Nov. 10, 1904.

healthy body, he whose mouth is shut, whose heart is kind, whose intentions are sincere, who does his best, who treats his patient as himself, who looks after justice as well as mercy in his dealings, is altruistic and egoistic both, is the ideal doctor." "Whose mouth is shut," -- do not ever permit yourself to be drawn into making an adverse criticism of a fellow-practitioner. It lowers you in the eyes of all who hear you. Although you might be honest in your criticism, yet there is a possibility that you may be unjust, because you cannot place full credence in what the laity tells you a certain doctor may say or do. If you are told that a brother physician has done you a serious injustice, do not believe the story, but go and see him and tell him the report.

The young physician without a *clientele* is likely to be hypersensitive and shut himself up in his shell whenever the older, prosperous practitioner approaches. Many times this extreme independence or false pride prevents the successful older man from extending a helping hand. Almost every busy practitioner wants several understudies. "I do not want to be a satellite to Dr. Jones," the stiff-necked young fellow may say. That is a bad spirit. While you are a "satellite," you will have an opportunity to gain knowledge, to gain experience, and to gain an acquaintance that will give you Dr. Jones's overflow, and thus will lay the foundation for a practice of your own. This may come slowly, but it will come.

To lay down rules for the conduct of gentlemen in their relations with each other is puerile. It is sometimes necessary to tell bores how to imitate gentlemen. The effort at imitation is laudable, but always transparent. The foundation of all ethics is the golden rule. When you enter the active practice of your profession, do so with the determination that you will deal mercifully, fairly and honorably with all people, and you will never need to study any code of ethics. For the sake of yourselves and your happiness in life, carry yourselves so that you will each day do the work that comes to your hand in the most thorough, unostentatious and beneficent manner possible, and you will thus leave to your children a noble heritage and add to the prestige and renown of this, your alma mater.

THE TREATMENT OF JOINT DISEASE, BY PASSIVE CONGESTION.

By H. F. FOWLER, M. D., B. S.

From the Orthopedic Clinic, of the Massachusetts General Hospital.

The introduction of any foreign substance into the tissues of the body brings about an hyperemia, and the most minute micro-organism will produce such a response. Thus it comes about that hyperemia is the essential feature in every pathological process. This reaction of the body is a useful effort of nature, and one must therefore

regard hyperemia as the most widespread of nature's healing processes. Nature works to produce a local hyperemia as a means of defense against her foes and accomplishes it either by increasing or by slowing the rate of the blood stream; by an increased rapidity of the blood stream where the process concerns a functional hyperemia which accompanies an increased activity of an organ; by slowing the stream where there is an injury to be made good or new tissue to be built up.

Between the rapidly flowing arterial stream and the slowly moving venous blood there is not only the most fundamental physical but also chemical difference. The rapidly flowing blood retains its fluid portions and its formed elements and sends them forward at an accelerated rate. It will be seen that this is needed in a functional hyperemia, where the increased work requires an increased supply of oxygen and the products of combustion which act poisonously and inhibitingly must be swept away. The slowly moving blood stream, on the other hand, sends its formed elements out into the tissues, where they can assume their activities. The combating of infection and the building up of tissue, therefore, is best served by passive hyperemia. A portion of the body is passively congested when its net-work of vessels on account of some obstruction to the venous outflow is more intensely filled with blood. Thus with few exceptions passive hyperemia is venous in contradistinction to active hyperemia which is arterial.

The first to make use of an artificially produced passive congestion for the purposes of healing was Ambrose Paré, who employed it to develop callus in ununited fractures. The treatment has been enormously extended by Professor Bier of Griefswald, and he has built up a technique which he has used in a vast number of cases. He is a most enthusiastic adherent of passive congestion, and employs it not only in all forms of acute and chronic joint affection, but has even extended its use to acute phlegmons, such as septic infections extending into the tendon sheaths. The method is so firmly associated with his name that in Germany it is always called the Bier Congestion.

The technique as it has been developed by Bier consists in the application of two or three turns of an Esmarch bandage about the limb above the affected joint. It should be applied just firmly enough to constrict the thin walled veins, but not enough to obstruct the arteries, or if at all only to a slight extent. The venous congestion thus induced extends not only through the superficial veins, but also to the deep ones. This is a condition which one can observe with a tourniquet which has been nas applied. When one sees a well developed hyperemia from all the deep tissues, even the bone marrow. The marrow cannot be directly influenced by a constriction around the surface and it must be that the blood is thus seeking a way of return at the wide channels there left open.

By means of more or less tight application of the band, all grades of congestion can be induced, from the light up to the severe. To obtain the mild grade, using a normal arm as an example, the bandage is put about the upper arm so as not to cause the slightest uncomfortableness. At first the veins on the back of the hand and on the anterior surface of the forearm appear prominent. The skin becomes a bluish to a rose color. In the palm a number of small white spots appear. By close application one is able to make out the fine network of veins in the skin. At the end of three hours the appearances continue about the same, except that there is a slight edema on the back of the hand. The pulse is full and strong and by compression with the finger the skin becomes white over the area compressed to immediately fill with venous blood when the pressure is removed. After twenty-four hours edema has extended to the arm. The skin maintains the same blue-red color. The subcutaneous veins, however, have become smaller. Their diminution in size is not due to their concealment by edema, as they are not the fully distended cords they were at first. That no obstruction to the return venous flow exists is shown by the arm becoming white again when it is repeatedly flexed and extended. A very important characteristic is that the temperature of the constricted extremity is made higher. This becomes much more noticeable when the congestion is applied to a pathologically inflamed part, when the temperature is raised several degrees. In contradistinction to the light grade of congestion there is the severe form where the bandage is placed much more firmly. With this form after a few minutes cinnamon red spots appear and these soon coalesce so that the white forearm becomes a cinnamon red color. After ten minutes there is a subjective feeling of weight and prickling, with changing sensations of cold and warm. Small carmine red spots appear in the forearm, which represent small hemorrhages. The limb begins to swell from the edema, which makes its appearance so early. After forty minutes the pain becomes so severe that the constriction can no longer be borne. In this form of congestion the temperature of the skin is lowered. It has been called by Bier the cold congestion in distinction to the lighter grade where the superficial temperature is elevated. This cold congestion is always to be avoided in treatment, as it is dangerous. In the great majority of cases the mild grade is applied, but occasionally where the period is a short one a form just between these two may be used.

For the practical application of the congestion an Esnarch bandage, made just long enough to encircle the limb two or three times at the desired tension and provided with a strap and a buckle at either end, is put just above the affected joint and secured by the buckle when the desired degree of congestion has been obtained. For the protection of the skin a few turns of a bandage may be interposed between it and the rubber. In

order to avoid a stasis of blood in parts of the body which do not need it, the limb which lies peripherally to the infected area may be snugly enveloped in a bandage.

This form of congestion is used in most cases of acute and sub-acute joints, continuously with short interruptions, in the beginning, while later the intervals between congestions are made longer. The greatest care should be taken that the so-called hot congestion is always obtained and that the congested limb is never cold to the touch. This congestion should never cause discomfort, but the patient should be able to go about his accustomed duties and forget the presence of the bandage. This mild constriction, however, is sufficient in an inflamed tissue to bring about a powerful hyperemia with edema.

With tubercular joints stasis is not kept up more than a period of an hour daily. Experience has shown that long periods of congestion produce marked edema and lead to the formation of cold abscess. A little severer congestion is produced in tuberculosis than where the treatment is applied for longer periods. The elastic bandage is placed preferably at a distance from the affected joint; if the wrist, for example, above the elbow. The subcutaneous veins become very prominent and the skin assumes a uniform bluish red color. Towards the end of an hour light prickling sensations appear in the hand, but there should never be discomfort. The portion lying peripherally to the constriction is not enveloped in a bandage. Recognizable edema does not as a rule appear with these short periods of congestion.

Bier was first led to the treatment of tubercular joints by congestion by the observation that in congestion of the lungs in insufficiency of the mitral valve there was relative immunity to tuberculosis, while in pulmonary stenosis where there is a marked anemia of the pulmonary circulation, tuberculosis was very frequently seen.

The most marked action of passive hyperemia in the treatment of joint disease is the lessening of pain. This effect is seen very soon after the application of the elastic strap. The motion of the joint, in so far as it is caused by muscle spasm, is indirectly influenced, the diminution of pain causing relaxation of the contracted muscles and consequently freer joint motion.

There is a killing off or at least a weakening of the infectious virus. The bactericidal effect of congestion is due to the properties of the blood serum, and has been explained by Bier on various theoretical grounds: by an increased number of leucocytes with enzymes wandering out of the congested veins, by the retention of the bacterial products of metabolism which are directly hostile to the organism, by increase by means of these metabolic bacterial products in the amount of the proliferating granulating wall which envelops the organisms and by the increased alkalinity of the blood making it a stronger bacteriicide.

In the inflammatory process the irritant which calls out the inflammation at first produces an increase in the rapidity of the blood flow and then

a slowing down of the blood current takes place, due to some agency which is entirely unknown. The congestion is an imitation of nature's healing process or it serves to strengthen it when nature is lacking, as this slowing down of the current is increased. Absorption is delayed by congestion, but one of the pupils of Bier has shown by experimental evidence that after the constriction is removed absorption takes place with much greater rapidity than before.

Through the kindness of Dr. Joel E. Goldthwait and Dr. Robert B. Osgood, I have had an opportunity of treating a small number of cases of joint disease from the Orthopedic Clinic at the Massachusetts General Hospital. They have almost all been ambulatory ones. In most of the tubercular cases some slight grade of fixation was worn, either a light plaster or a leather support. The proper degree of congestion was applied by ourselves at the hospital and then the patients were carefully instructed and taught how to apply the rubber straps at home. The congestion in these cases was not kept up longer than one hour in the twenty-four. The patients returned for inspection at frequent intervals, when the straps were reapplied to see that the proper amount of congestion was being obtained. The chief dangers in treating tubercular disease is from the formation of abscess and in cases with open sinuses from secondary infection. We have experienced both of these calamities. When considerable edema is produced by the treatment, the danger of abscess formation is greater. When an abscess has formed it is incised and allowed to drain and treatment is during this time suspended. When edema is a noticeable feature of the treatment, the attempt should be made to control it as much as possible by elevating the extremity in the interval of treatment. Great care should be used with open sinuses to prevent secondary infection, and these cases should be handled with the most rigid aseptic precautions.

No rule can be given in regard to the grade of joint tuberculosis which will react under congestion. Often the most advanced disease which will at first sight be considered doomed for amputation will clear up under this form of conservative treatment. Cases with well advanced lung disease or with amyloid will do better with amputation. The treatment must be considered an adjunct to mutilating operations rather than a substitute. It is an individual treatment, and its success depends on the quality of the blood which the individual presents to combat the disease.

In acute or sub-acute inflammations the best results are obtained in gonorrhoeal joints, especially in those which tend to ankylosis or where the inflammation leads to bony stiffness. In these not only the joint but the contiguous structures, especially the tendons, are involved. A relatively weakly applied constriction produces a high grade of congestion. After an hour's application the pain is much diminished or has disappeared, and where formerly the least

motion was painful, one can, after the congestion has been kept on a short time, make cautious passive motion without producing pain. In severe cases we must keep congestion applied ten to twelve hours. When pain is severe during the night the strap can be worn then. The main rule holds here, that the bandage should not produce pain, but should be loose enough so that it is comfortably borne. Fixation apparatus can be applied if the pain is severe. In the interval between the application of the strap the limb should be elevated to reduce the edema which the constriction has produced. After the acute symptoms have subsided, massage and passive motion should be begun to hasten the absorption of the inflammatory products. In chronic hydrops after acute inflammation no benefit can be obtained from congestion.

The duration of the congestion in acute and sub-acute joints other than tubercular depends on the effect it produces. If the patient states that after one or two hours' congestion the pain is relieved and motion is increased, this length of time is sufficient, but if the pain soon returns a longer period of congestion must be maintained.

The cases in detail are as follows:

CASE I. Tuberculosis, right ankle. Boy, sixteen years old, for past seven months had suffered from gradually increasing pain and swelling of right ankle. The joint has been fixed in plaster for two months.

Jan. 28, 1905. The right ankle is fusiform in shape and swelling extends to the base of the toes. The skin is reddened and over the dorsum of the foot pits on pressure. The surface temperature is increased. Measurements about the malleoli, 12 inches. Atrophy of right calf. Passive motion causes pain; 15° of flexion, no extension. No pronation or supination.

X-ray shows blurred shadow of tarsus with irregular outline of ends of bones forming ankle joint. Much bony atrophy. Trabecular structure only indicated. No distinct bony focus. A tubercular affection of ankle joint with periarticular involvement.

Congestion for two hours daily. Plaster fixation.

Feb. 7, 1905. A fluctuating area about the external malleolus has appeared. The congestion produces considerable edema and the leg must be elevated between the treatments. This was one of our first cases and we did not appreciate the importance of not carrying the congestion too far. An abscess formed under the external malleolus and broke on Feb. 28. Congestion was omitted for two weeks until the discharge from the sinus diminished.

March 15. Daily periods of congestion for one hour again resumed.

June 10. Discharge from sinus very slight. Redness of skin has disappeared. No fluctuation and little edema on dorsum. Motions of ankle do not cause sensitiveness. Plantar flexion about 20° dorsed to right angle.

During August congestion was omitted and the foot washed daily in sulpho-naphthol. Congestion again resumed Sept. 2.

Sept. 26. Almost no discharge from sinus. Dorsed flexion to right angle and about 45° of motion in plantar flexion.

X-ray shows considerable regeneration, a nearly round ankle joint, as shown by darker shadow. Bony trabeculae more distinct. The articular surface more irregular in outline, showing that some bony destruction has taken place.

Jan. 6, 1906. Sinus under malleolus has healed. No swelling on dorsum. About 40° plantar flexion. Measurements about malleolus, 11½ inches.

X-ray. Outlines of ankle joint shown by intense shadow, which represents cicatrizing bone tissue. Trabeculae in tibia and fibula more clearly defined.

CASE II. Tuberculosis, left wrist. Boy, twelve years old, who had bruised his left wrist in a fall eight months before. Ever since then the wrist had been swollen. He had been treated during this time with light fixation.

There is a marked family disposition to tuberculosis.

March 18, 1905. On back of left wrist is an abscess the size of a hen's egg. The skin covering the back of the hand is reddened and the palm is edematous. The edema extends into the fingers. The joint is absolutely fixed and the least motion, even in the fingers, produces pain. Measurements over styloids, 8½ inches.

X-ray. Hazy outline of whole carpus. Wide separation of bones by exudation. Atrophy of metacarpals most marked at carpal ends and of radius and ulna at lower ends.

The condition represents a diffuse process involving all the carpus.

Congestion for daily periods of two and one-half hours. Light fixation.

April 1. Abscess broke and congestion was omitted until discharge diminished.

April 15. Much less discharge from sinus on back of hand. Congestion for daily periods of one hour.

May 6. Less discharge from sinus, less swelling and redness of skin. Styloids measure 7 inches. Motions of wrist cause less pain. Flexion to 45°, no extension. Can fully flex two distal finger joints, but no motion at metacarpophalangeal.

During August congestion was omitted and daily soaks of sulpho-naphthol given.

Sept. 5. Superficial redness and tenderness have disappeared and there is no discharge from the sinus. Congestion for one hour daily.

Dec. 9, 1905. Sinuses have completely healed. Passive motion of wrist causes no pain. Styloids measure 6 inches. Motion in flexion, 45°; little extension. Metacarpophalangeal joints can be almost fully flexed.

X-ray. Bony outline of carpus is distinct and the normal trabeculated structure of the bones is visible. Carpal bones are now close together, as exudation between bones has disappeared.

Regeneration process shown in bony reproduction of lower end of metacarpals.

CASE III. Tubercular dactylitis, finger. Boy, two years old, was first seen on Feb. 13, 1905. Six weeks before, the middle finger of the right hand was jammed in a door, and since then the distal joint had been swollen.

The last knuckle of the middle finger is fusiform in shape and is red, tender and painful on motion.

X-ray shows tremendous involvement of soft parts about second phalanx, middle finger, but picture is too poor to show bone lesion.

General hygiene and fixation for finger.

March 13. As there is no improvement, the finger was incised.

May 13. The end of the second phalanx protrudes through an unhealthy looking wound on back of the finger. Since operation it has been dressed and fixed on a splint. It seemed hopeless to save the joint, but it was thought wise to try what congestion could accomplish, and it was applied for periods of an hour daily. Dressed with sulpho-naphthol.

May 27. Bare bone entirely covered by healthy granulation. Splint and congestion.

June 27. Exuberant granulation on finger, which is kept fixed and congestion applied daily.

Sept. 12. Except for small granulating area, finger entirely healed. Splint left off and congestion was omitted.

Nov. 11. Finger completely healed and there is only slight deformity. Good control of terminal phalanx in flexion and extension.

X-ray. Bone shadow of second phalanx of middle finger shows more lime salts than in other bones, and presumably represents bone cicatrix.

CASE IV. Tuberculosis of wrist and ankle. Man, forty-one years old, nine months ago first noticed swelling and tenderness in right wrist and left ankle, which increased rapidly, so that he soon had complete loss of function in both. He has more or less cough, and has lost weight and strength. Spent the previous summer in the country, with much improvement generally, but none locally.

March 13, 1905. Came into the hospital wards. The right wrist is spindle-shaped and over the flexor tendons are fluctuating areas. On the back of the hand is a sinus with slight discharge. There is little motion in wrist joint and almost none in fingers. Much edema of hand and fingers. The left foot and ankle are swollen, the skin is reddened, and there is much edema on the dorsum. Dorsal flexion of ankle much limited, while plantar flexion is freer. Measurements about malleoli, 11½ inches, around foot over scaphoid bone, 12 inches.

X-ray of wrist shows complete necrosis of joint surfaces and of carpal bones.

X-ray of ankle shows marked periarticular thickening, obscuring bone shadow. Irregularity of posterior portion of upper articular surface of astragalus. Atrophy of trabecular structure of lower end of tibia. No definite bony focus, but a diffuse involvement of ankle joint and tarsus.

There is a patch of consolidation at apex of the left lung.

March 20. Congestion of wrist and ankle for one hour, morning and afternoon. No fixation. Ankle and hand are kept elevated between the periods of congestion.

April 27. Congestion has been applied twice daily for one hour. Measurements show a slight decrease in swelling of foot and hand.

June 12. Congestion continued twice a day for hourly periods. Three days ago, preceded by a chill, wrist became painful. The skin over the hand and wrist is red and there is much more swelling. There is a discharge of creamy pus from the sinus on the posterior surface from which a culture of staphylococcus aureus and streptococcus was obtained. There is less swelling in the foot. Measurements about malleoli, 10½ inches and about foot over scaphoid bone, 11½ inches.

The x-ray of the foot shows an absence of any considerable amount of periarticular thickening. Bony outlines more clear. The upper articular surface of the astragalus shows smooth outline. Atrophy of bone structure in lower part of tibia persists, with slight extension into diaphysis.

The right arm was amputated above the elbow.

July 12. Patient left the hospital with amputation wound healed. Congestion omitted since operation.

Jan. 10, 1906. Patient reports by letter. Since leaving the hospital he has been living on a farm in the country, and he has followed out the congestion of his ankle conscientiously. The swelling has nearly all disappeared, and it is no longer hot, as formerly.

Jan. 1 he stood erect with his heel on the ground and bore all his weight on the foot for the first time in fourteen months. Since then he has walked on it several times with very little pain. No fixation has been worn.

CASE V. Tenosynovitis, extensor tendons, both wrists, tubercular. Woman, twenty-one years old, for two years has suffered from an obstinate tenosynovitis of both wrists. She had been treated without improvement by intermittent fixation during this time. She had previously had an affection of the right knee which was thought to be tubercular.

May 16, 1905. Both wrists are slightly swollen, the right more noticeably, and there is much pain on motion. On motion of fingers and wrist there is palpable crepitation over extensor and flexor tendons. Passive motion, left wrist, 45° in flexion; 20° extension; 20° adduction; slight abduction.

Right wrist, 20° in flexion, 10° extension, 10° adduction, no abduction. X-ray was negative. Light fixation of both wrists. Congestion for three-hour periods daily.

June 10. No pain on motion of wrists. Much less swelling in right, none in left. Motions of right wrist, 50° flexion, 45° extension. Those of left almost complete. Fixation of left wrist omitted. Congestion of both for three hours daily.

Aug. 13. Left wrist remains without symptoms. The right still has intermittent periods of pain, and there is slight swelling in extensor tendons. Fixation continued. Congestion kept up for daily periods of three hours.

Oct. 17. Motions of both wrists free, without symptoms. Fixation omitted. Congestion continued.

Nov. 16. No symptoms. Exercise with Zander machines. Congestion omitted.

Dec. 5. Both wrists show normal amount of motion. There is slight crepitation over right extensor tendons on motion of fingers. Has no pain and uses both wrists without symptoms.

CASE VI. Infectious arthritis, left elbow, gonorrheal. Woman, twenty-one years old, who says that eleven days ago, after suffering much pain in the right shoulder, the left elbow became swollen. The swelling was increasing and it was very painful. The least jar produces severe pain.

May 20, 1905, the left elbow is swollen and the skin over it bright red, with increase in temperature. Fluctuation on either side of the olecranon. Arm held at right angle, and there is about 5° of motion in flexion and in extension. Joint aspirated and 12 cc. sero-purulent fluid removed, from which a pure culture of gonococci was obtained. Congestion for two periods of one hour.

This was a hospital case and it was possible to supervise the congestion personally.

May 24. Periods of congestion increased to eight hours twice daily. There has been a very great diminution in the pain and joint motion is much freer. She is able to extend the arm fully. Edema over forearm and back of hand.

May 28. Pain has returned. Edema increased. Congestion omitted for two days to allow absorption of edema.

May 30. Less edema. Congestion for two eight-hour periods again resumed.

June 5. Inner portion of joint capsule has become infiltrated, brawny induration extending for two inches above the internal condyle. Edema of forearm and hand more marked. Axillary glands enlarged. Congestion omitted. Ice bag and elevation of arm.

June 10. Edema back of hand and forearm still

persists. Much pain. Congestion resumed for one-hour periods three times daily.

June 12. There is less superficial tenderness and no pain. Swelling less. Congestion for two-hour periods three times daily.

June 15. No tenderness about joint, but brawny induration still persists. Fairly free motion. Congestion increased to three-hour periods three times daily. The edema of the forearm and hand which it causes is well marked.

June 20. Passive motion in extension to 160° in flexion to right angle. No tenderness. Cautious massage begun on upper and lower arm with a little passive motion. Still considerable edema in forearm. Congestion for two eight-hour periods.

June 24. Induration about joint has softened. Congestion for three four-hour periods. Daily massage.

July 1. Massage and congestion have been continued daily. Patient left hospital.

July 22. Patient seen to-day. Is able to fully extend arm. Flexion at elbow somewhat limited. Very little swelling and no tenderness.

CASE VII. Infectious arthritis, right wrist, gonorrheal. Woman, forty years old, was first seen as a ward patient April 8, 1905, with a swelling of the right wrist, which came on suddenly eight days ago. One day before the left knee became similarly affected. The right wrist and left knee are very much swollen, painful and tender. The knee joint very much distended. She was given salicylates for two days without result.

April 9. Knee was aspirated and 90 cc. of sero-purulent fluid withdrawn from which gonococci were grown in pure culture. Patient left the hospital before treatment could be commenced.

April 27, 1905, she appeared as an out-patient, complaining of the right wrist. The right wrist is swollen both anteriorly and posteriorly, and is very tender. There is about 5° of motion in flexion, and in extension 6½ inches over styloids.

The left knee contains a slight amount of fluid, the capsule is rather flabby, but not thickened. There is free passive motion.

Congestion of wrist one hour daily.

May 2. There is twice as much motion in wrist and much less periarticular tenderness. Congestion for two hours daily.

May 9. No periarticular tenderness and very little swelling. Styloids measure 6½ inches. Motions of wrist 15° in extension and 25° in flexion. 4° of abduction and adduction. Congestion increased to eight hours daily.

Dec. 9, 1905. Patient reports that she kept up treatment for ten days after leaving the hospital, and that her wrist soon became normal. She now has no trouble in either wrist or knee.

CASE VIII. Infectious tenosynovitis, Achilles tendon, gonorrheal. Man, eighteen years old. He has had two attacks of gonorrhea. For eight months has complained of pain in left heel so that he has been unable to walk. He was treated with massage and passive motion for two months without relief.

Sept. 13, 1905. There is tenderness and swelling on both sides of the Achilles tendon of the left foot. Passive motion of foot limited and painful. Tenderness along bottom of os calcis.

X-ray shows no periosteal thickening.

Congestion for three-hour periods daily.

Sept. 24. No tenderness in os calcis. Patient unable to walk without pain. Slight swelling at insertion of Achilles tendon, but much less tender. Congestion three hours, as before.

Oct. 5. Swelling of Achilles bursa very slight and motion causes no pain. Has started work which requires constant use of ankle without any inconvenience.

CASE IX. Gonorrheal periostitis, both os calcis. Man, twenty-five years old, complained of pain in both heels, which had come on in three weeks previously and was growing worse. He was not able to walk without much pain. Had gonorrhea twice, the first time six years ago, and the last one and one-half months ago.

Aug. 19, 1905. Both heels are normal and there is no tenderness to pressure. Patient able to walk without discomfort.

CASE X. Chronic synovitis, left knee, gonorrheal. Man, thirty years old, who complained of swelling and pain in left knee for eight months.

Jan. 26, 1905. The left knee is distended with fluid, and there is thickening of the capsule. Motions are almost normal. Congestion for two-hour periods daily.

April 11. Congestion has been given daily without

The results of treatment obtained in these cases may be seen by the following table:

| CASE. | SEX. | AGE. | REGION AFFECTED. | DISEASE. | DURATION BEFORE TREATMENT. | DURATION OF TREATMENT. | DAILY LENGTH OF CONGESTION. | CONDITION BEFORE TREATMENT. | CONDITION AFTER TREATMENT. |
|-------|--------|------|-----------------------------|---------------|----------------------------|------------------------|-----------------------------|---|---|
| I | Male | 16 | Right ankle | Tuberculosis. | 7 months. | 11 months. | 1 hour. | Foot and ankle swollen. Little motion in ankle joint. Atrophy of all bony structure. | No swelling of foot, little of ankle. Slightly increased motion in ankle joint. Much bony regeneration. |
| II | Male | 12 | Left wrist. | Tuberculosis. | 8 months. | 9 months. | 1 hour. | Hand and wrist much swollen with large abscess. No motion in wrist or fingers. Exudation between carpal bones. Bony atrophy. | No swelling of joint. Fairly free motion in wrist and fingers. Absorption of exudation. Much bony regeneration. |
| III | Male | 2 | Finger. | Tuberculosis. | 4½ months. | 6 months. | 1 hour. | Phalanx bare and exposed. Terminal joint of finger useless. | Finger healed with slight deformity. Good control of terminal phalanx. Bony regeneration. |
| IV | Male | 41 | Right wrist. Left ankle. | Tuberculosis. | 9 months. | 10 months. | 2 hours. | Right wrist, bony necrosis of carpus, with open sinus. Left ankle, spindle-shaped, with swelling of foot. Periarthritic exudation. Diffuse involvement of ankle and tarsus. | Right wrist amputation. Left ankle. Little swelling of foot, able to bear weight on it. X-ray (at end of 3 mos.). Absorption of exudation. Bony regeneration. |
| V | Female | 21 | Both wrists. | Tuberculosis. | 2 years. | 7 months. | 3 hours. | Slight swelling both wrists with much pain. Limited motion. | No swelling. No pain. Normal motion. |
| VI | Female | 21 | Left elbow. | Gonorrhea. | 11 days. | 4 weeks. | 8 to 20 hours. | Acute suppurative synovitis with capsular infiltration. No motion. | Absorption of exudation. Little capsular thickening. Motion normal except slight limitation in flexion. |
| VII | Female | 40 | Right wrist. | Gonorrhea. | 4 weeks. | 4 weeks. | 2 to 8 hours. | Acute synovitis with periarthritic involvement. | Absorption of exudation. Good functional joint. |
| VIII | Male | 18 | Left Achilles bursa. | Gonorrhea. | 8 months. | 3 weeks. | 3 hours. | Tender and swollen Achilles bursa. Tenderness in under surface of calcis. Pain on motion of ankle joint. | No tenderness, and slight swelling bursa. No tenderness in os calcis. Motion of ankle without pain. |
| IX | Male | 25 | Both os calcis | Gonorrhea. | 3 weeks. | 5 weeks. | 2 hours. | Redness and tenderness both heels. Walking painful. | No tenderness. Walks without pain. |
| X | Male | 30 | Left knee. | Gonorrhea. | 8 months. | 10 weeks. | 2 hours. | Fluid in knee joint. Thickening of capsule. | No diminution of fluid, nor in thickening of capsule. |

July 7, 1905. There is slight redness in the skin of both heels and marked tenderness to pressure over both these regions. All the joints are negative with the exception of slightly guarded motion in the spine in the lower dorsal and lumbar regions. Inguinal epitrochlear and cervical glands palpable. There is a purulent urethral discharge.

Congestion applied to both ankles two-hour periods daily.

July 20, 1905. Area of tenderness under right os calcis has disappeared, while left is somewhat sensitive. Congestion on left foot only for three-hour periods.

influence on the amount of fluid in the joint. The only effect noted was a diminution in the pain.

Our experience in this case are in accord with the statement of Bier, who says that congestion is fruitless in cases of chronic hydrops.

The cases on which this report is based are few in number. Congestion was started in many more, but from lack of conscientious application of the bandage and from failure to attend the clinic, only this small number could be collected.

CASE I. Dec. 27, 1904. (Fig. 1.) Anteroposterior view. Large outline of effusion. The femur shows marked atrophy. There is a large, dark, irregular mass in the ankle joint with perforation of the bone.

CASE I. Dec. 27, 1904. (Fig. 2.) Lateral view. Large outline of effusion. The femur shows marked atrophy. There is a large, dark, irregular mass in the ankle joint with perforation of the bone.

CASE I. Nov. 1905. (Fig. 3.) Anteroposterior view. Intense chondrocalcinosis. The femur shows marked atrophy. There is a large, dark, irregular mass in the ankle joint with perforation of the bone.

CASE I. Nov. 1905. (Fig. 4.) Lateral view. Intense chondrocalcinosis. The femur shows marked atrophy. There is a large, dark, irregular mass in the ankle joint with perforation of the bone.

CASE II. Nov. 11, 1905. - Hazy outline of all carpal bones. Wide separation of bones by exudation. Atrophy of metacarpals, especially carpal ends, and of radius and ulna. Condition represents a diffuse process in carpal bones and articulations. No distinct bony focus.

CASE II. Sept. 2, 1905. - Bones show more intense shadow and bony outlines more clearly defined. Trabeculae more distinct.

CASE II. Dec. 9, 1905. - More distinct outline of all bones. Bone structure especially in radius and ulna more clearly defined and cortex is becoming thicker.

CASE II. Jan. 1, 1906. - Still more distinct outline of bones with more clearly shown trabeculae. This is better seen in carpal bones between which there is little open space, showing that exudation has been absorbed.

Regeneration process resulting in reproduction of bone seen in long tongue-like process of 2d metatarsal running between trapezoid and scaphoid.

little toe, and especially so if, as is so often the case, the skin is cut or torn. It is well known to those who have studied the habits of the chigger that the insect invades abraided or irritated surfaces oftener than sound skin. The fold of skin under the proximal joint of the little toe corresponding to the edge of the web between the toes is the point where wounds are oftentimes made by the sharp grasses, etc., through which the barefooted native walks and runs. The principal reason for this in the African is that the little toe of barefooted negroes lies separate from the others at an angle due to anatomical reasons connected with flatfootedness. As I have said, chiggers are oftentimes found on the under surface of this toe even when all the toes are intact. When wounds are once made here, however, the chiggers persistently invade them and must be removed constantly. While I do not wish to be read as advocating *S. penetrans* as the sole cause of anihum, it seems to me that these insects must play a part (in some instances, at least) in the continued irritation which, especially in blacks (who have a fibrogenetic tendency), may lead to the contracting fibroses occasionally resulting in the spontaneous amputation known as anihum. Such a theory goes far to account for the geographical distribution of the disease which is particularly common in the two great homes of the chigger, viz., tropical America and Africa.

The above conjectures which are, I admit, founded on slight evidence are not put forth in a dogmatic spirit but merely in the hope that they may prove suggestive to those working on the etiology of tropical diseases.

SUPPLEMENTARY NOTE ON A SPIROCHAETE FOUND IN YAWS PAPULES.*

BY F. C. WELLMAN, M.D., BENGUELLA, ANGOLA, AFRICA.

SEVERAL weeks ago I sent to Professor McFarland a paper in the course of which I mentioned the fact that I had found *spirochaetæ* in the papules of a case of yaws.

Only yesterday there reached me the report of the meeting of the British Medical Association at Leicester. At that meeting Dr. Aldo Castellani announced¹ the discovery of *spirochaetæ* in two cases of yaws in Ceylon. One of his observations dates back as far as February, 1904. My independent discovery of this organism in yaws papules (which may now be regarded as a confirmation of Castellani's previous observation) only dates from July 14, 1905. So I have thought it worth while to publish this additional note which will serve to obviate any misunderstanding that might arise from the tenor of my previous paper which was on its way to America before Castellani's announcement reached me.

It is significant that this observation (which has been spoken of as "one of the most important discoveries of recent times, considering the fact

that the *Spirochaeta pallida* has been found by Schaudinn in syphilis, and considering the relation said to exist between yaws and syphilis"²) should have been made almost simultaneously in two such widely separated countries as Ceylon and West Africa. It is to be hoped that observers in all parts of the tropics will avail themselves of every opportunity to thoroughly investigate the matter.

I have sent a statement similar to the above to the *Journal of Tropical Medicine*, London.

THE INFLUENCE OF DAMPNES OF SOIL AND CLIMATE ON THE DISEASES OF RESPIRATION.*

BY HENRY J. BARNES, M.D., BOSTON.

FORTY-THREE years ago the late Dr. Henry I. Bowditch of this city, in an address before the Massachusetts Medical Society, after a very laborious inquiry throughout the state, concluded "a residence on or near a damp soil, whether that dampness be inherent in the soil itself, or caused by the percolation from adjacent ponds, rivers, meadows, marshes, or springy soil, is one of the primal causes of consumption in Massachusetts, probably in New England and possibly in other portions of the globe." To this address and the report of Dr. Buchanan of England, in 1867, on the distribution of phthisis as affected by dampness of soil, reference is often made by writers of textbooks now in use, as authority for the opinion, dampness is not only a cause of this disease but others of respiration. Since the recognition of the bacillus of tuberculosis by Koch in 1882, dampness can only be considered a predisposing or contributing cause by authors quoting from the works of Drs. Bowditch and Buchanan. Little if any effort is made to show why this condition of soil should cause disease, although Dr. Billings writes, "It would be easy to construct a plausible theory in connection with the supposed cause of phthisis by a bacillus."

If the bacillus of tuberculosis, or any of the known pathogenic organisms causing disease of the respiratory tract, can preserve their virility in a damp soil, of which there is much doubt, chiefly because of the bactericidal influence of sunlight, the condition of dampness must be unfavorable for their transportation to the respiratory tract. Their presence in indoor air has been abundantly demonstrated, they may be rafted on particles of dust, but how they would be detached from damp surfaces is difficult to understand, unless released, and transported by an intermediary host of which we have little evidence. So long, then, as they remain in or on a damp soil they can have no influence on the organs of respiration.

If damp soil, then, is a factor in promoting diseases of respiration, it must be through the changes it produces in the air in the vicinity of

* This paper by Dr. F. C. Wellman as received by us Dec. 7, 1905. Owing to a misunderstanding its publication has been delayed.

¹ On the Presence of *Spirochaetæ* in two Cases of Ulcerated Parani ("Yaws"). Abstract in *Journal of Tropical Medicine*, Aug. 15, 1905, p. 253.

* Read at the meeting of the American Social Science Association, 1905.

such a soil. In warm or hot weather it may produce a fog, raising the relative humidity several per cent, either by evaporation, a lower temperature, or both. The presence of fogs over low, wet lands, and their absence from adjacent elevated lands, is very frequently observed, and employed by many persons as the only means of measuring the dampness or dryness of the air. Very erroneous conclusions result from this method of measuring moisture, for with a high relative humidity over the high lands, a fraction of one degree lower temperature over the low lands is sufficient to cause a fog. For example, the air at 70° temperature, 98 relative humidity without fog, will be 100 R.H., or saturated, if the temperature is lowered half of one degree, and a fog may result. As the difference is usually much more than this, the appearance of fogs will be of corresponding frequency over low lands. Fogs are probably more frequent in Boston than at Sharon or Rutland, yet the mean relative humidity of the three places is not materially different, the mean annual of each being between 70% and 74%.

In winter, when the temperature is at or below freezing, from the frozen ground, or the snow and ice, there is so slight an evaporation as to cause no appreciable increase in the relative humidity, and fogs are usually occasioned by warm currents of air passing over cold areas of surface and producing the same results over high and low lands, namely, a saturated atmosphere. The presence of fogs, then, while they are indicative of dampness, their absence is of little or no value in estimating the dryness of the air; only by measuring the relative humidity can we ascertain the actual condition.

The rain-fall is often mentioned as indicative of a damp climate. This is a worthless guide in the temperate zone, where rain-fall occurs at no particular periods of time. The relative humidity may be comparatively low for a period of excessive rainfall, or high for a period of little rain, as exhibited in the Sharon report for April 1904, when the precipitation amounted to 8.62 inches and the mean relative humidity for the month was 68, while that for September, 1903, was 127 inches of rain, with a monthly mean humidity of 78, thus showing a month with nearly seven times the rain-fall of another having a relative humidity of 10% less. While it appears then, in the restrictive meaning, local conditions influence but slightly the relative moisture of the air and only in warm weather mountain ranges, ocean, ocean currents and desert regions do occasion great variations.

The eastern coast of Great Britain has an annual mean relative humidity of 85%, caused by the gulf stream and elevated lands and is considered a damp climate. In New Brunswick at the mouth of the St. Lawrence 85 is the mean. Areas east of the coast range on the Pacific are examples of very low percentage of moisture, of which Fort Yuma, Ariz., is one, with an annual mean of 35%.

Denver, Col., having a mean of 50%, has what is

considered a dry climate; and except for peculiar topographic locations, other parts of the United States have what is called a medium climate as regards moisture, Boston, Albany, Buffalo, Chicago, St. Paul, Washington and New Orleans have an annual mean between 70% and 75%.

For purpose of classification we may say that all climates above 80 relative humidity are damp, about 70, medium, and 50, dry, below 45, arid. What effect, if any, this great variation has on death-rates from tuberculosis and other diseases of respiration is impossible to ascertain, because density of population, occupation, social conditions, etc., are all admitted to be very influential factors, of which we have insufficient record. We do know, however, that no condition of climate prevents them.

To a "damp and cold" climate is often attributed the prevalence of diseases of respiration in the winter, and many mortuary tables are cited showing the death-rate from these diseases is enormously increased during the winter months. This falls far short of proving weather, or dampness, is the cause. In the winter of 1903 and 1904, New York City exhibited an unusually high death-rate from pneumonia, Boston, a comparatively low rate. The meteorological conditions were practically alike, as reported by the weather bureau. We have enough cases of this disease in hot climates and in hot weather to prove a low temperature and a high relative humidity are unnecessary to cause this disease. Its prevalence in winter is better accounted for by the more intimate relations for the purpose of shelter, for this is often an infectious disease.

During the Civil War, in 1861, six thousand colored troops were quartered in barracks at Fort Benton, Mo. From January to May, 700 cases of pneumonia occurred among these troops and the epidemic was stopped only by breaking up the barracks. The surgeons in charge reported, "men occupying the same bunks with those affected were very much more liable to be attacked than those more remote." In 1871, 75 cases occurred among 735 inmates of a prison at Frankfort, Ky. Netter reports 30 cases among persons sleeping in the same bed with the sick. Much more evidence could be produced showing this to be a transmissible disease and should therefore be reported to the health authorities as such. Dr. Loomis writes Pepper, vol. 2, p. 315: "The more dense the population, the greater the pneumonia rate, which rainy seasons, or moist districts do not influence. Wind, weather, seasons or race have but slight influence. Resistance of the individual is the most important factor."

Report of epidemic influenza. This prevails irrespective of soil, season or climate. Tinkler says: "We cannot at the present time predict the appearance of this disease from any existing atmospheric conditions." Pepper, "There is no known condition of climate, soil, elevation or season which affects it." Oliver: "Outbreaks of this disease are independent of all seasonal or meteorologic conditions." C. J. Wilson.

"The condition of the air as regards moisture or dryness does not influence the spread of this disease. It has occurred at sea, on the low sea coast, and in the driest climates, for example, upper Egypt, and has no known connection with any known atmospheric condition."

Tuberculosis.—That this is an infectious disease need only to be stated. If the tubercle bacilli are cast upon the water, or damp soils, they are likely to remain there, often exposed to the germicidal influence of the sun's rays. We have, therefore, to consider what effect, if any, the dampness has on the resisting powers of the individual. The fact that the disease occurs among people living under all conditions of dampness or dryness of soil is evidence that neither of these conditions prevents the disease. The dryness of the soil and air of Denver, Col., has long been rightfully esteemed favorable for recovery from tuberculosis, yet from 1893 to 1897 there was an increase from 11.25% to 19.7% of deaths of natives to foreign population, and while we must admit the force of Dr. Bonney's statement, that "these figures are vitiated by an uncertain number of foreigners leaving just before death, who die at home," the fact remains, that the disease can be contracted in the dry climate of Denver.

"*Colds.*"—That "colds run through schools and families" has been a common experience for generations. The infectious nature of this disease is suggested where Boswell relates a conversation with Dr. Johnson, after his return from St. Kilder, more than a hundred years ago. "The inhabitants all complain," says Johnson, "that after the arrival of a ship at their port, all set to coughing and sneezing."

In New Brunswick, five years ago, during the month of August, in a hotel population of about 300 I saw 61 cases of this disease. An individual case came to the cottage of his mother. In three days his sister and mother were attacked. They visited a family in the hotel, in which three cases occurred. I was able to trace the disease to a third family with whom the second family was intimate. About the middle of the month, on the second and third days after a drive whilst party, there were fifteen new cases. Beyond this I could not trace the infection. The disease was mild, permitting most of the patients to be up and about with what they called a "head cold"; there were, however, a number of well developed cases of bronchitis.

Dampness of soil or air could not have been a factor in causing this epidemic. The month was unusually dry, as indicated by the absence of dew and the yellow grass in the fields, and without great variation of temperature.

Thus far I have only attempted to show that natural conditions of soil or climate are not necessarily factors in the causation of the diseases of respiration, and that there are other influences of great importance. Unfortunately, but few of our mortuary tables furnish details necessary to prove a higher or lower rate results from conditions of soil or air as regards moisture or tem-

perature. We have, however, a number of well-known facts relative to the subject.

Dr. William Ogle has shown that fishermen, who are, from the nature of their occupation, exposed to the greatest amount of moisture in the air and surroundings, have the lowest death-rate from respiratory diseases; and that occupations necessitating an indoor life the highest, where presumably they are more protected from dampness and the vicissitudes of the weather. The late Dr. Abbott of our State Board of Health, conclusively demonstrated tuberculosis to be essentially an indoor disease, and the outdoor treatment in our so-called "damp and cold" climate in winter, at Sharon and Rutland, presents results indicating a fair proportion of recoveries. The expression "damp and cold," however, has little, if any, significance when used without the thermometer and psychrometer, for in all temperatures below freezing, the air has the feeling of dryness, even though the measurement may indicate saturation, or 100% moisture.

Has the arid climate of desert regions with a mean relative humidity below 45% any influence on the diseases of respiration? They are not sufficiently inhabited or recorded for us to be able to answer. But this we do know, that under the influence of the arid atmosphere of our houses in winter, we have the most sickness and mortality from lung diseases. I have observed in winter the relative humidity in a hospital ward in Boston to go as low as 15%, which is 5% less than the lowest requirement for kiln drying lumber. Dr. Cowles, Mr. De C. Ward's and my own observations cover a period of time sufficient for the statement that we live in a mean relative humidity of about 30%, when artificial heat is employed. Fort Yuma, Ariz., has an annual mean of 35, and the inhabited parts of Sahara 40 to 50%.

We also know drying does not impair the vitality of the tubercle bacillus, but does render it more buoyant in the atmosphere. We know that all the diseases of respiration chiefly prevail in cold weather, attacking those of indoor life and occupation, where the air is excessively dry, and are not nearly as numerous in the summer when the air of our houses is relatively much damper than outside air. I have observed for the entire month of August 100 relative humidity in my office, and damp walls and the swelling of furnishings are well nigh universal in our houses during warm weather as a result of a high relative humidity and a lower temperature than that outside. On the other hand, in winter, when we have the greatest number of cases, the artificial heat employed lowers the relative humidity to such an extent no arid inhabited region in the world furnishes a parallel. Our furnishings shrink after being kiln dried, and windows and doors do not fill the spaces to which they are fitted. Yet none of the pathogenic organisms causing diseases of respiration appear to be injuriously affected, but rather appear to be more virulent. Possibly this may be due to their greater buoyancy when dried. Can this arid air contribute towards making humanity less resistant to these diseases?

When we remember the anatomical structure and the physiological action of the ciliary lining of the respiratory tract over which a thin watery fluid is constantly flowing upwards and outwards, in health, it would seem the respiration of air so deficient in moisture would, by evaporation, thicken, if not exhaust this fluid and thus impair the motions of the cilia and the flow of fluid, which evidently is designed to expel foreign matter, including pathogenic bacteria. The frequency with which these organisms are found in the upper air passages without causing sickness, suggests the probability of unfavorable soil, and inability to reach the deeper air passages under the circumstances. Colds may be contracted in warm weather but they usually end quickly, and only involve the upper air passages. In winter the disease, beginning with exactly the same symptoms, more often extends gradually down the trachea, and finally to the bronchi of the lungs, and we call it bronchitis.

The conclusions to be drawn from the evidence presented, is that all the diseases of respiration are common enough, regardless of dry, or damp soils, in hot or cold, moist or dry, climates, to at least raise a doubt if these conditions have any influence whatsoever as a cause of the diseases of respiration; but that an excessively dry air, which nature nowhere provides, but which we create in winter by raising the temperature of air holding a very small volume of watery vapor, and thus lower the relative humidity to an extent sufficient to impair the resisting powers of the mucous membrane lining the respiratory tract, may be a factor in the increased prevalence of respiratory diseases in cold weather.

A CONSIDERATION OF THE TREATMENT OF AUTO INTOXICATION OR AUTO INFECTION WHERE THEY ARE THE CAUSE OF MENTAL DISTURBANCE

BY J. SPENCER KINNEY, M.D.,

Physician to the Mental Department of the Boston Dispensary.

(Continued from No. 17, p. 490.)

C. SPENCER KINNEY, M.D., of the Eaton Sanitarium, Pa., in a letter to the writer, says: "The subject of auto-intoxication is of the greatest importance to me. For nearly fifteen years I have advocated colonic flushing, using it daily in my ward work to the advantage of my patients, have taught my students the importance of it, and have urged its use in society meetings." He also says in an article on "Melancholia," which he published in 1897: "In some cases antiseptic measures are resorted to as many cases of melancholia have auto-intoxication as a prominent feature."

Dr. John Lovett Morse, of Boston, in a recent paper on "Acid Auto-Intoxication in Infancy and Childhood," says that Czerny attributed the acid intoxication to the abnormal products of decomposition of feces and proteids. He divides the symptoms into two classes, nervous and gastric. The nervous symptoms are changes

of disposition, excitability, restlessness, irritability and insomnia. The gastric, anorexia, vomiting, thirst and constipation.

Dr. Charles E. Page, in the *Medical News*, Oct. 13, 1900, says he "found piperazine water a preventive of auto-toxemia caused by absorption of ptomaines from the gastro-intestinal tract, and he employed it to advantage in chronic dyspepsia and constipation with mental depression."

H. R. Stedman, M.D., of Brookline, in a paper on "Insanity," in the *Boston Medical and Surgical Journal*, of Nov. 24, 1904, which shows the result of exhaustive research, says that "Bruce considers that katatonia is an acute toxic disease with a definite onset and course."

In the *Journal of the American Medical Association*, of Oct. 28, 1905, William Howse, M.D., of the Mount Taber Nervous Sanitarium, Portland, Ore., publishes an interesting paper on "The Psychoses of Heart Disease," giving numerous cases. He contends in these psychoses that the heart disease is the exciting cause, and he says "a special insistence is placed on the relationship of mental improvement to therapy directed against the heart trouble."

Dr. Max E. Witte, superintendent of the State Hospital at Clarinda, Iowa, writes me that he has been convinced by the careful study of many cases of insanity coming under his care during a period of years, that the first beginning of many forms of insanity or acute affective disorders, such as melancholia and mania, often, if not altogether, have their primary inception not in the brain, but elsewhere, usually in the organs of the abdominal cavity. He says further, he is satisfied that researches in this direction will be rewarded by important discoveries in the future, and adds, "A routine examination of the cases coming in for many years have on the whole revealed a deterioration of the blood, more especially a diminution in the formed elements of the blood, particularly in the red corpuscles, also a corresponding lowering in the percentage of hemoglobin. These uniform findings certainly argue disordered and diminished metabolism, but, of course, I have not the exact data to determine definitely whether this diminution should be looked upon in the light of result or of cause, possibly both, since it seems to be a sign of a vicious circle."

As to auto-intoxication, it is a matter of every-day experience and observation that insane patients coming here, whether the disease has existed a long or a short time, are usually abnormally constipated, and one of the first indications in *trephena* is a marked tendency for the evacuation and regulation of the intestinal tract. So far as the constipation, then, from inquiry of the more intelligent patients, or from their friends, the condition has existed during the duration of the disease and often prior to it. Now and then it is met with even in mild and grave melancholia associated with a considerable duration of the disease, who are promptly relieved and recovered under the adminis-

tration of thyroid extract. We have no true cretinism so far in this part of the country."

Dr. George O. Welch, the medical superintendent of the State Hospital, Fergus Falls, Minn., says that the larger part of their cases suffer from auto-intoxication on admission to the hospital, and that "it certainly has a considerable effect in prolonging the unbalanced mental condition and making it more severe. That in most cases restoring the physiological functions to healthy action, especially paying particular attention to the digestive tract, so that the food is properly assimilated, produces a marked change for the better in the patient's mental condition."

Dr. J. Thomas Wright, of Winston, N. C., in an article read before the North Carolina Medical Society on May 23, 1905, on "Neurasthenia," says: "It is often the result of other diseases such as auto-intoxication, impaired metabolism, and in women, menstrual and other troubles. There is a starvation of the nerve cells due to deficient metabolism. There is an accumulation of waste products of the body, which, entering the circulation, cause an auto-intoxication and irritation of the cortex and through the nervous system an inhibition or perversion of the functions of the various organs. That uric acid accumulates and adds to the irritability. That there is an absorption of toxins from the intestinal canal caused by changes in the digestive juices by impaired digestion, fermentation and by bacteria, which is the chief cause in perpetuating the trouble." In addition to the usual treatment he gives high irrigation of the colon, mercurial purge, phosphate of sodium, lavage with stomach tube, nitrate of silver in $\frac{1}{2}$ -gr. pills, salicylate of soda, sulpho-carbolates and creosote.

Dr. W. A. Gordon, superintendent of the Northern Hospital for the Insane, of Wisconsin, writes me: "As to auto-intoxication, bilious, rheumatic, typhoid, syphilitic and fecal intoxications are about all that we recognize here so far as tabulation goes. The idea of elimination dominates our treatment. We eliminate by mercurial and saline cathartics, by the wet, hot and cold packs or sweat box, electrical and steam; by frequent bathing and copious ingestion of water. We have for a number of years used various intestinal antiseptics. Various conditions which are called acute mania are, I believe, caused by different intoxicating elements, and some melancholias are undoubtedly toxic. We seek to eliminate and at the same time improve the patient by liberal easily digested diet. It is in this field, I believe, the greatest advances will be made in our knowledge of the causes and in the treatment of the insanities."

Dr. Albert G. Stern, of Indianapolis, Ind., writes me that it is his custom to treat mental cases, notably of the acute variety, as persons physically sick, and that his best results have been obtained by elimination and rest.

D'Orsay Hecht, M.D., chief of the Neurological Clinic in the Northwestern Medical School, Chicago, in the *American Medical Journal* of

Nov. 4, 1905, gives an interesting case of "Acromegaly," in which the usual enlargement of the hands and feet took place, the changes in the skin, the eyes, the features, etc., were in keeping with the hypertrophy of the pituitary body. He also says, "She had severe headaches, nervous prostration and a series of hysterical attacks, one of which eventuated in a stupor that lasted several days. This was after a prolonged mental storm as the result of opposition." But what is of the most importance in relation to the subject of this paper is that there has been much drowsiness and no refreshing sleep for some time prior to the date of his reading the paper. Administering 3 gr. tablets of the pituitary extract rather intensified her headaches, which makes it an interesting case.

Dr. J. Montgomery Mosher, the first physician in this country to successfully establish a hospital of observation, which he did at Albany, N. Y., in an address to the Medical Society of the county of Albany, in October, 1904, says, "It is difficult to understand why work should be prescribed for exhaustion. And long journeys, amusements, changes of occupation causing an expenditure of nervous force, which is detrimental and not curative." He further says, "Auto-intoxication should be combatted and prevented by abundant activity of the intestinal tract and this excretion supplemented by the duties of the kidneys and the skin. Elimination of waste products is of prime importance."

Drs. Daniel R. Brower and Henry M. Bannister in their "Practical Manual of Insanity," speak of strychnine as particularly indicated in certain forms of depressed toxic insanities. They say that sometimes there appears to be a sort of intestinal paralysis, and it is quite a while before the normal action of the bowels can be reinstated. That the mere unloading of the clogged and distended bowel has often at once a most happy effect to all appearances, and that it seems probable that we cannot altogether reject the agencies of a reflex action on the brain in these cases. Continuing, they say: "It is probable that the modern notions of auto-intoxication have their application here, and that the conditions may be largely influenced by the toxic products with a sort of continuous absorption that is at once relieved by the evacuation and thorough cleansing of the lower bowel. As a practical fact, this matter of attention to the condition of the bowels is one of the most important of all in the treatment of insanity. It is a point that has been to some extent neglected or not sufficiently emphasized by some writers. We have seen patients apparently regular in going to stool who were nevertheless suffering from fecal accumulation, and occasional colon flushing with a normal saline solution, if the discharge is at all insufficient, or if the patient's general symptoms suggest any intestinal indication of reflex irritation from this source, is often followed by marked general improvement for the time. The use of gastric and intestinal antiseptics, especially the latter, may be indicated in

some of these cases with pronounced derangement in the entire intestinal tract."

On page 178, they say: "The principal facts to be borne in mind in the treatment of confusional insanity, are that we have to do with a condition of brain exhaustion and malnutrition; that also besides this, there is in mania, if not in all cases, an element of auto-intoxication to be always taken into account. The treatment usually is first to restore nutrition, to secure rest and to eliminate whatever toxic features there may be that are actively or otherwise assisting in perpetuating the disordered conditions in the brain. These patients should be treated as veritably sick individuals and the methods and nursing applicable as such to be applied. It is a good plan to commence treatment with a thorough cleaning out of the lower bowel by enema and a prolonged warm bath at a temperature of 93° to 95° F. for half an hour or more."

On page 282, they say: "The development of hysteric insanity is sometimes due to anemia or an auto-intoxication or both, and the early recognition of these pathological conditions and their correction may result in recovery. The treatment for this trouble should be mildly alterative and tonic; laxatives, massage, electricity and from time to time colonic flushings."

Again on page 329 in the treatment of mania they say: "One of the first essentials is to attend to the condition of the bowels which in the majority of cases are constipated, to do away with an auto-intoxication that may exist, and also we believe to put an end to the possible reflex irritation that is mechanically set up by the overloaded colon. They advise a prolonged warm bath of twenty minutes or over, followed by a thorough irrigation of the lower bowel. Then to give a full meal of milk and eggs or a meat broth and put the patient to bed. The patient will often go at once to sleep and get a good night's rest."

In a paper written by Dr. Bruce and Dr. Peebles of the Muthly Asylum, Perth, Scotland on "Katatonia," in October, 1903, they say: "Our conclusions are, that katatonia is an acute toxic disease with a definite onset and course, in which the symptoms vary according to the resistive power of the patient, but in which the following diagnostic symptoms are never absent. A prodromal period of gradual onset which lead into a period of acute onset, with aerial hallucinations, mental confusion, paroxysms of excitement, impulsive actions, katatonic spasms of the muscles, a hyperreflexia, which at the termination of the acute stage indicates a violent toxemia. In the second stage, a condition of stupor with muscular resistiveness to passive movements."

Livingstone says that W. Handlenger of Leipsic, who in 1848 published a work on "The Extraordinary Powers of Ergot in Nervous Diseases," states: "In many cases of headaches, especially the congested variety, I have at times a great deal of success, often combining it with bromide."

Charrin and LePlay in an article in the *Semaine Médicale*, Paris, November, 1901, say: "The experiments reported in this article demonstrate that the alimentary canal nominally contains innumerable poisons including toxic substances such as the distasteful, which are required for the nutritive processes." They have further established that frequently a disease is due to the disorganization of its defenses rather than to the intrusion of any special pathological agent. "In therapeutics, while it is necessary to attack the enemy, yet in many cases it is important that more attention should be paid to strengthening the ramparts. The normal organic products may become morbid under certain circumstances."

Prof. Carl von Noorden, in his little book on "Auto-Intoxication," says: "Within recent years the idea has become firmly established in the minds of physicians that a variety of morbid phenomena are due to auto-intoxication, and are, in other words, attributable to certain poisonous metabolic products. At first we Germans were by no means inclined to accept the theory of auto-intoxication, which was being so extremely proclaimed. Of late years, however, our attitude has become more friendly to the doctrine. This change of front is due to the fact that a number of toxic products of metabolism have actually been isolated and their mode of origin in the organism and their pathological effect determined, to the satisfaction of the former critics of the doctrine. We do not, of course, know all that we should properly know about the poisonous metabolic products that we incriminate in so many morbid states, but in a large group of important symptom complexes we are fortunately in possession of a number of facts that suffice to ground the doctrine of auto-intoxication on a solid chemical basis."

L. Meyer of Königsberg in the *Arch. F. Psych. u. Nervenk.*, Bd. 39, H. 1, reports eight cases of psychoses which developed apparently on a basis of auto-intoxication. The mental symptoms are insufficient to make a diagnosis without the presence of bodily symptoms, among which were headache, dizziness, fainting and tremor. Meyer calls attention to the difficulty in studying metabolism and the uncertain value of indican estimations. He concludes: "That the mental condition is so similar to that seen in other toxic and exhausted conditions that we cannot talk of a specific auto-intoxication and psychoses." "It is the physical condition," he says, "which enables us to diagnose the cause and justify the name."

Dr. F. W. Webster of Göttingen, in an article on "The Relation of Physical Diseases and Mental Disorders," includes intoxications and acute infectious diseases in his classification, and says: "The assumption of an auto-intoxication as the basis of physical disorder shall be more than a probable hypothesis in many cases, it must be required that the origin of the questionable poison be shown in a certain organ of the body, and again, the poison be demonstrated somewhere in the organism, either at its present

point of action in the brain, in the blood, or among the excretory products. The first condition is fulfilled in a certain measure in the psychoses, which occur in consequence of severe organic diseases (kidney, liver, thyroid glands, chronic gastro-intestinal diseases), while we are still unclear as to the sort of poison thus arising. How far the assumption of an auto-intoxication psychosis is justified will be shown in the discussion of the several organic diseases." Kraepelin states that "In the mental disorder named by him dementia precox, in which a connection with auto-intoxication is not excluded, heredity taint is found in 70% of all the cases."

Maurice Craig, M.D., of Bethlem Hospital, London, says, that "in katatonia most of the bodily functions are disorganized. The bowels are constipated not uncommonly to an extreme extent. Tongue furred, mucous membranes of the mouth unhealthy." Of dementia precox he considers it improbable that the disease is produced by auto-intoxication, but acknowledges that at present nothing is actually known as to its pathological basis. His advice as to treatment, is "early diagnosis, removal from home, correcting bad habits and a very regular life."

Of the treatment of the insane in general, he says, "There is no doubt that many of the insane are effected by the continual absorption into the blood of poisonous substances which are generated by putrefaction and fermentative changes taking place in the intestines." He does not, however, apparently agree that there is much advantage to be gained by the administration of intestinal disinfectants, but regards it as more useful to have the stomach washed out daily with warm water before breakfast.

I picked up in London a book of one hundred and seventy pages on the "Virtues of Tar Water," published in 1744 by the Right Rev. Dr. George Berkeley. The tar water was to be taken internally and was made by adding a quart of water to a quart of tar, stirring them together and letting the tar sink to the bottom. It is prescribed in ulceration of the bowels, in asthma, smallpox, and other diseases with apparent success. On page 47 he says, "For hysterical and hypochondriacal disorders so frequent among us, I have found that it raiseth the spirits and is an excellent antihysterie."

Regis says that in the variety of Brightie insanity which is due to the intoxication, we ought not to advise asylum treatment, unless very guardedly. The insanity, not of a dangerous type, following the course of albuminuria, may improve as it improves, and sometimes disappear, in case there are no profound cerebral lesions.

Again he says: "Simple constipation, angina and gastric uneasiness are enough at times to cause depression, sadness, melancholia with refusal of food, hallucinations of taste, delusions and insanity. Diseases of the intestines have also a very powerful action on the development of mental alienation."

Esquirol, it is well known, affirmed that

melancholia was due to a displacement of the transverse colon. Wiehmann, Hasselbach and Greting have also made the same observation. Bayle has also shown in his theses that enteritis and gastro-enteritis may produce sympathetically cerebral disorders. Dr. Holahof has shown that duodenal catarrh, especially after it has passed into the chronic condition, gives rise to a marked state of depression in the subjects; but in individuals already predisposed to neuroses, it may become the source of more serious mental disorder. In nearly every case the symptoms are those of hypochondria; at other times it develops into a regular melancholia with ideas of persecution, of unworthiness, with morbid exaggeration of conscientiousness, etc., or else the patients become unquiet, fretful, quarrelsome and excessively irritable. Alterations of the peritoneum and its folds, the mesentery and the epiploons, may also give rise to mental troubles. It is not uncommon to see dyspepsia bring on mental alienation, and it is especially in these cases that the chronic gastric disorders improve with the appearance of the insanity, to reappear when it, in its turn, has passed away. It should be added, for the sake of completeness, that the dyspeptic troubles, whether they are the actual cause of the insanity, or occur in persons already insane, usually give rise to two mental symptoms that are almost characteristic. These symptoms are: (1) Refusal of food, so intimately connected with dyspepsia which is not a mere sitophobia not connected in any degree whatever with gastric disorders. The second symptom consists in the almost constant existence in these disorders of the sensibility which have been called internal hallucinations and illusions, and which lead the patients to believe that their stomach and abdomen are the seat of extraordinary diseases, that they have been poisoned, that their food smells of phosphorus and arsenic, that they have living animals in their abdomen, that they smell badly, that they are rotten, etc. The usual result of this mental condition is a suicidal tendency, which is, in fact, quite marked in insanity of gastric origin.

The prognosis of the mental disease in all these cases is entirely dependent on the nature and the severity of the organic disease that gave rise to it.

Burrows and Hammond assigned to hepatic disorders one of the first places in the development of mental alienation.

Among the affections of the liver that appear to really influence the mental condition, hypertrophy and especially abscess are found in the first rank.

Clouston, in his last edition, says that the use of thyroid extract, of which he gives 60 gr. a day to produce a short five or six days' fever, is recommended by Dr. Lewis Bruce as a most powerful therapeutic means in most cases. No case should be allowed to become incurable without a trial of this method. It works marvels in some cases threatened with dementia, and even in some cases that have seemed to pass

Medical Progress.

REPORT ON THE PROGRESS OF SURGERY.

BY HERBERT L. BURRELL, M.D., BOSTON, AND H. W. CUSHING, M.D., BOSTON.

ETHYL CHLORIDE AS A GENERAL ANESTHETIC.

McCARBIE¹ believes that it is indicated for short operations needing longer and deeper anesthesia than nitrous oxide or nitrous oxide mixed with oxygen will give. He believes that it is particularly valuable as a preliminary to the administration of ether. It is contra-indicated in cases where there is inflammation or narrowing in the upper air passages. He considers that it occupies a ground midway in usefulness between nitrous oxide and ether. He considers that the drug would be very useful in military surgery, owing to its small bulk and the fact that it acts very rapidly. It certainly is far less depressing in its action than chloroform.

LUMBAR ANESTHESIA WITH STOVAINE.

O. Tilmann² has used stovaine in forty-two cases. As yet few mishaps have been reported in using stovaine. Chaput has reported a death and also a case of transient collapse after stovaine anesthesia.

PRESENT STATUS OF SPINAL ANESTHESIA.

A. Bier,³ although recognizing that the technic of spinal anesthesia is far from perfect, believes that spinal anesthesia in many instances is less dangerous than general anesthesia. He believes that it is particularly indicated in elderly or debilitated patients. Spinal anesthesia failed in only 4% of his last 300 cases; excluding those where the technic was at fault there was only 2.33% of failure. He adds a suprarenal preparation to the cocaine or stovaine as an important adjunct. In the 305 instances of spinal anesthesia he has not had a serious result.

IMPORTANCE OF SPINAL ANALGESIA FOR DIAGNOSIS AND TREATMENT OF AFFECTIONS OF THE ANUS AND RECTUM.

Neugebauer⁴ states that in 79 instances where he used this method of anesthesia in rectal cases, there was paresis or paralysis of the sphincters, which enabled him to visually investigate the rectum. He states that spinal analgesia in rectal cases is of great value.

NEW METHOD OF STERILIZING THE SURGEON'S KNIVES.

Grosse⁵ places the knives resting in a wire frame in a test tube. The tube is then corked tightly. The tube and its contents are then sterilized for ten minutes in steam, at a temperature of from 98° to 100° C. The knives come out dry, sharp and unspooled.

CARBOLIC ACID AND CAMPHOR IN THE TREATMENT OF INFECTED WOUNDS.

Chlumsky⁶ has used in wounds that are infected a solution of carbolic acid, 30 parts, camphor, 60 parts, and alcohol to make 100. This is used in all types of infected wounds. He evacuates the pus and pours the mixture into the wound. The mixture can be kept if the evaporation of the camphor is prevented.

THE PATHOLOGY AND PREVENTION OF SECONDARY PAROTITIS.

There are many theories as to the cause of secondary parotitis, and the operations that are most frequently followed by parotitis are those on the abdomen and particularly on the pelvic organs. An exhaustive summary of this subject is given by Bucknall⁷ and an analysis of the different theories. He summarizes the subject as follows:

"From a study of these facts it seems highly probable that secondary parotitis is invariably due to an infection of Stenson's duct, dependent on a septic condition of the mouth, and that its onset may be prevented by attention to the following details: (1) The patient's mouth should be carefully cleansed and rendered aseptic before operations and at the commencement of long febrile illness. If necessary causes of nasal obstruction leading to mouth breathing, such as adenoids, should be removed. (2) The anesthetic apparatus should be sterile. (3) The mouth should be periodically cleansed afterwards, especially after every attack of vomiting. (4) The bowels should be opened early and food by the mouth, and especially solid food, should be given as soon as possible. (5) Opium should not be given unless absolutely necessary. (6) The head should not be placed too low nor the binder fixed too tightly and the dorsal decubitus should be given up as soon as possible."

The treatment he recommended is the following: "Should parotitis threaten to appear, every effort should be made to cleanse the mouth and to prevent continued re-infection of the duct, as it is probable that resolution of the inflammation is then far more likely to occur. The administration of a sialogogue and an aperient should also be entertained. If the disease progresses it is most important not to wait for fluctuation before incising the region of the swelling, for in the most dangerous cases in which the pus is most likely to burrow and to lead to serious trouble it lies so deeply beneath the tense parotid fascia that fluctuation may not appear until it is too late. If the symptoms progress, therefore, for four days and the swelling increases and becomes edematous an incision should be made, as also in cases in which the temperature becomes high and intermittent, whether fluctuation can be detected or not. A transverse incision should be made over the point of greatest prominence, having due regard to the situation of the branches

⁶ Cent. für Chir., xxvii, No. 33.

⁷ The Lancet, Oct. 31, 1905, p. 1158.

of the facial nerve and Stenson's duct; the parotid fascia should be freely incised and not opened by Hilton's method as usually recommended. The finger should be introduced into the abscess cavity as in an abscess of the breast in order to break down the interlobular septa and to convert the various loculi of the abscess into one large cavity, which should then be drained. Otherwise undrained loculi will continue to grow and to burrow and a further operation may be called for, or burrowing may occur and lead to a fistula or other troubles."

RESUSCITATION BY DIRECT MASSAGE OF THE HEART.

Sencert¹ has reported an instance where, while operating to remove obstruction in the biliary passages, respiration stopped abruptly while the patient was under chloroform. Attempts at resuscitation, continued over seven minutes, failed to relieve. Sencert then introduced his hand through the laparotomy wound and, notwithstanding the interposition of the diaphragm, succeeded in stroking the heart rhythmically with his thumb in front and his fingers behind. In about five minutes the heart was felt to grow hard and large and in a few moments a contraction of the heart occurred. This continued to increase in strength and the patient finally recovered completely.

A REVIEW OF FIVE HUNDRED CASES OF GASTRO-ENTEROSTOMY, INCLUDING PYLOROPLASTY, GASTRODUODENOSTOMY AND GASTROJEJUNOSTOMY.

Dr. William J. Mayo.² It is a great satisfaction to find the review of Dr. Mayo's work on gastro-enterostomy. After all, the end results of these cases are what we need at the present time to establish their value. This article does not give end results, but it is a valuable one in that it gives the indications and technical values of the different operations. Dr. Mayo recapitulates as follows:

(1) The gastric opening should be placed on the posterior wall, obliquely from above downward, and left to right.

(2) The lowest point of the gastrojejunostomy should be at the lowest point of the stomach, on a plane perpendicular with the cardiac orifice.

(3) To insure this effect, the gastric incision should extend one fourth to one half of an inch on to the anterior wall.

(4) The incision in the intestine should be longitudinal, opposite the mesentery, and begin from one to three inches from the origin of the jejunum, measuring on the anterior surface (Peterson's point of election). The exact distance depends on the ease of attachment as shown as can be conveniently done without tension.

A description of the operation is, briefly, as follows:

(a) The abdominal incision is made 4 in. in length, $\frac{1}{2}$ in. to the right of the middle line, the fibres of the rectus muscle being separated. The

lower end of the external wound lies opposite the umbilicus. This opening also enables inspection of the duodenum and gall bladder and is reliable against hernia when closed.

(b) The transverse colon is pulled out and the mesocolon made taut by traction upward and to the right, in this manner bringing the jejunum into view at its origin.

(c) About 3 to 4 in. of the jejunum opposite the mesentery are drawn into a slightly curved clamp. The handles of the clamps should be to the right, to enable a short grasp on the intestine. Three fourths of the circumference of the bowel is pulled through; the posterior border is not included, to prevent entanglement of the suture with the redundant posterior mucous membrane. The holding clamps are applied sufficiently tight to check hemorrhage and prevent extravasation of intestinal contents.

(d) The ligament of Treitz is a short muscular mesentery covered by a variable peritoneal fold (too variable for a reliable landmark) extending upward from the origin of the jejunum on to the mesocolon. This peritoneal fold lies at the base of the arterial loop of the middle colic artery which supplies the transverse colon. The mesocolon is opened within the vascular loop and the posterior inferior border of the stomach pushed through. A small separation of the greater omental attachment to the stomach enables the anterior gastric wall to be drawn out posteriorly. The posterior gastric wall is drawn into a clamp, with the handles to the right, in such a manner as to just expose the anterior wall at the base.

(e) The two clamps are laid side by side and the field carefully protected by moist gauze pads. With fine, celluloidal linen thread, on a straight needle, the intestine is sutured to the stomach from left to right by a Cushing suture at least 24 in.

(f) The stomach and intestine are incised $\frac{1}{2}$ in. in front of the suture line and the redundant mucous membrane excised flush with the retracted peritoneal and muscular coats. With a No. 4 chrome catgut on a straight needle, the posterior cut margins of the entire thickness of the gastric and jejunal wall are united by a button-hole suture from right to left; at the extreme left the suture changes to one which passes through all the coats of each side alternately, from the peritoneal to the mucous, then directly back on the same side from the mucous to the peritoneum. This acts as a hemostatic suture, and also turns the peritoneal coats into apposition. It passes around the anterior surface and is tied to the original end, which has been left long to this purpose. If silk or linen is used for this suture it may bring on the suppuration for months.

(g) The clamps are now removed and the linen thread cut and secured until it is tied to the original cut freely, carrying the blood vessels in sight along the suture line. The parts are carefully cleaned and inspected. If necessary, a suture or two is applied, to accurately clamp or to check the oozing.

¹ *Bour. de Med. de Paris*, Sept. 24, 1903.

² *Annals of Surgery*, November 1903, 347.

(h) The margins of the incised mesocolon are now united to the suture line by three or four interrupted sutures, and the parts returned into the abdomen.

After Treatment.—On being placed in bed, a glass female douche point is passed just above the internal sphincter ani, attached to a gravity bag filled with one half strength normal salt solution. The elevation should not be greater than 6 in. The small stream passing into the rectum is readily absorbed without irritation. One or two quarts are taken up in an hour. (Murphy.) The patient is then placed in the semi-sitting posture.

Beginning at sixteen to twenty hours, an ounce of hot water is given every hour; this is rapidly increased, and in thirty-six hours the usual experimentation with liquid feeding is instituted. Rectal feeding is unnecessary. The operation is, in all of its essential parts, that of Mr. Moynihan.

(To be continued.)

Reports of Societies.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

PROCEEDINGS OF THE FIFTEENTH ANNUAL MEETING
HELD IN KANSAS CITY, MO., DEC. 28, AND
29, 1905.

(Concluded from No. 17, p. 474.)

TWENTIETH CENTURY SURGICAL PROBLEMS.

DR. H. D. NILES, Salt Lake City, Utah, president, selected for his address this subject. No one who has kept in touch with recent experiences in the surgery of the brain, lungs, pancreas, spleen, peritoneum and other organs can escape the conviction that with a clear definite idea of the physiology of these parts the result of surgical endeavors will be infinitely more satisfactory than we are able to obtain with present knowledge. In brain surgery many failures cannot be charged to any lack of operative skill, but to inability to locate accurately the exact pathology early enough to insure its safe removal or correction. The same may be said of the morbid conditions of the spleen, pancreas and, in a degree, of the stomach. Until we are better informed by the physiologist of the normal functions of these organs, we cannot hope always to differentiate between the normal and the abnormal. The evidence that points to the one and excludes the other can only come to us through concentrated specialized efforts which the average surgeon is technically unfitted to undertake.

The line that divides surgical diseases from non-surgical is still somewhat vague and indistinct, and one of the most common sources of error in the treatment arises from the fact that we are often in doubt as to when and how far we may safely trust to the reparative resources of nature, and under what conditions prompt operative interference should be resorted to.

Thus far success in surgery has been measured largely by the ability to cope with advanced disease after it has become an immediate menace to life and health. But the time cannot be far distant when the

importance of recognizing the antecedent pathology of cancer, ulcer, surgical kidney, pus tubes, prostatitis, and many other grave lesions, will be impressed upon the profession, and the public will be educated to choose preventive rather than last resort surgery. If we are ever to solve the problems that baffle our endeavors to-day, and place surgery upon a much higher plane than it now occupies, he thinks scientific workers must become more practical; practical workers must become more scientific, and physicians and surgeons must become more nearly united in their ideas of pathology and treatment. And this can only be accomplished by an organized movement tending to bring all workers in closer touch and sympathy with one another.

CHYLOUS CYSTS OF THE MESENTERY.

DR. MILES F. PORTER, Fort Wayne, Ind., said that a study of the literature together with the reports of twenty cases, including one of his own, forms the basis of his paper. The literature is very meagre; the best of it is to be found in current publications. The history is bound with that of mesenteric cysts in general. Cysts of the mesentery were first classified by Portal, in 1803. Killian reported the first chylous cyst treated surgically; but Bramann's was the first one operated. Carson is probably the first in America to report a case of chylous cyst treated surgically. These cysts are very rare, more so than are serous cysts. The origin of chylous cysts must be regarded as manifold. They may be single or multiple, unilocular or multilocular, and multiple cysts may become multilocular single cysts and later unilocular by pressure absorption. There is nothing distinctive in chylous cysts save their contents and location. An exact diagnosis is neither possible nor necessary. A centrally located movable tumor crossed by bowel will be almost diagnostic of mesenteric cyst. Puncture for diagnostic purposes is condemned. Belly pain is a common symptom, and recurrent attacks of pain accompanied by vomiting and other symptoms of bowel obstruction are very significant. Chronic increasing constipation is a frequent symptom. A history of trauma is common. The treatment is surgical and the technique depends on the finding in each case. The fear of permanent chylous fistula in cases treated by drainage is unfounded.

TREATMENT OF GENERAL PERITONITIS.

DR. DONALD MACRAE, Jr., Council Bluffs, Ia., read a paper on this subject in which he advocated the Fowler position in all suspected peritoneal infections; also the institution of free drainage at the time of the operation by means of large sized rubber tubing only. Drainage of the most dependent part of the pelvis peritoneal pocket is imperative. He urges the removal of the primary pathological factors when possible, and spoke against the use of gauze and flushing. He said the drainage tubes should be sucked at frequent intervals.

APPENDICITIS.

There was a symposium on this subject.

DR. I. B. PERKINS, Denver, read a paper in which he gave further reports from physicians who have suffered from this disease. He discussed the diagnosis of chronic appendicitis and the prodromic stage in acute cases. He expressed himself in favor of early operation in all cases. The interval cases should be operated. Fatalities are usually chargeable to delay. The management of delayed cases was discussed; also attitude of the profession and public toward operation.

TREATMENT OF APPENDICITIS.

DR. O. BEVERLY CAMPBELL, St. Joseph, Mo., followed with a paper in which he drew the following conclusions: (1) In incipient appendicitis, until the patient is placed in the hands of the surgeon, all food and drink should be withheld, and the patient nourished per rectum. (2) Every patient should be advised of the advantages of an early operation. (3) The removal of the appendix, or the closure of an opening in the cecum, should be made, in abscess cases, when it can be done without additional risk to the life of the patient. (4) The practice of merely draining in every abscess case should be condemned as non-surgical. (5) Operation during a progressive diffuse peritonitis is attended with a higher mortality than the method of procedure recommended by the writer. (6) If the internist will direct his efforts in the treatment of appendicitis toward the protection of the peritoneum until he can transfer his case to the surgeon the mortality in this disease will be greatly lessened. (7) The adoption of the more rational method of dealing with diffuse peritonitis will convert a large percentage of these cases into circumscribed peritonitis, when they can be rightly classed as large abscess cases, having the same mortality.

TREATMENT OF APPENDICITIS IN ITS VARIOUS STAGES AS IT COMES TO THE SURGEON.

DR. C. H. WALLACE, St. Joseph, Mo., in a paper on this subject, summarized by saying: (1) That appendicitis is always a surgical disease. (2) That every case should have and is entitled to operative measures within the first forty-eight hours. (3) The rapidly progressing stage is the stage of applicability of the Ochsner treatment, and by it offers the lowest mortality. (4) Cases coming to the surgeon with evidence of gradually subsiding symptoms should be deferred for a more favorable operative period. (5) That every interval or chronic case should be urged to the operating table. (6) That abscess cases should be given two safe rather than one hazardous operation. (7) That diffuse peritonitis should have all accumulated dependent cavities primarily and carefully incised and drained and not flushed, and secondarily the offending organ incised.

DR. VAN BUREN KNOTT, Sioux City, Ia., followed with a paper in which he set forth his ideas at length concerning the management of cases of appendicitis based upon one thousand operations.

EXTRA-UTERINE PREGNANCY.

DR. J. W. ANDREWS, of Mankato, Minn., reported having operated on a woman who was ten weeks pregnant; the sac ruptured, and the operation was delayed thirty-six hours. He reported the case in detail. The steps of the operation he performed were not very different from those of an ordinary laparotomy. He argued in favor of accuracy and rapidity in operating on these cases, and emphasized the necessity in many cases of thrusting the hand down through the pool of blood and securing the blood vessels before attempting to mop out or otherwise remove the blood and blood clots. He thought drainage, as a rule, should be employed after laparotomy for extra-uterine pregnancy.

POST-CLIMACTERIC HEMORRHOIDS, THEIR CAUSE AND TREATMENT.

DR. A. L. WRIGHT, Carroll, Ia., called attention to the frequency of occurrence of post-climacteric hemorrhage after the establishment of the menopause. He spoke of how often it is passed over slightly, with the thought that it is incident to the woman's age, until grave complications are at hand, or the true cause

carcinoma in most instances — is so far advanced as to place the patient beyond the pale of surgical interference. Dr. Wright called attention to the several changes that take place in the uterus at this time, and cause hemorrhage. The trend of his argument is to early recognize the pathological changes taking place in the uterus, and if in doubt remove the organ rather than take chances that will invariably result in death.

GUNSHOT INJURIES OF THE STOMACH.

DR. J. N. WARREN, Sioux City, Ia., gave the history and analysis of 141 cases of gunshot injury of the stomach. He spoke of the character and location of the lesion in uncomplicated cases in determining the prognosis. In operated cases the time elapsing from the time of injury and the operation shows that the earlier the operation is performed, the more favorable is the result. In complicated cases the number of lesions found and viscera injured add to the gravity of the case. He referred to the results in the cases that were not operated. He said the presence of food in the stomach with the discharge of the same into the abdominal cavity adds to the danger of general peritonitis, either with or without operation.

THE SYMPTOMS OF SPINAL DISEASE.

DR. S. C. BALDWIN, Salt Lake City, Utah, called attention particularly to the early symptoms of spinal disease, in order that suffering may be earlier relieved and deformity avoided. The general or more common symptoms, and then such symptoms as rigidity, gait, pain, paralysis, abscess, etc., were considered. The symptoms differ when different regions of the spine are involved. For instance, in the cervical region the first symptom noticed may be pain in the head, and, according to Whitman, cataplexy may be a symptom of cervical disease. Before there is any sign of deformity the patient may complain of difficulty in swallowing and even in breathing. In the cervical region there may be and often is the grunting respiration. Such general symptoms as weakness, loss of appetite, loss of weight, rigidity and general change of gait in walking are apparent in disease of all parts of the spine. The writer has seen a number of cases of Pott's disease developing in patients over forty years of age, and two cases which he recalls developed after fifty. Weakness may show itself in a general drooping of the trunk, in an unsteady and stumbling gait, and exhaustion requiring rest after the slightest exertion.

DRAINAGE OF THE MALE PELVIS.

DR. WILLIAM JENSON, Sioux City, pointed out the indications for drainage of the male pelvis, and spoke of the obstacles in the way of instituting such drainage as compared with the female pelvis. He described a method of instituting drainage of the male pelvis and reported the results he obtained in 19 cases. In all of these cases there existed a diffuse pelvic peritonitis, with accumulation of purulent fluid often elevating the distended bowel high into the abdomen, and in two cases as ending between the mesentery and descending colon and overflowing from the pelvis into the left sub-diaphragm, which was also opened and drained. In all but five cases there existed in the space to the outer side of the ascending colon, which in each instance was drained through the described space. In one case the distended pericolic bowels necessitated opening and the establishment of an artificial anus. Three of the cases thus treated had one, after an illness of nearly five months, died, while the time death in three or four cases was shortened by intestinal distention, while a number of abscesses followed in the abdominal wall. Death resulted from

exhaustion incident to the prolonged suppuration. In the second fatal case death took place ten days after the operation, due to toxemia.

GASTRIC DYSPEPSIAS AMENABLE TO SURGICAL TREATMENT.

DR. WILLIAM E. GROUND, Superior, Wis., said it is now recognized that many forms of digestive disturbance are dependent upon conditions entirely outside the stomach, and involve this organ either by direct extension of the pathological process, or indirectly by nerve influence. Among these may be mentioned inflammatory or irritative conditions in the biliary apparatus, pancreas, duodenum, or appendix, and adhesions of the stomach to the surrounding viscera. Within the stomach conditions remediable by surgical means are perforative and non-perforative gastric ulcer, chronic gastric ulcer, hemorrhage, pyloric obstruction, gastric dilatation with stasis, hyperchlorhydria, and cancer. The question of operative interference in some of these conditions is still in dispute, but the wisdom of referring cases of perforating gastric ulcer with or without adhesions, cicatricial stenosis of the pylorus, adhesions of the stomach to any of the surrounding structures and perhaps chronic gastric ulcer, to the surgeon is now pretty firmly settled.

Closely associated with ulcer is the sequence of cicatrization and contraction, and when this process involves the pylorus it leads to stenosis and obstruction, and later, if this is prolonged, gastric dilatation and atony will result. When the pylorus is obstructed by spasm due to the presence of the ulcer or to hyperchlorhydria, which almost always accompanies non-malignant ulcer, or to the cicatricial contraction following the healing of an ulcer, the pylorus is rendered incapable of readily transmitting its contents, the stomach becomes distended, and its muscular walls weakened, leading ultimately to permanent atonia gastrica. Stomach dilatation may be due to atony alone, but it is much more frequently due to mechanical obstruction at the pylorus. In this condition of gastric stasis, food may remain in the stomach a day or more, whereas it should empty itself within seven days at the most. In fairly advanced cases, when the obstruction has given rise to a compensatory hypertrophy of the stomach, the peristaltic movements may be seen and felt through the abdominal walls, usually accompanied by pain and vomiting. Later, when the stomach begins to dilate and assumes a more passive state, the patient complains of fullness and epigastric pains after meals. Fermentation takes place, causing eructations and heart-burn, and frequently vomiting. Vomiting is a most prominent symptom when gasterectasia and fermentation are well established. When this sequence of events is set up, there is but one remedy, and that is surgical intervention.

In view of the information of the curative effects of operation, they cannot be attributed alone to drainage of the stomach or to short circuiting of the food current, as is so often contended, for unless the pylorus is closed, food will pass through it. The explanation the writer has arrived at is to the effect that the cutting off of the circular fibers in the pyloric end of the stomach does away to a considerable extent with the muscular unrest accompanying gastric digestion, especially where ulceration is present. To the author's way of thinking, a gastro-enterostomy acts much the same as cutting the fibers of the sphincter and in anal fissure. In this latter condition the feces continue to pass over the ulcer, but the paralyzed sphincter prevents friction and it heals readily.

RESTORATION OF THE PERINEUM.

DR. HOWARD HILL, Kansas City, Mo., said that the perineum is divided into three layers: A superficial sphincter layer, a middle ligamentous layer, and a deep layer consisting of the levator ani muscle and its fascia. An ideal operation consists in restoring the different planes of tissue to their normal position. It matters little which incision is used to expose the structures mentioned, but he has used a transverse incision which consists in raising a flap of the posterior vaginal wall and has done the operation by using three layers of sutures. The first includes the levator ani and its fascia, reattaching that portion of the muscle which helps to form the perineal center in front of the rectum. Next he identifies and sutures the triangular ligament and attaches the sphincter ani to the perineal center. A single suture is used for the bulbo-cavernosus.

GLUTEAL CAVERNOUS ANGIOMA.

DR. J. E. SUMMERS, Jr., Omaha, Neb., reported a case and said that cavernous angiomata of voluntary muscles are comparatively rare, and in the case of this report the size of the growth is exceptional. It was excised while the circulation was controlled by direct digital pressure of the common iliac artery through an abdominal incision.

PRE-OPERATIVE THROMBI IN THE REGION OF THE FIELD OF OPERATION AS A CAUSE OF POST-OPERATIVE COMPLICATIONS AND DEATH.

DR. A. W. ABBOTT, Minneapolis, Minn., in a paper with this title said that thrombosis, especially of the veins, is often to be found, if looked for, in the vicinity of the field of operation. Thrombi may result from the pressure of a tumor, from cancer, or tuberculosis, etc., or may be the result of adjacent inflammation or traumatism. Usually no attention is paid to the condition. Thrombosis in the field of operation increases the danger.

Are there any practical methods for avoiding these dangers? The author believes many cases of fatal sepsis, pulmonary embolism, and particularly many cases of so-called ether pneumonia can be rightly ascribed to the infection of a clotted vein or its disturbance by rough handling, or both, that are otherwise inexplicable, so also pyemia, abscess of the liver, osteomyelitis, and other evidences of metastatic infection. Aural surgeons have formulated a definite operation for thrombi of the lateral and sigmoid sinuses, namely, ligation of the internal jugular vein and clearance and drainage of the sinus. This is an eminently successful operation, considering the desperate condition which calls for the interference, and, so far as the speaker knows, is the only established operation for thrombosis complicating operation. He thinks a similar course should be pursued in all operations complicated by thrombosis.

CONSERVATISM IN POST-OPERATIVE TREATMENT.

DR. S. C. BEEDE, David City, Neb., referred to the increasing tendency among surgeons to hasten their patients out of bed and hospital after grave operations. His attention was first directed to this matter when members of the laity began to mention frequently the shortness of time patients were detained by this or that surgeon. Nurses would speak with pride of the fact that their favorite operator would send a hernia or an appendix case home in two weeks. Then another one, not to be outdone, made it twelve days instead of fourteen. Another, to make a better showing than his competitor, shortened the period of disability to

ten days, only to be met by a more daring rival with an eight-day period for a clean abdominal section.

This, he says, is not the limit of extravagance in this strife to make it appear easy to be operated, but patients after extensive abdominal work have been carried out of bed and placed in a chair on the third day, and allowed to walk about the room on the fourth. It is creditable that the many weeks in bed once necessary can now be avoided by a more perfect technique, especially in the matters of more perfect control of hemorrhage, aseptic precautions, discarding irritating antiseptics, avoiding unnecessary traumatism and care in suturing and suture tension. These give the best possible opportunities for nature to do her reparative work, but nature will work only so fast, and he thinks there is a limit in time beyond which it is unsafe to urge her. His contention is that this limit has been overstepped, and that the perfect result which should be the aim in every case is thereby marred.

OFFICERS.

The following officers were elected for the ensuing year: President, Dr. Malcolm L. Harris, Chicago, Ill.; First Vice-President, Dr. A. L. Wright, Carroll, Ia.; Second Vice-President, Dr. C. Lester Hall, Kansas City, Mo.; Secretary-Treasurer, Dr. Arthur T. Mann, Minneapolis, Minn.

Salt Lake City, Utah, was selected as the place for holding the next annual meeting.

Recent Literature.

Military Hygiene. By ROBERT CALDWELL, F.R.C.S., D.P.H., Lieut.-Colonel R.A.M.C. Pp. xi, 416. New York: William Wood & Co., 1905.

This is a distinct departure from the usual line of works on military hygiene, and a welcome one. The author has "endeavored to give a short account of those principles of sanitation which most nearly affect the soldier in his every-day life, whether at home, abroad, or in the field." Following a preliminary chapter on "The work of the microbe" are chapters devoted to thorough discussions of typhoid fever, dysentery, malaria, plague, cholera, Malta fever and other scourges of military camps and expeditions, in which the author presents facts and opinions based upon personal experience and observation, with becoming modesty and freedom from dogmatic assertion in matters open to argument. Concerning some questions he is very frank in disclaiming personal knowledge, and this tends to add to one's respect for his opinions based on experience. The difficulties in conserving the health of troops, especially in handling epidemic diseases where outbreaks are inseparably connected with the habits and customs of native populations in the East, are very graphically set forth. The chapters on water, air, food, clothing, refuse disposal, climate, sick transport, etc., are in the main sufficiently full for practical purposes. The book is attractively illustrated, and as a piece of workmanship is a credit to both author and publisher. The price, however, suggests a very handsome gift to the library, and we hope a larger royalty than usual to the former.

THE BOSTON Medical and Surgical Journal.

THURSDAY, MAY 3, 1906.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 507 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE, (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE ETIOLOGY OF RELAPSING FEVER.

HARDLY a year passes in which renewed evidence is not forthcoming that at least the infectious diseases will soon be understood; and the hope is not too great that when their etiology is definitely established their eradication will follow. The interest of late seems to have turned particularly toward the spirochetæ as causative of disease. There is the strongest probability that the long awaited organism which is the cause of syphilis has been found in the *Spirocheta pallida*. There is a rather unusual unanimity of opinion on the part of those best qualified to judge that this organism has a direct causative relation with the disease. The consequences which may result from this discovery we cannot at present predict, but that they will be fruitful and a benefit to the human race cannot be questioned.

A research also of the great importance relates to the etiology of the so-called relapsing fever of East Africa. In the latter part of 1904 two English investigators, Dr. Dutton and Todd, announced their discovery of the pathogenic agent of the so-called tick fever, occurring in certain provinces of the Congo Free State. They were able to infect monkeys through the bites of ticks with the spirochetæ which they believe to be the etiological factor of the disease. They concluded therefore that tick fever was produced by a spirochete which was transmitted by the bite of a certain tick the larvae of which they were able to cultivate in a suitable medium. Although subsequent to the work of Dutton and Todd.

Important confirmation of their work of the past

ness of these observations has recently been obtained by Dr. Robert Koch who has published his results in the *Berliner klinische Wochenschrift* for Feb. 12. Previous to the publication of Koch's results skepticism had prevailed in Germany regarding the part played by the tick in the spread of the disease, hence the reinvestigation of the entire matter by Koch himself. He dissected a large number of ticks and by most careful microscopic examination found in some of his specimens spirochete closely resembling the parasites which had previously been found in relapsing fever as observed in Europe. Carrying his study further, he investigated particularly *Ornithodoros moubata*, suspected by Dutton and Todd of being the special variety connected with the disease. This tick is a blood parasite, having a special fondness for human blood, lives in dry soil during the daytime, comes out at night to feed, and frequents the huts of the natives. It is easily kept in captivity. The females deposit their eggs in the earth. The disease, which is now definitely shown to be related to the bite of these insects, is strikingly analogous to European relapsing fever, although differing in certain details, particularly in regard to duration. The number of parasites found in the blood is less in the African than in the European variety.

Regarding the morphology of the spirochete Schaudinn and Koch differ. The former regards the spirochete as a transitional form of a trypanosome, whereas Koch believes that they represent more permanent forms. In studying the life history of the organism in its host, the tick, Koch made the interesting observation that during the first and second days no changes either in appearance or number of the parasites which the tick had absorbed were found; later that coincidentally with their disappearance from the stomach they were found in increasing numbers in the ovaries where they rapidly multiplied. A study of the eggs then showed that spirochetæ could be demonstrated in great numbers in the older eggs. From the various researches made, it appears to be proved that this variety of tick is the intermediary host of the disease, hence the importance of determining the geographical distribution of the insects. It was found that they were widely spread over various caravan routes and elsewhere, and that many of them contained the spirochete. The disease was not always, however, coextensive with the parasites, hence Koch assumed an acquired immunity. In this connection we beg

to call attention to the important work represented by F. C. Wellman's communications published in this issue. Discoveries of moment in this line of research have followed each other rapidly during the past few years. Methods of study have been perfected, and the direction in which investigation may most profitably be prosecuted has been established. It is not to be questioned that further results may soon be expected in the elucidation of the fatal and widespread diseases of the tropics.

PRIORITY IN THE USE OF THE LARYNGOSCOPE.

HOWEVER unfortunate it may be, it is none the less inevitable that when a discovery has proved its usefulness dispute will arise as to priority. The doctrine of evolution and many other scientific discoveries have received this treatment, and it is, therefore, no matter of surprise that so useful an instrument as the laryngoscope should now be a subject of dispute as to its actual discoverer. It has been generally accepted, at least by English-speaking people, that Manuel Garcia was the first to make practical application of an instrument for the study of the larynx by reflected light. The *British Medical Journal* calls attention to a somewhat heated controversy which has been going on in Germany, throwing doubt upon Garcia's claims to priority, and giving the credit rather to Türek and secondarily to Czermak. Professor Kohler, a Berlin jurist, has taken up the cudgels against Garcia, maintaining that his observations were so incomplete that they cannot be regarded as an actual discovery. He thereupon grants to Türek the authorship of laryngoscopy and attributes to Czermak improved technique and application of the method to clinical study. Sir Felix Semon has entered the lists in support of Garcia's claim and, replying to Professor Kohler, he discusses at length the investigations which led up to the use of the laryngoscope and gives to Manuel Garcia the credit of being the actual inventor. He not only established a definite method but demonstrated its value; hence to him, according to Sir Felix, belongs the scientific discovery, although Türek was the first systematically to examine patients by the laryngoscopic method. To Czermak also is given the credit for doing much toward the establishment of clinical laryngoscopy.

Our contemporary concludes its comments on the subject as follows, and there is small

question that the sentiment here expressed will meet with the general approbation of those conversant with the development of the science of laryngology:

"Garcia's work was sound physiology, and as such was capable of a direct and simple application to medical practice. This application of his discoveries to clinical work was obviously the medical man's business, and not Garcia's, just as, to quote a parallel instance aptly suggested by Sir Felix Semon, it was the business of the surgeon, and not of Professor Roentgen, to employ the x-rays for purposes of clinical diagnosis. But the surgeon, attaching more importance to common-sense principles of elementary ethics than to forensic subtleties, acknowledges, as a matter of course, that the discoverer of diagnosis by the x-rays is Professor Roentgen; the question as to what particular surgeon happened to be the first to diagnose a fracture by their aid is so childishly trivial that it does not even enter his mind, and the laryngologist is as much indebted to Garcia as the surgeon is to the distinguished physicist. He fully appreciates the professional zeal and ingenuity of Türk and Czermak, but no amount of doctrinaire argumentation about a quite unnecessary 'Prioritätsfrage' will ever blind him to the fact that to Garcia belongs the credit of having founded the science of modern laryngoscopy."

MEDICAL NOTES.

UNIVERSITY OF JENA.—In August, 1908, the University of Jena will have been in existence three hundred and fifty years.

LECTURES ON HYDROTHERAPY.—Dr. Simon Baruch has been giving a course on hydrotherapy at the College of Physicians and Surgeons in New York. This marks a step in therapeutic advance.

PROFESSOR ASCHOFF THE SUCCESSOR TO PROFESSOR ZIEGLER.—The chair in pathology at Freiburg, vacated by the death of Professor Ziegler, after having been offered to Professor Schmorl, has been accepted by Professor Aschoff of Marburg.

APPOINTMENT OF DR. EDWARD A. SPITZKA.—It is announced that Dr. Edward A. Spitzka has received the appointment of professor of general anatomy at the Jefferson Medical College of Philadelphia. Dr. Spitzka has been associated with the medical department of Columbia University since his graduation, and has devoted himself largely to investigations relating to the anatomy of the nervous system.

A TEMPTING TRIP TO JAPAN AND CHINA.—The Great Northern Railroad Company offers tempting facilities and fares for a trip to Japan and China, leaving St. Paul the last of June and sailing from Seattle on a Great Northern steamer. Dr. Alexander J. Stone, of St. Paul, is endeavoring to organize a party of one hundred physicians with their families to take advantage of this favorable proposition.

THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.—The ceremonies attending the opening of the laboratories of the Rockefeller Institute for Medical Research, at the corner of Avenue A and 66th Street, in New York, will take place on the afternoon of Friday, the 11th of May. The Board of Directors have issued invitations and announce that addresses will be made by President C. W. Eliot of Harvard University, by President N. M. Butler of Columbia University, by Dr. W. H. Welch of Johns Hopkins University, who is also the president of the Board of Directors, and by Dr. L. E. Holt, the secretary of the Board.

NEW YORK STATE JOURNAL OF MEDICINE: CENTENNIAL NUMBER.—The March number of the *New York State Journal of Medicine*, which is the journal of the medical society of the state of New York, is presented as a centennial number. The last meeting of the society, held at Albany the last days of January and the first of February, was a centennial meeting. The present issue contains, among other things, the first chapters of a history of the medical society of the state of New York by Dr. Thomas J. Welch. It also contains the centennial addresses which were delivered at Albany on the occasion of the one hundredth anniversary.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, May 2, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 44, scarlatina 35, typhoid fever 5, measles 117, tuberculosis 46, smallpox 0.

The death-rate of the reported deaths for the week ending May 2, 1906, was 18.93.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending Saturday, April 28, 1906, was 225 against 210 the corresponding week of last year, showing an increase of 15 deaths and making the death-rate for the week 19.72. Of this number 112 were males and 113 were females;

220 were white and 5 colored; 142 were born in the United States, 80 in foreign countries and 3 unknown; 45 were of American parentage, 149 of foreign parentage and 31 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 43 cases and 5 deaths; scarlatina, 47 cases, 1 death; typhoid fever, 5 cases and no deaths; measles, 95 cases and 2 deaths; tuberculosis, 48 cases and 30 deaths; smallpox, no cases and no deaths. The deaths from pneumonia were 37, whooping cough 3, heart disease 25, bronchitis 4, and marasmus 3. There were 6 deaths from violent causes. The number of children who died under one year was 41; the number under five years, 61. The number of persons who died over sixty years of age was 43. The deaths in public institutions were 61.

There were 2 cases and 1 death reported from cerebrospinal meningitis during the week.

BOSTON LYING-IN HOSPITAL. REGISTRY FOR NURSES. — The Trustees of the Boston Lying-in Hospital opened on May 1, 1906, a registry for nurses for obstetric cases where a list of nurses who have graduated from the hospital and have registered is kept.

A nurse may be applied for at any hour of the day or night. A list of nurses who can be engaged for any future date is also kept. A fee of two dollars is charged for each nurse furnished.

Further particulars may be had of Mrs. E. J. A. Higgins, the superintendent.

NEW YORK.

NEW BELLEVUE HOSPITAL. — Dr. M. S. Gregory, physician in charge of the psychopathic ward of Bellevue Hospital, has been sent to Europe by the trustees of the Bellevue and Allied Hospitals on a two months' tour of the principal English and continental hospitals, with a view to the adoption of such of their arrangements as may seem advisable in the construction of the new Bellevue Hospital.

AMERICAN SOCIETY OF SUPERINTENDENTS OF TRAINING SCHOOLS FOR NURSES. — The twelfth annual meeting of the American Society of Superintendents of Training Schools for Nurses was held at the New York Academy of Medicine on April 25, 26 and 27. At the first session an address of welcome was made by ex-Mayor Seth Low, and on April 27 Miss Mabel Boardman, of the executive committee of the American Red Cross Association, read a paper on "The Red Cross Nurse."

A LEGACY FOR THE CELEBRATION OF MASSES DECLARED VOID. — On April 20, the Appellate Division of the New York Supreme Court handed down a decision affirming a decision rendered by Justice McCall, in special term, to the effect that a legacy in the will of the late Joseph Hughes, amounting to three fourths of the estate, to the trustees of St. Francis Hospital for the celebration of masses for the dead, was void. In the opinion of the Appellate Division, affirming the decision of the lower court, it seemed clear that the object of this gift was not within any of the purposes of the hospital corporation.

RELIEF FUND FOR THE SAN FRANCISCO MEDICAL PROFESSION. — The Medical Club of Brooklyn, of which Dr. J. S. Waterman is President, met at the Hamilton Club on April 23 and appointed a committee to raise funds, to be transmitted through the Kings County Medical Society, for the relief of members of the profession in San Francisco. One hundred dollars was voted from the treasury of the club, and \$400 additional was contributed by the individual members present. In a letter received in New York since this meeting a leading San Francisco physician writes: "I lost all my manuscripts, and all my instruments and records went up in smoke. . . . What the doctors need here is operating chairs and surgical instruments of all kinds — immediately. This is very important, and I hope the matter will not be overlooked by the generous public."

Obituary.

JOHN COMBE PEGRAM, JR., M.D.

JOHN COMBE PEGRAM, Jr., of Providence, died at the Corey Hill Hospital on April 26, 1906. He had been successfully operated on for chronic appendicitis nine days before. Convalescence seemed fully established when, without apparent cause, the left parotid and submaxillary glands became the seat of a streptococcal infection which rapidly spread to the pharynx and larynx. Tracheotomy and drainage gave only temporary relief.

Dr. Pegram was thirty-six years old. In 1892 he graduated from Brown, and in 1896 from the Harvard Medical School. He was surgical house pupil at the Massachusetts General Hospital in 1895-96, where his work was such as to attract especial commendation, and where he made many warm friends. A year later he finished his course at the Children's Hospital. He was visiting surgeon to the Rhode Island Hospital; orthopedic surgeon to St. Joseph's Hospital; consulting surgeon to the Butler Insane Asylum and medical examiner for the state of

Rhode Island. His work, first in orthopedics and then in general surgery, was of the highest order. Already he had won an enviable position as a surgeon in Providence, where he was held in the greatest respect and affection. It is not too much to say that he had before him a career of exceptional brilliancy and usefulness.

Miscellany.

THE CLIMATE OF HAWAII.

THE following extract from a report written by Dr. Leland E. Cofer bears directly upon the climate of Hawaii, and is being circulated by the Hawaii Promotion Committee:

"The element of charm, which enters so potently into all things Hawaiian, makes even the climate conditions almost impossible of description.

"Indeed, one lives so comfortably here that the character of the climate is practically never thought of, in the same way that a sound man lives oblivious to his liver. A person newly arrived from the lands where snows and sun-strokes prevail could give a more convincing description of our days and nights than one who through sheer content has lost all sense of perspective.

"The weather statistics tell the truth but hardly the whole truth. They show, and with all accuracy, a rather high rainfall, yet the layman, either because our rains usually occur at night or else because he usually sees them as 'liquid sunshine,' would invariably pronounce the climate as the dry marine variety. The temperature, humidity and rainfall varies widely with the exposure and elevation selected as the point of observation. Therefore, so long as it is possible to run by automobile over good roads in a few hours, from the humid warmth of the coast to the dry cold of the highlands, so long will the opinions of men differ as to the climate taken as a whole.

"As Honolulu is the natural center and distributing point, one forms his impressions from local climate conditions. It may be said in general that the climate is of the semi-tropical variety in which the mean extremes are never reached.

"The fair days are no warmer, nor the rainy ones more disagreeable, than those prevailing during the month of June in New York City, and withal there is the certainty that these conditions will obtain throughout the whole year. While a great many men dress just as they do in the eastern states, the large majority of the population enjoy the privilege not to say the luxury of being comfortable in white every day in the year.

"Surf bathing and aquatic sports, pleasures which are known to comparatively so few people on the mainland, are indulged in, particularly by children, in January and July alike. In this

latitude and longitude such conditions, it is needless to say, are unique and would be impossible were it not for the trade winds which keep intact health, comfort and commerce and make out-of-door sports a part of the daily routine. As every one may live constantly in the open air, the pleasures of those in good health are shared by health-seekers. The medical 'don'ts' which are necessary in so many really good climates are unknown here. Therefore the convalescent in Hawaii has not the identity which is so often his, and which proves not infrequently a barrier to rapid recovery from ailment. Unlike some climates it is not good for every disease to which the human economy is liable. For example, persons suffering from pulmonary tuberculosis will usually thrive far better in Colorado than here. On the other hand patients suffering from nervous complaints, kidney disease, etc., are justified in coming here from almost any part of the world. In short, I believe the influences in Hawaii offer the least resistance to bodily well being of any of the well-known health resorts of the world. Even if the meteorological findings are similar in other places, it is doubtful whether they make their impress upon the people as they do here.

"This climate breeds happiness and laughter, a natural and appropriate reflection of the sunlight, rainbows and purple hills, and for those who enjoy such things—there's Hawaii."

THE STATISTICS OF THE MEDICAL STUDENTS IN GERMANY.

STATISTICS published by the *Frankfurter Zeitung* as to the number and distribution of medical students throughout the German universities show in a general way that the popularity of medical studies increased progressively from 1860 to 1890, since which year it has declined. During the winter session 1905-06 the total number of medical students in Germany was 6,080, last summer it was 6,032, during the previous year 6,153. In 1885 the total was 7,725, in 1890, 8,986 and in 1896, 7,551. These figures include foreign students, of which there are at present 895 registered in the universities. Last summer there were 751. German subjects registered as medical students numbered in 1861, 2,000; in 1872, 3,365, and in 1881, 4,389. The proportion per 100,000 inhabitants, shown by medical students of German nationality at the present date is 8.5; in 1890 it was 11; in 1881 it was 9.7; in 1872 it was 8.5 and in 1861 it was 7.6. The proportion of medical students in the different universities is shown as follows: Since 1882 the number of medical students at Berlin, Munich, Freiburg, Heidelberg, Bonn, Kiel, Göttingen and Rostock has increased 50% and at Leipzig over 25%. At Greifswald it has been cut 100% and at Breslau 50%. At Tübingen and Würzburg more than 25% and at Königsberg and Halle more than 20%. Münster, where no German university has no medical faculty. *Continued.*

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 21, 1906.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING APRIL 28, 1906.

E. J. H. OLD, assistant surgeon. Detached from the Naval Medical School, Washington, D.C., and ordered to the Naval Training Station, San Francisco, Cal.

F. J. B. CORDEIRO, surgeon. Discharged from treatment at the Naval Hospital, New York, N. Y., and ordered to Washington, D. C., May 2, for examination in conformity with title 15, chapter 3, Revised Statutes, and thence home to wait orders.

R. E. HOYER, passed assistant surgeon. Detached from the Naval Academy and ordered to the "Newark."

E. U. REED, assistant surgeon. Ordered to the "Charleston," May 1.

P. T. DESSEZ, assistant surgeon. Detached from the "Charleston," and ordered to the "Severn."

SOCIETY NOTICES.

ASSOCIATION OF AMERICAN PHYSICIANS.—The Association of American Physicians will hold its twenty-first annual meeting May 14 and 15 next at the Willard Hotel, Washington, D. C. On Wednesday evening at the Hotel Willard a joint session of the Association of American Physicians and of the Association for the Prevention of Tuberculosis will be held.

AMERICAN CLIMATOLOGICAL ASSOCIATION.—This association will hold its twenty-third annual meeting May 12-14, 1906, at the "Marlborough-Blenheim," Atlantic City. First day, Saturday, May 12: Scientific Session, 9:30 A.M. to 12 M. Business Session, 12 M. to 1 P.M. Scientific Session, 2:30 to 3 P.M. Annual Dinner, 7 P.M. Second day, Monday, May 14: Scientific Session, 9:30 A.M. to 12 M. Business Session, 12 M. to 1 P.M. Session, 2:30 to 5 P.M. Adjournment.

GUY HINSDALE, M.D., Secretary.

E. L. SHURLY, M.D., President. Hot Springs, Va.

NEW ENGLAND ASSOCIATION FOR THE EDUCATION OF NURSES.—There will be a meeting at Huntington Hall, Massachusetts Institute of Technology, Boylston Street, on Friday, May 11, 1906, at 4 and at 8 P.M. Paper for afternoon: "What proportion of a nurse's training should be spent in district nursing?" Miss Annette Fisher. Discussion. "The present curriculum from the point of view of the nurse." Dr. Hugh Cabot. Discussion.

8 P.M.: "Are the applications for admission to training schools diminishing in number?" Statistics read by Dr. G. Volcovich. Discussion. "The advantages of separate organization for training schools for nurses from that of the hos-

pital." Dr. Alfred Worcester. Discussion: Dr. G. H. M. Rowe, Dr. Edward Cowles, Dr. Herbert B. Howard, Mrs. W. W. Vaughn, Dr. F. W. Patch. A cordial invitation to be present is extended to those interested.

MISS EMMA A. ANDERSON, Secretary.

DR. RICHARD C. CABOT, President.

RECENT DEATHS.

JOHN COMBE PEGRAM, JR., M.D., M.M.S.S., of Providence, R. I., died April 26, 1906, aged thirty-five years.

CHARLES FRED MOULTON, M.D., M.M.S.S., died in West Roxbury, April 24, 1906, aged forty years.

BOOKS AND PAMPHLETS RECEIVED.

Sex and Character. By Otto Weininger. Authorized Translation from the Sixth German Edition. London: William Heinemann. New York: G. P. Putnam's Sons. 1906.

Recent Advances in Physiology and Biochemistry. Edited by Leonard Hill, M.B., F.R.S. Contributors: Benjamin Moore, M.A., D.Sc.; Leonard Hill, M.B., F.R.S.; J. J. R. Macleod, M.B.; M. S. Pembrey, M.A., M.D., and A. P. Bedard, M.A., M.D. With diagrams. New York: Longmans, Green & Co. London: Edward Arnold. 1906.

Case Teaching in Medicine. A Series of Graduated Exercises in the Differential Diagnosis, Prognosis and Treatment of Actual Cases of Disease. By Richard C. Cabot, A.B., M.D. (Harv.) Boston: D. C. Heath & Co. 1906.

Illustrations of Human Vivisection. Vivisection Reform Society. 1906.

A Treatise on Surgery. By George Ryerson Fowler, M.D. Illustrated. Vol. 1. Philadelphia and London: W. B. Saunders Co. 1906.

A Text-Book of Materia Medica, Therapeutics and Pharmacology. By George F. Butler, Ph.G., M.D. Fifth edition. Thoroughly revised and rewritten and adapted to the eighth revision (1905) of the U. S. Pharmacopoeia. By Smith Ely Jelliffe, M.D., Ph.D. Philadelphia and London: W. B. Saunders Co. 1906.

A Text-Book on the Practice of Gynecology. For Practitioners and Students. By William Easterly Ashton, M.D., LL.D. Second edition. Illustrated. Philadelphia and London: W. B. Saunders Co. 1906.

Diseases of the Eye. A Handbook of Ophthalmic Practice For Students and Practitioners. By G. E. de Schweinitz, A.M., M.D. Fifth edition. Thoroughly revised. Illustrated. Philadelphia and London: W. B. Saunders Co. 1906.

Reference Handbook of the Diseases of Children. For Students and Physicians. By Prof. Dr. Ferdinand Fruhwald. Edited with additions, by Thomas S. Westcott, M.D. Illustrated. Philadelphia and London: W. B. Saunders Co. 1906.

A Handbook of Climatic Treatment, including Balneology. By William K. Hugdard, M.A., M.D., F.R.C.P. Lond. London: Macmillan & Co., Ltd. New York: The Macmillan Co. 1906.

The Operating Room and the Patient. By Russell S. Fowler, M.D. Illustrated. Philadelphia and London: W. B. Saunders Co. 1906.

Nursing: Its Principles and Practice. For Hospital and Private Use. By Isabel Hampton Robb. Third edition, revised and enlarged. Illustrated. Cleveland: E. C. Koerkert. 1906.

Nursing in the Acute Infectious Fevers. By George P. Paul, M.D. Illustrated. Philadelphia and London: W. B. Saunders Co. 1906.

Saunders' Question-Compends, No. 13. Essentials of Genito-Urinary and Venereal Diseases. Arranged in the form of Questions and Answers. Prepared especially for Students of Medicine. By Starling S. Wilcox, M.D. Illustrated. Philadelphia and London: W. B. Saunders Co. 1906.

Gynecological Diagnosis. A Manual for Students and Practitioners. By Arthur E. Giles, M.D., B.Sc. Lond., F.R.C.S. Ed., M.R.C.P. Lond. Illustrated. New York: William Wood & Co. 1906.

The Treatment of Gonorrhea in the Male. By Charles Leedham-Green, M.B., F.R.C.S. Illustrated. New York: William Wood & Co. 1906.

Transactions of the Obstetrical Society of London. Vol. XLVII. For the year 1905. Part IV., for October, November and December.

Atmokausis und Zestokausis die Behandlung mit Hochgespanntem Wasserdruck in der Gynäkologie. Von Dr. Ludwig Pinus. Second edition. Illustrated. Wiesbaden: J. F. Bergmann. 1906.

Address.

1806-1906.

THE BOSTON MEDICAL ASSOCIATION.*

BY DAVID W. CHEEVER, M.D., BOSTON.

ONE hundred years ago this Association was founded in Boston, by a few physicians, practising in a semi-rural town. Gardens, orchards and common fields or pastures divided the scattered houses. If any streets were paved, they were with beach cobblestones. There were no street lights; there were no street cars; there was no steam; no electric usage; no telephone; no ether; probably no coal and no matches. The Doctor rode in town in a chaise, whose two wheels turned easily at sharp angles; out of town, he rode on horseback. There were no hospitals, and no abuse of charity. The almshouse was the clinic. Crude opium, or ipecacuanha supplied the place of modern alkaloids, vegetable leaves were infused and drank as senna and other teas; the followers of Galen who were herbalists disputed the field with those who used minerals; for the latter, antimony and calomel were the standard remedies. The lancet was often unsheathed and the emetic was an anti-febrile remedy. Books were few, knowledge traditional; observation, acute, and eyes, undulled by instruments of precision; deductions were slow and durable; judgment, careful; professional pride and status, higher than to-day. And yet from these scanty resources a few doctors founded a medical school, a hospital, a medical society, and an association. The school was the medical school of Harvard, the hospital was the Massachusetts General, the society was the Massachusetts Medical Society, and the association was the one whose centenary we celebrate to-day.

My grandfather, Dr. Majah Cheever, was practising in Hanover Street, at the North End. At this period, Dr. John Warren was lecturing on anatomy and surgery out in Cambridge, which he sometimes had to reach by ferry, when other means failed. Life was simple; medical knowledge was filtered from the great distance of England; very few men saw Laroque or Abernethy or Cooper, although some did later.

This was a community isolated by forests and by seas, with a currency shaken by an eight years' war, with few advantages and no neighbors. There was no rapid transit, New York was five days away. Men relied on themselves, *totus teres et rotundus* there developed the all-round practitioner, reserved in manner, clerical in dress. We shall see presently how well he did, and how worthy he was of our imitations.

Again how different was from 1670 to 1700, when my ancestor, Ezekiel Cheever, from whom I am of the seventh generation, the master of the Latin School, kept his classes in a little frame building on School Street, near King's Chapel.

Cotton Mather, Increase Mather, Sewall and other worthies then ruled the private life and

manners of all citizens. Decorum prevailed; Boston was a small town; its habits and social customs regulated by the reverend clergy.

A century after the death of the old teacher of the classics, and rising from the throes and poverty of the Revolution, a new order of things had come about.

In 1781, before the Revolutionary War was over, thirty-one doctors had founded the Massachusetts Medical Society. The statute of the Commonwealth thus defines it:

"As health is essentially necessary to the happiness of society, and as its preservation and recovery are closely connected with the animal economy, and with the properties and effects of medicine; and as the benefit of medical institutions, formed on liberal principles, and encouraged by the patronage of the law, is universally acknowledged; Be it therefore enacted that Nathaniel W. Appleton [and thirty others] are formed into a body corporate by the name of the *Massachusetts Medical Society*."

One hundred years ago, Boston had thirty thousand inhabitants. Its directory of the year 1806 registered thirty-nine doctors.

Twenty-six were fellows of the Massachusetts Medical Society, and thirty belonged to this Association.

Many familiar and family names of physicians occur among them: John Warren, John C. Warren, James Jackson, Lemuel Hayward, William Ingalls, John Jeffries, Benjamin Shurtleff, William Lusk, Samuel Danforth, James Lloyd, Isaac Rand, John Fleet and eighteen others, thirty in all.

Now Boston has six hundred thousand inhabitants, six hundred and nine physicians, and two hundred and fifty-two are members of this Association.

Samuel Danforth, James Lloyd, Isaac Rand and John Warren, who are among the founders of the Massachusetts Medical Society, are also quoted among the thirty who established this local medical association for the town of Boston.

In 1806 the war was over, the states had united, the currency had improved, Boston had considerable wealth, and the style of living had grown less narrow and more liberal. Republican license was displacing Puritanism.

It was to meet these conditions and to adjust the fees of the doctor, justly to them, that this Boston Medical Association was formed in 1806. What were the reasons for the need of a fee table? They are as well explained in the transaction of our Association, that I cannot do better than quote them.

"An agreement among physicians in regard to a fee table would not be prejudicial to the cause of humanity. Such agreement implies that a physician would not afford his aid unless he were compensated, and compensation is a moral duty. It will hardly be disputed that a man who has not full share of those of any other man, in his gratefulness serves to the society. Surely indeed would it be, while their duties are con-

* Remarks made at the Centenary Meeting of the Boston Medical Association, May 7, 1906.

stantly bringing before their minds the wisdom and goodness of God their creator, if they should not be disposed to extend their aid to the sick and suffering from any other motive than a reward to themselves. But men without fortune would not enter the profession of medicine, if they did not look to their labors, as men do in other professions, for an adequate maintenance, and, if successful, for the accumulation of some property. With us, almost every one who engages in medical studies is altogether dependent on his business for support. The fees are indispensable; so much so, that the young practitioner is liable to the temptation of undervaluing his services for the attainment of immediate support; and those who are no longer young may also offer their services at a low price, hoping to compensate themselves by an increased amount of business. This will be done by those who think more of the amount of business than of the services due to their patients.

"It is at this point that we may consider what is for the interest of the public,—what is for the interest of the sick, who look to the physician or surgeon for their cure. Which would be best, that the medical men should contend who would do the work for the lowest fees, or that they place their claims on their education, or their devotion to their profession, and on whatever goes to make up the qualifications for the proper management of the sick,—in short, on their professional skill and merit? It is true that professional skill and merit are not always duly recognized and rewarded; the battle is not always to the strong. But, in general, the strong will ultimately succeed in the contest; and it is better for the community that every medical man should rely on his qualifications to be truly useful, than that he should be compelled to contend with his neighbor and brother as to which would serve the sick at the lowest rate.

"From this view of the subject, we conclude that the establishment of a uniform fee-table among physicians and surgeons living in the same city or in a near vicinity is justifiable and proper.

"With regard to the principles on which a fee-table should be constructed, it may be assumed that the fees should be high enough both to induce men of talents and good character to enter the medical profession; and also to satisfy them, so that they should never cease to study their art, and to cultivate all branches of science which would aid them in it. The physician should be able to obtain a subsistence in the early years of his life by such a moderate share of business as can be obtained in those years; and, if successful and fully occupied after he has arrived at middle life, he should be able to live in a style consistent with his rank in society, and to make provision for his old age, or for such a family as he may leave behind him."

Mark the changes in our fee-table in a century; how gradual they have been; taking the charge for a visit as the unit: 1788, sixty-seven cents (four shillings); 1798, one dollar (new currency);

1808, one dollar and a half; 1851, two dollars; 1864, three dollars; 1905, three to five dollars. Since the Civil War, changed conditions have come in. The inflation of a paper currency, the demoralized habits engendered by four years of war, the great expansion of business since 1897; the high tariff; the growth of monopoly; exaggeration of expenses; high cost of labor,—have swelled the expenses of all out of proportion to income. A falling rate of interest, a sharper competition, a flood of immigration, have lowered the standard of the middle class, shrunk the resources of the employee; tended to divide society into two classes,—the very rich and the poorer class.

It may be asserted as more than probable that the doctor's "plant" is the most expensive of all callings. From eight to ten years, according to the most complete preparation, comprising college, medical school and hospital, will make the young physician from twenty-five to twenty-eight years old when he is ready for practice.

Many of these years, in other callings, are often working years, productive years.

It is safe to say that the expense of such a medical education, including support for from eight to ten years, is not less than \$6,000 or more than \$10,000.

Is it unreasonable to count the annual interest loss on this outlay at \$500. forever? Is it probable that the young doctor is self-supporting under three to five years more? One must be past thirty years of age to have acquired some medical practice. Now comes in the nature and resources of his *clientèle* and the wise course to pursue in charging.

What can the doctor do to adjust himself to these new demands? He must spend more, he must earn more. How?

The physician, like every one, is driven by the inexorable laws of political economy to consider the probable amount of property or of income of his patients that he can draw on for his compensation. There must be, more than ever, a sliding scale. The rich must pay well; the middle class moderately; the poorer class something. This course combines justice and necessity. These are cold facts not to be obscured by sentiment.

Let me not be misunderstood. The doctor is and should be charitable. He probably does more for the poor than any class of citizens does. He is oftener cheated and imposed upon by fraudulent clients; he has to bear all that and be a gentleman and an altruist; but he must look after his own living, though merciful and just.

The general principles laid down in our fee-table cover all this. A sliding scale; deductions for good reason; free advice to the poor; a minimum fee, but not a maximum.

A fair bill promotes business and confidence; but an opinion is abroad that surgery is very costly; specialties all too costly; obstetric charges prohibitory of large families.

This is a wrong condition; it is contrary to political economy to kill the goose that lays the golden egg.

The effect of very large fees is:

(1) To make a false standard; to distort the professional spirit; to discourage the patient who desires operation or treatment.

(2) To drive many to hospitals and free treatment and thus to play directly into the hands of that great abuse, the abuse of charity.

It is of great importance in seeking to do justice to both physician and patient that the latter should, if able, pay something, even if the fee be small. Gratuitous service, indiscriminately given, pauperizes the community. The doctor must live and to live he must be paid, and I am one of those who believe that half a loaf is better than no bread. The beginner in medicine will have to treat humble clients. Let him collect and be satisfied with one third of the usual fee. One dollar may be afforded when two or three dollars is a hardship.

It is no derogation of our dignity to accept what people can afford to give for our services. A minimum may be elastic and a maximum certainly should be. The sliding scale is indispensable in our professional prices. The maximum must be left to the individual conscience; why should not the minimum be also? A standard of fee, as three to five dollars, is necessary in disputed claims, in settling accounts and, above all, in courts of law.

You will say, "This is my regular and lawful fee, say five dollars, and I am entitled to it; but I do not limit my right to charge more, or, in poverty, to accept less."

Stand up to a fixed rate as your due; and claim all that is proper, in addition, from those whose wealth demands night and day continuous service, increased responsibility, and results which may be far reaching in questions of the value of some lives over others, and in the just settlement of great estates.

I cannot too strongly insist that you should be paid, and well paid, for the exhausting services and sacrifices which our profession entails, as no other calling does.

To solve these problems let us inquire what are the average incomes of different classes of citizens of Boston.

The old rule used to be that it took one thousand people to support a doctor.

That ratio is about right still; it prevails here, — six hundred regular physicians to six hundred thousand people.

We must throw out of consideration just now the irregular quacks.

The successful Boston regular physician has, or may have, 1,000 people to support him. How, and in what proportion?

Out of his 1,000 prospective patients, 100 are rich or very well to do, 650 are very moderate indeed, 250 pose as paupers and seek charity in hospitals and dispensaries.

How do we prove this? Of the 600,000 people in Boston somewhat over 60,000 pay all the taxes except a poll tax; one tenth acknowledge or are proved to have taxable property. One in ten of the population makes the 100 rich, or very well off, in each 1,000.

There were 300,000 charity visits or hospital patients in Boston last year (see Dr. Gay's paper on "The Abuse of Charity").* Suppose we concede that one half of these come from out of town, leaving 150,000, — one fourth of the population; that gives the 250 assumed or real paupers. There remain 650 moderate people to complete the 1,000: 100 rich, 650 poorer, 250 pauper, total, 1,000.

Of course, every doctor has some suburban or distant practice. We must admit this source of error.

Now, calling the family an average of five persons, and the doctor has 20 rich families, 130 very moderate families, to whom he can look for support.

Take the moderate class, — what do they earn? The laboring class, \$600 a year; the shop girl, \$500 a year; the female servant, \$200 to \$500 a year net; the good mechanic \$3 to \$4 a day, \$900 to \$1,200 a year; higher grade employees, \$1,500 to \$2,000 a year. A much, much smaller class, \$2,500 to \$3,000; \$5,000 to \$10,000.

The latter should be counted among the rich.

Of the 650 persons, or 130 families, of the moderate class, the breadwinner (often one) earns from \$600 to \$2,000 a year. The sickness which calls the doctor often stops the income; proprietary medicines and apothecary practice diminish the calls.

One dollar to the poorer; two dollars to the very moderate class; three dollars to the better grade; five dollars (as a minimum) for each visit to the well to do, does not seem to be far out of the way.

Is there any other way for the doctor to adjust himself to the new conditions than to return to first principles and adhere to a sliding scale, a wise and moderate discrimination, being as careful of not charging too high as of charging too low? What our table does not prescribe is a maximum; every man must use his judgment on his own cases.

Our fee-table has been copied as a model in many other places. I believe that our fee-table gives him all the aid anything can so judiciously guide his career. A few wise maxims from it may be fitting here:

"X. It is not designed by these regulations to prevent the members of this Association from rendering their services gratuitously to persons who are incapable of remunerating them without distressing themselves or their families; and in every case, in settling his account, the practitioner may make any deduction which he conscientiously believes that the circumstances of the patient render necessary.

"XI. No member of this Association shall omit charging any necessary visits made on the same day on account of their number.

"XII. No member of this Association shall make a previous contract with any family for a definite sum as a remuneration for his attendances on that family."

The standing committee of the Boston Medical

* BOSTON MEDICAL AND SURGICAL JOURNAL, May, 1901.

Association (Drs. John Warren, Lemuel Hayward and John Fleet, were instructed, on the first Wednesday of March, 1807, to prepare a code of medical police. They speak with no uncertain sound, as follows:

"Medicine is a liberal profession; its practitioners are, or should be, men of education; and their expectations of business and employment should be founded on their degrees of qualification."

The conduct of medical life at that early period is carefully considered.

"The *esprit du corps* is a principle of action founded in human nature, and when duly regulated is both rational and laudable. Every man who enters into a fraternity engages not only to submit to the laws, but to promote the honor and interest of the Association, so far as they are consistent with morality and the general good of mankind. A physician, therefore, should cautiously guard against whatever may injure the general respectability of the profession."

With such sentiments I cordially invite the three hundred and fifty members of the Suffolk District Society, who have not done so, to come forward at once and join this Association. The fee is small, and there are no assessments. The organization is simple, the purpose worthy. A few earnest men have kept this Boston Medical Association alive for a century. *Esto perpetua!*

Original Articles.

THE PAST OF THE BOSTON MEDICAL ASSOCIATION. CHANGES IN THE FEE-TABLE.*

BY JAMES C. WHITE, M.D., BOSTON.

I HAVE been asked to give you some brief comments on the past of our Association, and shall confine my remarks to one or two features of its history mainly, as Dr. Cheever has so satisfactorily covered all points of interest.

I was, early in my professional life, moved to express publicly my opinion of its shortcomings in relation to the inadequate fee-table it had adopted. I was at the time an editor of the BOSTON MEDICAL AND SURGICAL JOURNAL, and in the issue of Jan. 7, 1864, in the midst of the Civil War, be it remembered, was led to publish the following editorial:

"How much or how little truth there may be in the popular belief in relation to the want of unanimity of opinion among medical men we do not care to consider, but we do not hesitate to affirm that upon one subject, at least, which has been brought before every member of our profession during the past week there has been no difference of opinion. At the end of the year we cannot help reflecting, as we apply ourselves to the pleasant task of making out our bills and strike the balance between our expenditures, in which there can be no mistake, and our prospective income, of the amount of which,

alas! we are never sure, how unfairly the times are affecting us. Our marketman, our grocer and tailor and coal merchant and all our patients in their various callings have not failed long ago to discover that a dollar no longer represents what it once did, and, like sensible men, have advanced their prices in conformity to the depreciation of money. If M. is obliged to pay C. twelve dollars for a ton of coal, he demands an equivalent price for the beef he sells him, so that at the close of the year, all find their balance unaffected by the universal increase in the expenses of living. We, however, have gone on paying them on the spot all they demand, while for our own services we have been foolishly content to ask them to pay, if they please, a price fixed for us long ago, and almost as little proportionate to the present standard of money as if it were expressed in wampum; and it is this reflection which should have come to every physician during the past week, in sight of the immense difference in the relative increase in the amounts upon the debit and credit columns of his account book, that some concerted and immediate action should be taken with regard to the reformation of the present fee-table. We say concerted, for we know that certain gentlemen, whose patients are the rich, and whose incomes are such that household expenses need cost them no anxiety, have taken independent action in the matter, and pay little, if any, regard to the laws of our medical police, while the young and less fortunate are obliged in most cases to be content with the old minimum fee and dare not exceed the maximum in their few best families. Did the amount of practice like other business increase in proportion to the surrounding prosperity, we might find in such increase the remedy for our present wants; but, fortunately for mankind, plenty and joy do not make the sick list longer, but smaller, and the physician's services are most in demand when adversity and poverty deprive the patient of the means of repayment. We trust, therefore, that the Boston Medical Association will take the matter into earnest consideration and revise its present code at this opportune season, so that the public may be informed at the beginning of the year of a change which should have been made long ago."

These opinions were regarded by many of the older and most influential members as imprudent and almost revolutionary, and the editor received many remonstrances from them. Nevertheless, in April, just before the annual meeting of the Association, he reiterated these views in a second editorial, adding: "We have always been far too modest in our estimate of the value of our services, and in order to obtain anything like the competency which follows a successful career in the law, have been obliged to do at least twice the amount of work. Hence the necessity of continuing active practice far into old age, and the non-attainment of that leisure for study so essential to the future rank of medicine in this country. We may place what

* Remarks made at the Centennial Meeting of the Boston Medical Association, May 7, 1906.

value we please upon our labor, but unless the profession consider its own services as worthy of as high reward as those of any other, it can hardly expect the public to recognize their importance."

In the meanwhile the younger members especially had become convinced that some action should be taken with regard to the question, and at the annual meeting held May 2, 1861, after a so-called "animated discussion," a committee, consisting of Drs. J. Mason Warren, George Bartlett, Charles E. Buckingham, George H. Gay, Charles D. Homans and James C. White was appointed to revise the rules and regulations and fee-table. Their report was presented on June 13, and after debate was adopted. The most important changes made in the fee-table were: the increase in the ordinary charge for a visit from one or two dollars to three dollars, and the maximum for a consultation from five dollars to ten dollars. I may add that before the year 1861 had run its course I had received many confessions from the principal opponents of the increase of their satisfaction that their conservative views had not prevailed.

I may be permitted to make one or two other comments upon some features of the fee-table then adopted and the Rules of the Society. I quote the following paragraph from the former:

"It is recommended that in the treatment of gonorrhea or syphilis the first charge shall be from five to ten dollars" instead of that of three to five dollars as in other diseases. Here a discrimination was made on the basis of morality. Could any measure be more uncharitable or bigoted? Affections of the gravest character, often contracted in the most innocent ways, liable to be communicated to members of the patient's family and transmitted to offspring, requiring utmost skill at times for early recognition, of which our profession itself is the frequent victim, to be thus stamped as a disgrace rather than a misfortune, and forced in this way into the claws of quacks, or neglect for economy's sake or false shame! In the last edition, 1903, this clause remains unchanged.

I want to say a word also in reference to the "Code" regarding consultations. It reads: The attending physician "should deliver all the medical directions as agreed upon." In my opinion this procedure is often a mistake at least as concerns consultations with specialists. Diagnosis is only one of the objects of such meetings, and the success of special treatment depends largely on the exactness with which the details of the measures advised are carried out. The more directly, therefore, these are given to patient and nurse the better, and I believe they should be communicated first hand to them, or at least be given in their presence. I am convinced, moreover, that it would be better in my own department if in some cases subsequent consultations were held, or the patient were placed in the immediate charge of the specialist, so that the results of the remedies advised could be observed by him, and the treatment be mod-

fied according to the natural changes of the affection. Speaking without conceit or motives of self-interest I am sure that in such way only can the best results be secured to the patient.

Other questions concerning the relations between specialists and the general practitioner have arisen since the formation of the code, which are not defined therein and are at times the cause of jarring and ill-feeling between members of the profession. It is not so long ago that the so-called family physician felt that he held full control over all medical relations of his families, and that with him rested the whole authority of deciding when any outside advice should be sought; that is, that no surgeon or specialist should be consulted without his suggestion or consent, and in those days there was strong opposition to the very existence of the specialist. I have known men holding high and official positions in the profession to exhibit outspoken opposition to their recognition in any form, and to express open anathema against them on all occasions. There was justification, perhaps, for this feeling towards the surgeon until surgery became a real specialty or an exclusive department of practice, because sometimes, no doubt, he may have used his occasional service as a means of securing an additional family upon the list of his general practice, but there were no just grounds for such animosity towards the specialist who did no work outside his department. Now that our knowledge of medicine has enlarged so vastly that no man can possibly acquire it all, it has slowly become recognized both by the profession and laity that specialists are a necessity, and the latter have come to believe that they have the right to consult them independently of the relations of the family physician. Without such freedom on their part it is evident that the specialist in some branches could not exist, to the detriment of medicine and humanity. Although this new order of the division of labor has been accepted by the body of the profession, there still lingers a considerable opposition to this condition of independence, and if codes could regulate completely the ethics of our profession, it might be advisable to recognize in ours the changed relations of modern practice in this respect. Reverence for commandments or ordinances, however, is no longer a powerful factor in our professional conduct, and we must leave to time the complete adjustment of such differences. There can be no serious clashing where mutual respect prevails.

A BIOGRAPHIC CLINIC ON TCHAIKOVSKY

BY DR. H. W. GALT, M.D., CHICAGO, ILL.

"Nervous tension," "nervous irritability," "depression," "illness," and such terms are constantly met in the biography and letters of Tchaikovsky. That these symptoms began to appear early in his life and were always connected with study, school life, or literary work, may be seen by the following quotations:

The numbers following the quotations indicate their place in the

This nervous tension began to be apparent, not only in his pallor and emaciation, but in frequent ailments that kept him from school. There was also a moral reaction, and the boy became capricious, irritable and unlike his former self. (Biog. S.)

Peter's nervous irritability was much increased by the illness, and the doctors believed he was suffering from some spinal trouble. All work was forbidden, and the invalid rested for six months. After a time, quiet and freedom from lessons improved the boy's physical health, but his moral character did not entirely regain its former cheerful serenity. The wound was healed, but the scar remained. (Biog. 9.)

The change from St. Petersburg, while it proved beneficial to Peter's health, did not cure his indolence, capriciousness and irritability. (Biog. 10.)

His parents did nothing, however, to further his musical education, partly because they were afraid of a return of his nervous disorder. (Biog. 10.)

When one seeks the data for a biographic clinic upon a patient, it seems at first glance that there is given a dearth and inexactness in the hints such that the results must be too vague and unscientific to yield an undoubted diagnosis. The untruth of the criticism, however, is turned to surprise when it is found that in a score of such cases the patients suffer in the same ways; that although unknown to each other, they express themselves in almost the same terms; that their physicians could not guess what ailed them, nor how to cure them; that the disease kept on despite all the "cures," drugs, dietaries, journeys and spas, ordered by the physicians; and that unconsciously the sole relief (never permanent cure) was by one common procedure. We feel sorry that Tchaikovsky destroyed those diaries which would have made conviction more certain, and yet, putting the composite photographs of the score of cases on the same plate, they cover and reinforce the lineaments and expressions as if but one sitter were present. Then when the reader is a modern physician, who has seen a thousand identical cases in his daily practice, and has cured them, there remains no scintilla of doubt as to what was the essential cause and nature of the single disease with which the dead patients were tormented.

The cause that produced Tchaikovsky's "nervousness," "irritability," "tension," "illness," "spinal trouble," etc., when he was eight, nine and ten years of age, and forced him to stop study, and his musical education, grows more and more evident to the reader in the history of the following years. When he was twenty-six, he had "a terrible nervous breakdown" (the term is as common and as senseless now as it was fifty years ago), he "narrowly escaped madness," — all caused by composition at night.

By 1875 the chronic malady had made considerable progress. It did not return at intervals as heretofore, but had become a constant trouble. According to his own account, he was depressed all the winter, sometimes to the verge of despair. He felt he had reached a turning-point in his existence, similar to that in the sixties. (Biog. 35.)

Tchaikovsky's health broke down. According to a telegram which he sent to Petersburg, he left Moscow

suddenly on Sept. 24 (Oct. 6), in a condition bordering upon insanity. (Biog. 37.)

The mental and moral disorder which attacked Tchaikovsky during the course of this season, and gradually took firmer hold upon him, until in 1877 it reached a terrible crisis which nearly proved fatal to his existence. (Biog. 37.)

Anatol says that his brother was scarcely recognizable when he met him on the platform of the Nicholas Station in Petersburg; his face had entirely changed in the course of a month. From the station he was taken to the nearest hotel, where, after a violent nervous crisis, he became unconscious, in which state he remained for forty-eight hours. When this crisis was over, the doctors ordered a complete change of life and scene as the sole chance of recovery. (37.)

I am still quite a sick man. I cannot bear the least noise as yet. Yesterday in Florence, and to-day in Rome, every vehicle that rolled by threw me into an insane rage; every sound, every cry exasperated my nerves. (Biog. 37.)

The dangerous crisis in his illness was over and a slow convalescence began. (Biog. 37.)

I am ill, mentally and physically; just now I could not live in any situation in which I had to be busy, agitated and conspicuously before the world. (38.)

There were moments when I experienced such a complete loss of strength that I feared for my life. (49.)

From the 1st to the 19th of November I endured martyrdom, and I am still marvelling how I lived through it all. (49.)

"Curious fact," he remarks in his diary, "I seek solitude, and suffer when I have found it." In this state of fluctuation between *bad* and *worse* Tchaikovsky had spent his time since he left Russia. (Biog. 49.)

Every careful oculist has found that his patients report that their headaches, nervousness, irritability, dyspepsia, catarrh of the stomach, "migraine," sick headache, insomnia, depression of spirits, etc., depend upon the use of their eyes in reading, writing, sewing, and other kinds of "near-work." In every one of the twenty cases studied in the *Biographic Clinics* I have reported, the same cause of suffering has been overwhelmingly evident. In that of Tchaikovsky the proofs are abundant. For instance:

He began this work in Moscow during the spring, and it was the cause of his nervous disorders and numerous sleepless nights. These difficulties were partly caused by his want of experience in composition, and partly by his habit of working by night as well as by day. At the end of June he had a terrible nervous breakdown, and the doctor who was called in to see him declared he had narrowly escaped madness, and that his condition was very serious. The most alarming symptoms of the illness were his hallucinations and a constant feeling of dread. That he suffered intensely is evident from the fact that he never again attempted to work through the night. (26.)

This feverish work told upon Tchaikovsky's nerves. His health was so far impaired that he gradually lost strength, until he became quite exhausted and the doctor ordered him to the seaside, or to an inland watering-place, enjoining absolute repose. (Biog. 29.)

The composer's melancholy became a shade darker. "I just idle away the time cruelly," he writes, "and my opera, *The Oprichnik*, has come to a standstill at the first chorus." (Biog. 30.)

At the present moment I am absorbed in the symphony I began during the winter. Add to this, I am in a very nervous, worried and irritable state, highly

unfavorable to composition, and even my symphony suffers in consequence. (37.)

I was horribly out of spirits all the time I was composing this symphony last winter. (38.)

On Aug. 7 Tchaikovsky finished the third act of *The Maid of Orleans* and, suffering from physical and nervous exhaustion, left Kamenka for Simaki. (Biog. 37.)

It is my chief anxiety to write more easily and simply as time goes on, and the more I try, the worse I succeed! It is dreadful! (39.)

I am very tired after my day's work. To-day I wrote the love duet in the second act, and it is very complicated, so that at the present moment my brain works with difficulty. I jumped from the first scene of the third act to the fourth, because it is not so easy and I wanted to get the most difficult scene — between Lionel and Joan — off my mind. On the whole I am pleased with myself, but feel rather exhausted. (39.)

To squeeze music out of one's brain every day for ten weeks is indeed an exhausting process. (39.)

... the resolve which already existed in his inmost heart, never to return to his old way of life. He attributed this dislike of his former existence to his ill-health, and cherished the hope that the ideal conditions of his life abroad would restore his nerves and soothe his irritability; he was convinced that he would completely recover and took up his professorship once more with a stout heart. (Biog. 38.)

But it proved otherwise. From the month of January, when he was able to arrange his life as he pleased, when, with improved health, the desire to compose awoke once more — from the moment, in fact, in which his real recovery began — life in Moscow seemed to him to be more dreadful and impossible. (Biog. 39.)

Maizeppa creeps along tortoise-fashion, although I work at it daily for several hours. I cannot understand why I am so changed in this respect. At first I feared it was the loss of power that comes with advancing years. (42.)

It now takes me three days to orchestrate a thing that I could formerly have finished in one. (42.)

This undefinable, horrible, torturing malady which declares itself in the fact that I cannot live a day, or an hour, in either of the Russian capitals without suffering, will perhaps be explained to me in some better world. (42.)

The Valse gives me infinite trouble. I am growing old. (44.)

After dinner I squeezed the unsuccessful movement out of my head. What does it mean? I now work with such difficulty. Am I really growing old? (44.)

On returning from a journey he invariably began with his correspondence, which, next to proof-correcting, he found the most unpleasant work. In the nineties his correspondence had attained such volume that Tchaikovsky was frequently engaged upon it from morning till night and often answered thirty letters a day. (Biog. 45.)

A few weeks ago I accidentally took up his *Germania*, began to read it, got interested and only finished it late at night. I was so upset that I had palpitation and sleep was impossible. Next day I was quite ill. (45.)

My age — although not very advanced — begins to tell. I get very tired now, and can no longer play or read at night as I used. (48.)

I enjoyed writing the first movement, whereas the others were the outcome of strenuous effort, in consequence of which — as far as I remember — I felt quite ill for a time. (48.)

For a long time past letter-writing had ceased to

be a pleasant duty; still, it remained a duty, which he could only neglect under special circumstances. (Biog. 49.)

Just two months ago I began the composition of the opera. To-day I finished the pianoforte score of the second act. This is to me the most dreadful and nerve-exasperating occupation. I believe my ill-health is simply the result of this confounded work. Nazar says I have very much altered the last week or two, and have been in a dreadful state of mind. Whether it is that the worst and most wearisome part of my work is nearing an end, or that the weather is finer, I cannot say, but since yesterday I feel much better. (50.)

My brain is empty; I have not the least pleasure in work. *Hamlet* oppresses me terribly. (51.)

I finished the sketch of the ballet yesterday. You will remember my boasting when you were here that I should get it done in about five days. But I have taken at least a fortnight. Yes, the old fellow is getting worn out. Not only is his hair turning white as snow and beginning to fall, not only is he losing his teeth, not only do his eyes grow weaker and get tired sooner, not only do his feet begin to drag — but he is growing less capable of accomplishing anything. (51.)

Just now I am busy looking through the pianoforte score of *Iolanthe*. It bothers and annoys me indescribably. Before I went abroad in May I had sketched the first movement and finale of a symphony. Abroad it did not progress in the least, and now I have no time for it. (52.)

Tchaikovsky so often speaks in his letters of his dislike to this kind of work (corrections of orchestral score) that he must have needed extraordinary self-abnegation to take this heavy burden upon his shoulders. (Biog. 52.)

At last, at the very end of August, the vast accumulation of proof-correcting was finished, which, as he himself said, would have almost driven him out of his mind, but for his regular and healthy way of life. (Biog. 52.)

His persistent use of minor keys — the vehicle of doubt, aspiration, longing, morbidly self-bounded thoughts. (Mason.)

Despite his everlasting journeyings and walking, there was a solid basis of eye-labor and accomplished work in Tchaikovsky's life:

A glance at the number of his works, which reaches seventy-six, including ten operas and three ballets, at his letters (I possess, in all, four thousand); at his literary work (sixty-one articles); at his translations and arrangements, and his ten years' teaching, will suffice to convince the most-skeptical that his nature knew no moods of *delirium*. (Lariche.)

It appears strange that the sufferer should so persistently see that his "ill-health was the result of his confounded work," and still not recognize its connection with ocular labor, but to-day both the public and the profession still stick fast in the same error of observation and logic: both continue to attribute the morbid results to "brain-fag," "intellectual labor," and all the rest — oblivious of the fact that intellectual labor does not exhaust and that the function of the eye, the most important, complex and delicate of all the organs of the body, is forgotten.

What then shall be said of the obverse of the fact — the ever-freshly illustrated truth, that

ocular rest, or walking, journeying, country life, living out of doors, etc., are the sole but certain means of getting relief from the suffering due to near-work with the eyes? As with others, so with Tchaikovsky, winter and bad weather, which confined him to the house and compelled greater use of the eyes at near range, increased all sorts of misery and ill-helath, while spring and summer and a warmer climate (especially in the Russias) at once brought health and happiness. Note the proofs of this clinical experience in Tchaikovsky's case:

Before the summer holidays came, Tchaikovsky's health was in an unsatisfactory condition. He complains in his letters of insomnia, nervousness and the throbbing sensations in his head, to which he often refers as "my apopleptic symptoms." At the end of April his depression became very apparent and he wrote to his brother Anatol:

"My nerves are altogether shaken." (26.)

We had a monotonous existence, and are dreadfully bored, but for this very reason my health is first rate. The saline baths do me a deal of good, and, apart from them, the way of living is excellent. I am very lazy, and have not the least desire to work. (30.)

I rush about like one possessed and never feel tired. (30.)

His constitution was so shaken and impaired by his nervous illness that at least a year's rest was necessary for his complete restoration. (Biog. 37.)

The condition of his health needed complete repose. (Biog. 37.)

His ideal of a summer residence, for which he longed as soon as the trees and fields began to show the first signs of green. (Biog. 30.)

Although the spring is still far off and the frosts are hardly over yet, I have already begun to think of the summer, and to long for the early spring sunshine, which always has such a good effect upon me. (30.)

These periods of hypochondria. All this winter I have been depressed to the verge of despair, and often wished myself dead. Now the spring is here the melancholy has vanished, but I know it will return in greater intensity with each winter to come, and so I have made up my mind to live away from Moscow all next year. (35.)

The few days spent here have done me a great deal of good. First, I have been able to work a little, so that my brother will take the second scene of the opera—not quite finished—back to Moscow with him. Secondly, I feel much better, although I was not very well yesterday. It is only a slight chill, however. (37.)

With the coming of spring Tchaikovsky's depression passed away, and he spent the Easter holidays very happily. (Biog. 37.)

On the point of taking leave of foreign lands and turning my face homewards, a sound, sane man, full of renewed strength and energy. (38.)

The sense of increased energy and strength, which always came to him in the lonely life of the country, was unknown in the bustle and stress of the city. (38.)

I know no greater happiness than to spend a few days quite alone in the country. (38.)

Wandered for whole days together in the forest, spent the evenings on the low-lying steppe, and at night, sitting at my open window, I listened to the solemn stillness, which was only broken at rare intervals by some vague, indefinite sound. During this fortnight, without the least effort—just as though I were under the influence of some supernatural force

—I sketched out the whole of *The Tempest* overture. (38.)

There came over me that feeling of intense delight which I so often experienced during my country rambles in Russia, and for which I have longed in vain since I have been here. I was alone in the solemn stillness of the woods. Such moments are wonderful, indescribable, not to be compared with any other experience. The indispensable condition is—solitude. I always like walking alone in the country. (38.)

I am feeling splendidly well. My physical health is first rate, my head clear and strong. I observe myself with delight and have come to the conclusion that I am now completely recovered. (38.)

Now I am quite recovered I ought to return to Russia to take up my duties at the Conservatoire and my old ways of life. (38.)

The fact that I profited by your wealth to travel abroad for my health's sake. (38.)

I am in a rose-colored mood. Glad the opera is finished, glad spring is at hand, glad I am well and free. (38.)

I am doing nothing whatever, only wandering through the forests and fields all day long. I want to take a change from my own work, with its eternal proof-correcting. (40.)

Throughout the whole year I have led a calm and cheerful life, and have been happy, so far as happiness is possible. (40.)

My mental condition was such that I had to collect myself first. What produces this terrible state? I do not understand it myself. . . . Everything has tended to make to-day go pleasantly, and yet I am so depressed, and have suffered so intensely, that I might envy any beggar in the street. It all lies in the fact that life is impossible for me, except in the country or abroad. Why this is so, God knows—but I am simply on the verge of insanity. (42.)

It seems my lot to be always hurrying to finish something. I know this is equally bad for my nerves and my work, but I cannot control myself. I only rest when I am on a journey; that is why travelling has such a beneficial effect on my health. (43.)

After the terrible illness in 1877 he found in Kamenka, far more than in San Remo, Clarens or France, all he needed for his recovery; during these seven years, it was at Kamenka that he gathered force and recuperated for the life which was becoming infinitely more strenuous and many-sided. (Biog. 37 to 44.)

Wet or fine, Tchaikovsky always went for a walk after dinner. He had read somewhere that, in order to keep in health, a man ought to walk for two hours daily. He observed this rule with as much conscientiousness and superstition as though some terrible catastrophe would follow should he return five minutes too soon. (Biog. 45.)

Before supper, which was served at 8 p.m., Tchaikovsky always took another constitutional. (Biog. 45.)

The three months I spent abroad were lost time as regards work, but I feel I have gained in strength, and can now devote my whole time to it without exhausting myself. (46.)

If only I were twenty years younger!! One thing is certain: my nerves are much stronger, and things which formerly were not to be thought of are now quite possible. Undoubtedly I owe this to my free life, relieved from all anxiety of earning my daily bread. (47.)

My health is not good. . . . In Carnival week I suffered from the most peculiar nervous headaches. . . . As I felt sure my accursed and shattered nerves were to blame, and I only wanted rest, I hurried into the country. (48.)

I find more and more delight in the cultivation of flowers, and comfort myself with the thought of devoting myself entirely to this occupation when my powers of composition begin to decay. (50.)

He was always fond of moving about. He could not remain long in one spot. But this was chiefly because it always seemed to him that "Every place is better than the one in which we are." Paris, Kamenska, Clarens, Rome, Brailov, Simaki, Tiflis—all in turn were his favorite resorts, which he was delighted to visit and equally pleased to quit. But apart from the ultimate goal, traveling in itself was an enjoyment rather than a dread to Tchaikovsky. (Biog. 52.)

No sooner had he reached home again than he began planning yet another tour. It seemed as though he had become the victim of some blind force which drove him hither and thither at will. This power was not merely complaisance to the demands of others, nor his old passion for traveling, nor the fulfillment of a duty, nor yet the pursuit of applause; still less was it the outcome of a desire for material gain. This mysterious force had its source in an inexplicable, restless, despondent condition of mind, which sought appeasement in any kind of distraction. I cannot explain it as a premonition of his approaching death; there are no grounds whatever for such a supposition. Nor will I, in any case, take upon myself to solve the problem of my brother's last psychological development. (Biog. 52.)

All day long I wander in the forest and bring home quantities of mushrooms. (53.)

Many of his works were planned and his themes invented in these long rambles across country. Mason.

Without the key supplied by the oculist, any reader of the Life and Letters of Tchaikovsky must be as unable, as was his biographer, to explain the apparently insensate necessity for country life, journeys, concert tours and travel over all the countries of Europe, with one trip to the United States. If, at least earlier in his life, he had made a trip to the United States solely to get a scientific pair of spectacles, I scarcely doubt that he might be living to-day. It was certainly not the love of music that caused us to send for him, nor that motivated his own coming. The sorry account of his visit here would be ludicrous if it were not underlain with tragedy for the composer, and shame for us. To those who have not learned that personal happiness depends upon the little and overlooked blunder or habit, it will appear ludicrous to say that the one thing which all Europe could not have given him, and which we alone were capable of giving him, would have been of infinitely more value to him than all the money, buzzes, interviews, and advertising with which we prided ourselves in cursing him.

But resistance, reaction, recuperability, under long-continued "insults" and after unheeded warnings, are finally lost. This loss, as we have so often seen, is likely to fall in the period of presbyopia, when eye-strain is doubled, and the two misfortunes unite to bring about the final catastrophe. Without needless repetition and emphasis, it is particularly noteworthy that Tchaikovsky's maladies increased in intensity as he entered upon the presbyopic period, and

they became more and more unendurable as he advanced in it. There is nothing more pathetic than the added poignancy of his cries with each year from thirty-eight to fifty, and it is most pitiable that when reaction is no more possible the old relief and happiness, once so evident, from country-life and journeying, no more returns:

I will not conceal it: all the poetry of country life and solitude has vanished. I do not know why. *Nowhere do I feel so miserable as at home.* If I do not work, I torment myself, am afraid of the future, etc. Is solitude really necessary to me? When I am in town, country life seems a paradise; when I am here, I feel no delight whatever. To-day, in particular, I am quite out of tune.

I am passing through a very enigmatical stage on my road to the grave. Something strange, which I cannot understand, is going on within me. A kind of life-weariness has come over me. Sometimes I feel an insane anguish, but not that kind of anguish which is the herald of a new tide of love for life, rather something hopeless, final, and—like every *finale*—a little commonplace. Simultaneously a passionate desire to create. The devil knows what it is. In fact, sometimes I feel my song is sung, and then again an uncomprehensible impulse, either to give it fresh life, or to start a new song. . . . As I have said, I do not know what has come to me. For instance, there was a time when I loved Italy and Florence. Now I have to make a great effort to emerge from my shell. When I do go out, I feel no pleasure whatever, either in the blue sky of Italy, in the sun that shines from it, in the architectural beauties I see around me, or in the teeming life of the streets. Formerly all this enchanted me, and quickened my imagination. Perhaps my trouble actually lies in those fifty years to which I shall attain two months hence, and my imagination will no longer take color from its surroundings. But enough of this! I am working hard. Whether what I am doing is really good is a question to which only posterity can give the answer. (50.)

This thought and experience gives significance to the awful and hot-pressed beauty of the Pathetic Symphony, the last and greatest of the composer's works. Mason asks:

. . . Has not disease, as well as health, its relations to our fortunes? . . . His mental temper, never bright, was shadowed with a pathological gloom throughout his life.

To be continued.

THE TREATMENT OF UNUNITED FRACTURES OF THE NECK OF THE HUMERUS BY OPERATION, WITH REPORT OF A CASE.

BY E. A. C. DE M. J. DE N. M. D.,
Surgeon at the Hôtel de la Marine, Antwerp, Belgium.

THE obtaining of bony union in ununited, intra-capsular fractures of the neck of the humerus, those fractures which he wholly within the capsule of the joint is rare under any form of treatment by apparatus alone. This is due to the fact, because of the meager blood supply to the head of the femur, emphasized by its position. It is chiefly because of the distal blood supply, and the rate fixation of the parts, of the distal end, that

The various methods of extension apparatus, with straps or swathes around the pelvis, or of plaster of Paris spica bandages with the lower extremity in abduction, with or without screw pressure over the trochanter, are all uncertain and tedious procedures, which in the majority of cases will fail to cause union. These methods require long periods of confinement in bed and make large drafts upon the strength of the patient, and in cases advanced in years are not infrequently the cause of death.

The only certain method is that of pegging or nailing the fragments together in their proper relation, as was done in the case reported below. In fresh fractures, especially in cases of advanced age, or feeble condition, the question should be raised as to whether or not the method of direct nailing without an open incision should be adopted, as has been done most brilliantly in many cases by Nicolaysen¹ of Christiania. Later in this paper this very important work of Nicolaysen will be described; it is worthy of marked consideration. In those cases in which several weeks or months have elapsed since the injury, the method of nailing after the fragments have been examined and scraped through an anterior incision is doubtless preferable. It is the opinion of the writer that the method adopted in the case to be reported is the simplest and gives the best opportunity of examining the surfaces of the fragments and of placing the nail with accuracy.

It is surprising how few of these operations for ununited intracapsular fractures of the neck of the femur have been reported. Freeman² could find reports of but thirteen cases up to 1904 beside his own. In addition to these the writer has been able to find reports of six additional cases operated upon in this country and England: the cases of Morris,³ Thompson⁴ (2), Guthrie,⁵ Cheyne,⁶ and Peckham.⁷ So far as is known, the twenty-one cases of direct nailing without open incision reported by Nicolaysen have never before been included in any paper.

Report of the writer's case:

J. H., eighteen years old, was admitted to the south surgical service of the Massachusetts General Hospital in July, 1902. Through the kindness of Dr. H. H. A. Beach, the senior surgeon of the service, the writer, his assistant surgeon, was given charge of the case. The boy had been sent to the hospital with a diagnosis of dislocation of the hip, which diagnosis was found to be in error, especially after the x-ray plates were seen. Nine weeks before entrance, while crossing the street, he fell injuring his right hip; total disability and loss of motion with much pain in the hip followed. As long as he could remember his right leg had been shorter than the other, the result of some children's disease, yet he could always walk upon it with but slight limping and could run and play as well as the other boys. He evidently had had for years a somewhat shortened and atrophied leg, the result of infantile paralysis. He had been confined to bed since the injury.

Examination.—A fairly well nourished and developed boy; nothing abnormal aside from the condition of the right lower extremity found. The right thigh

and calf showed more muscular atrophy than could be accounted for by the comparatively recent injury. The right extremity was three inches shorter than the left. There was some flattening of the right buttock and some tilting of the pelvis. The top of the trochanter could be felt three inches above Nelaton's line; this upward displacement of the shaft of the femur could not be reduced. The x-ray plates showed an intracapsular fracture of the neck of the femur, with much upward displacement of the shaft. A small amount of callous formation was seen to have taken place.

The patient was operated upon by the writer July 31, 1902. With the patient lying upon his back, an incision down the front of the thigh, from the anterior-superior spine of the ilium was made. By blunt dissection between the tensor vaginæ femoris, sartorius, and rectus extensor muscles, the capsule of the hip joint was exposed. It was not found necessary to cut any muscle fibres, and by using strong retractors to pull the sartorius and rectus muscles inward a good exposure of the anterior surface of the capsule of the joint was made. The capsule was opened by an incision parallel with the fibres of the "Y" ligament, upon which the diagnosis of ununited intracapsular fracture was found to be correct.

With a chisel and curette the surfaces of the fragments were scraped and a slight amount of loose callus and some fibrous tissue was removed. By extension and traction on the foot, with some abduction, the trochanter was brought down so that the neck came in proper relation to the head of the bone, which was in the acetabulum. While the extremity was held in this position, an incision was made in the outer part of the thigh, directly over the external surface of the trochanter, and a long steel wire nail, freshly polished, was driven through the trochanter and neck of the femur into the head of the bone in its socket. The anterior wound gave full opportunity to guide the nail with the finger, so that one could make sure of its direction and proper fixation in the head of the bone; this is one of the most important parts of the operation. After driving the nail, the capsule was closed with two catgut stitches and the muscles and fascia approximated as carefully as possible. The anterior skin incision was closed without drainage with silkworm gut stitches, and the external incision, which was made to take the nail, was closed over the head of it. This was done to prevent any possibility of infection traveling down the nail shaft. The extremity was put up in a plaster of Paris spica bandage from the waist to the toes, great care being taken to hold the limb rigid and fixed in position during the application.

There was almost no reaction from the operation and no sign of wound infection. On the tenth day after operation, windows in the plaster were cut over the lines of incision and the stitches removed from both wounds, which were found to have healed by first intention. The plaster bandage was then reinforced. On Sept. 12, six weeks after the operation, the plaster of Paris bandage was taken off and the nail removed after cutting down upon and exposing it under cocaine anesthesia. It was pulled out with little difficulty. The union appeared to be firm at this time, but the plaster of Paris spica was re-applied. On the 28th of September, two months after operation, the plaster of Paris spica was removed finally and the patient allowed to lie in bed without any dressing. At this time the fracture had united firmly and there was motion in the hip joint, half flexion and some rotation, but abduction was slight. On the 1st of October he was up and about on crutches. On the

20th of October, less than three months after the operation, he was able to walk about as much as he pleased with his shoe built up somewhat.

It has been previously stated that before the injury his right leg was shorter and smaller than the other. The result of the operation has been that there is somewhat more shortening in the extremity than before the injury, and examination showed that union had taken place with the top of the trochanter higher than it was supposed to be when the fracture was put in accurate position and the nail driven. This may have been the fault of the technique at the time of operation, either in driving the nail or in holding the extremity in position while the plaster of Paris bandage was being applied. In this connection, however, Nicolaysen, whose experience in nailing this form of fracture is larger than that of any other man, although he does not use an open incision, has called attention to the fact that this recoil of the shaft is to be expected in nearly all nailing operations, because of the early absorption of the cancellous bone around the nail.

This young man obtained, however, perfectly solid union and a useful hip joint. The writer has had the opportunity to examine this case from time to time since the operation. When last seen, three years after operation, the result was very satisfactory. The patient thought that his leg was but slightly shorter than before the injury and that he had just as useful a limb.

The main points in the technique of the operation are as follows: Scrupulous preparation of the skin for a period of two days, if possible, before the operation, inasmuch as the anterior incision is near the fold of the groin; blunt dissection, with division of the capsule parallel to the fibers of the "Y" ligament; clearing of the fragments from callus and fibrous tissue; careful placing of the nail and suturing of the skin over the head of it; this is of the greatest importance to prevent infection and suppuration along the nail track; and the application of a strong and close-fitting plaster of Paris spica bandage while the extremity is held by a skilled assistant with a view to preventing any displacement. It has been found that an ordinary round wire nail with three-cornered point is superior to any form of ivory peg or screw.

As was stated at the beginning of this paper, the operation of pegging or nailing fractures of the hip is an uncommon one, but in most cases is a necessary procedure to secure union. The operation in this country has been done seldom in fresh fractures, surgeons have preferred in most instances to await the result of treatment by apparatus, and have chosen to operate only in cases in which such treatment was unsuccessful. The difficulty of determining whether or not a fracture is entirely intracapsular may have had something to do with this. The form of fracture in which union is least likely without such an operation is the complete intracapsular variety.

There has been much difference of opinion as to whether true bony union in unimpacted intracapsular fracture of the neck of the femur ever takes place without operation. Senn⁸ has written much to prove that such true union can take place. He collected fifty-four cases up to 1883 in which he thought that bony union could be proved. There is no doubt but that bony union has occurred and can occur, but the opinion of Kocher⁹ in regard to the subject is in all probability the most accurate. He thinks that pure intracapsular fractures are very rare, and that many of the cases that have been called such in the past are real intertrochanteric fractures which are partially extra- and partially intra-capsular, with more or less tearing of the capsule. He states that he had only seen ten cases in his experience up to 1895 in which a diagnosis of complete intracapsular fracture could be made. He admits that true bony union may take place, however, but very seldom. He regards most of the fifty-four cases reported by Senn as mixed fractures.

In all probability, the cases reported in which union resulted from treatment by position and bandages were cases of intertrochanteric fractures and not true intracapsular fractures. Since the days of the x-ray obviously there has been a chance to form more accurate opinions as to the location of the fracture and the comparative value of treatment. It seems rational to begin a fresh study of this subject with the aid of x-ray photography. The old difficulties of accurate localization of the fracture and uncertain proof of the kind of union in living cases no longer exist; the old figures as to the relative frequency of extra- or intra-capsular fractures are of comparatively little value to-day. It can be stated positively that true intracapsular fractures are very rare.

The first operation was done by von Langenbeck in 1858 with fatal result. Sir William MacCormac,¹⁰ speaking of this operation, stated that he had used pointed iron nails with good results; that Lister had had a similar case in which he was not successful in securing union; that König had repeated von Langenbeck's operation, using a silver screw with a successful result in every way. The method of these earlier operations was to make a small incision down to the trochanter and to drill more or less at haphazard through the neck of the femur, drilling and driving the nail or screw without the guidance of the eye or finger. The difficulty in this procedure is the uncertainty of getting the nail or drill into proper position and into the small and unstable fragment of the head of the bone. The head is very difficult to keep steady during the boring or nailing, and to pierce it at the proper point from without, in the experience of the writer is far from easy. The first operation in this country was done by Wm. Meyer¹¹ of New York in December, 1892. He used the von Langenbeck incision and used two nails; the operation resulted in union and a useful limb. The operation performed as outlined in the writer's case

and the operation of choice by most surgeons, was suggested by Trendelenburg.¹²

Dr. A. J. Gillette¹³ has reported three cases in which this form of fracture was treated by the use of ivory pegs instead of nails, and with a different incision than the one adopted by the writer, namely, making a horseshoe-shaped incision, beginning it an inch below and an inch posterior to the anterior-superior spine of the ilium, carrying it down two inches below the trochanter major and bringing it up the buttock to about the centre of the gluteus maximus muscle; the skin, superficial and deep fascia are dissected *en masse*. A chain saw is then passed between the posterior border of the tensor vaginæ femoris muscle and the gluteus medius, hugging the neck of the femur and the base of the trochanter major, and is brought out between the posterior surface of the gluteus medius and anterior surface of gluteus maximus, thus sawing off the trochanter major and its muscular attachments, which are then turned back, making an exposure of the capsule of the joint; the line of the fracture through the neck of the femur can be easily seen. The surfaces of the fractured ends are denuded and a bone peg driven through the neck of the femur, thus holding the ends together. The capsule is then stitched with catgut, the trochanter major nailed with a small bone peg back to its original position, the skin and fascia flap is then sutured and a silicate spica applied. There can be no advantage from this incision; on the other hand it must be decidedly disadvantageous and dangerous to divide so many muscular attachments and to separate temporarily the trochanter from the rest of the femur; the simple anterior operation is all that is necessary.

Sayre, of New York, in discussing Gillette's paper and this radical incision, stated that he had made an anterior incision, freshened the ends of the bone, then pinned them together with a gimlet and two nuts. Parkhill¹⁴ suggested a modification of his well-known fracture clamps, but so far as can be ascertained these clamps have never been used. Davis,¹⁵ of Philadelphia, has used substantially the same method adopted by the writer in two cases with good results. Freeman reports a successful case and discusses the possibility of using clamps; he used a steel screw instead of a nail.

The work of Nicolaysen, in Norway, has been very successful and demands recognition. So far as known, the results of his work have not as yet been published in English. A study of his cases and results leads one to believe that his methods are deserving of frequent use in fresh cases of unimpacted intraepicapsular fracture. The method is specially noteworthy as applicable to fractures in individuals of advanced age. Nicolaysen has practiced this form of treatment at the state hospital in Christiania since 1894. He has reported, up to 1900, 21 cases, 8 males, whose ages ranged from thirty-nine to seventy-eight years, and 13 female patients, whose ages ranged from fifty to eighty-two years. The

results in all cases were satisfactory, a firm union and useful joint resulted. Nicolaysen states that the functional ability at the time of discharge from the hospital was so nearly normal in some cases that it was impossible to notice from the walk that there had ever been a fracture of the hip. Nicolaysen recommends this method as routine treatment in fresh cases because of the uncertainty of obtaining union by any other method and because of the length of time and suffering, especially to those past middle age, from treatment by apparatus. In most of his cases Nicolaysen used no anesthetic. It would seem as if the employment of anesthesia in these cases would facilitate the correction of deformity and permit easier handling of the limb by overcoming all muscular resistance. Nicolaysen's method is as follows:

After a thorough cleaning of the trochanteric region of the injured side, the patient is placed on the uninjured hip and a competent assistant, by manipulation and traction, draws the trochanter down into place. The operator directs this procedure until Burow's angle has been enlarged to a right angle. When this position of the trochanter by extension and abduction has been secured, a pointed steel wire nail about 15 cm. in length, starting from $4\frac{1}{2}$ to 5 cm. below the top of the trochanter, is hammered through the neck and through the head of the femur into the acetabulum. Nicolaysen states that there never has been any difficulty in pounding the nail in, and that a characteristic sound is elicited when the nail reaches the acetabulum. The end of the wire nail is covered with antiseptic gauze and a plaster of Paris spica bandage is applied from the toes to above the crest of the ilium. After three or four weeks a hole is cut in the plaster bandages over the wire nail and the nail is removed. It is stated that the nail was invariably found loose at this time. The plaster bandage is removed at the end of eight or ten weeks, but the patient is allowed to be up on crutches for some time previous. Burow's angle, which Nicolaysen refers to frequently and depends so much upon, is a special method of measuring used by him and also by Professor Heirberg of Christiania. By it, as Nicolaysen admits, no more information in regard to the position of the trochanter is obtained than by the application of the well-known Nelaton-Roser line and Bryant's ileo-femoral triangle. He believes it just as accurate, however, and much more readily applied and with much less disturbance to the patient. The angle under discussion is an angle formed at the top of the trochanter by a line from the anterior-superior spine of the ilium and a line from the middle of the crest of the ilium. With the trochanter in normal position, this angle should be a right angle.

A study of Nicolaysen's reported cases shows very successful results with no fatalities. It is noteworthy that the majority of his cases were advanced in years, most of them over sixty and a number between seventy and eighty years of age.

The following conclusions in regard to this form of fracture and its treatment can be made:

1. Fractures entirely intracapsular are very rare.

2. When they do occur and are unimpacted, the obtaining of union by any form of fixation apparatus is exceedingly doubtful.

3. The operation of nailing the fracture with or without open incision is to be adopted whenever possible.

4. In the young and middle-aged, when no contra-indications to operation are present, such as obesity, general debility, marked arteriosclerosis or complicating disease, the method with open incision is more accurate and preferable.

5. In persons of advanced age and those with definite contra-indications to surgical interference, the direct method without incision, as practiced by Nicolaysen, should be used in all cases if seen sufficiently early.

6. In employing the method of Nicolaysen, a general anesthetic should be given.

A DIETETIC STUDY

BY C. E. BENDISCH, M.D., M.

Consultant in Digestive Diseases, City and General Hospital, Attending in same, Massachusetts General Hospital.

The statement has been so generally made that Americans eat too much, that most of us have resigned ourselves to whatever odium is connected with it and have ceased to try to be abstemious. Some dietetic studies of patients

who have declared that their dietary was about the same as in health and observations of healthy persons, have convinced the writer that this sweeping condemnation is scarcely deserved and that many persons in good circumstances and in fairly good health really ingest considerably less than the older standard ration.

Partly as a matter of convenience and partly because each one of us ought to make practical application of his theoretic knowledge of hygiene, the writer has made an approximate but sufficiently accurate estimate of his own dietary. It may be said that this dietary has been selected from a liberal though not elaborate bill of fare presented at a family hotel; that various circumstances, including a good cook and a good appetite, have tempted to overeating, and that the diet commonly followed was not influenced by scientific knowledge; and that, indeed, until the study was begun, the writer could not have guessed within a 50% error of the weights of the various viands eaten. This diet represents a slight restriction from previous habits of eating, on account of moderate increase of weight, and the only rule followed was the utterly unscientific and even unhygienic one of eating small quantities of plain foods that did not appeal particularly to the palate so as to allow freer indulgence in desserts, etc. It may also be said that, previously to the arithmetical computation, the writer had no idea as to how closely the diet followed the standards, either of the total number of calories or of the proportionate amounts of protein, fat and carbohydrate.

Breakfast

| | Protein | Fat | Carbohydrate |
|--|---------|-----|--------------|
| 1 shredded wheat biscuit, | 4 | 1.8 | 19.2 |
| 100 cc cream, | 3.5 | 20 | 7.5 |
| Total, usually amounting to about 10 gm fruit sugar and negligible amounts of protein and fat. About twice as much as bananas about 10-15 gm or 6 gm protein as 110 of carbohydrate. | | | |
| 2 cups of weak coffee, including 100 cc cream and 6 lumps of sugar, weighing on the average 6 gm each, | 1 | 10 | |
| | 4.5 | 20 | 94.5 |
| A approximate total for breakfast, | 11 | 45 | 72 |

Dinner

| | Protein | Fat | Carbohydrate |
|---|---------|------|--------------|
| Meat, 30 gm, | 6 | 0.4 | 0.4 |
| Beef, mutton, etc., about 10 gm, 3 or 4 times, also bread equals 30 gm. Half of bread will do the same. | 1.5 | 10.5 | 20 |
| Butter, ordinarily, about 10% of food, | | 10 | |
| Potatoes, if always taken, sometimes exchanged for fruit, etc., as 1 lb of bread contains a quantity of food equal to 1 lb of fruit, actual weight 50 gm, | 1 | 10 | 10 |
| Fruit 50 gm, about 30% sugar in preserves, etc., or when sugar is added to fruit. | | 10 | 10 |
| Cake, pudding, etc., or fruit, as 1 lb of fruit, sugar, and starch cake, etc., and that only 5 gm each, | 1.5 | 1 | 20 |
| Cocoa, 200 cc cream, sugar, about 100 cc milk and 18 gm sugar, | 4 | 4 | 25 |
| A approximate total for dinner, | 18 | 36 | 90 |

Dessert

| | Protein | Fat | Carbohydrate |
|--|---------|-----|--------------|
| Simple little cake, as in health, healthful etc., or cake, as in overeating, that is, sugar and fat, | | | 10 |
| Fruit, 25 gm, 10% sugar, 10% starch, etc., used as dessert, or fruit, as 1 lb of fruit, sugar, and starch cake, etc., and that only 5 gm each, | 1 | 10 | 10 |
| Potato, 50 gm, | | 10 | 10 |
| Bread, cream, etc., as 1 lb of bread, etc., and that only 5 gm each, | 1 | 10 | 10 |

DINNER—Continued.

| | Proteid. | Fat. | Carbo- hydrate. |
|--|----------|------|--------------------|
| Six small crackers (average, sometimes exchanged for bread). Weight, 5 gm. each. | 3 | 2.7 | 21 |
| Allowance for butter, gravy, etc., only occasionally used. | | 5 | |
| Dessert (counted as half of ordinary serving of 150 gm. ice cream and 50 gm. cake, usually supplanted by fruit pie, pudding, etc., or fresh fruit. Liberal allowance). | 5 | 13 | 40 |
| Coffee as at breakfast. | 3.5 | 20 | 39.5 |
| Approximate totals for dinner, | 25.5 | 43.5 | 125 |

ADDITIONAL FOOD PER WEEK.

| | Proteid. | Fat. | Carbo- hydrate. |
|--|----------|------|--------------------|
| About 100 gm. of mixed nuts (net weight), 500 gm. candy (a little over a pound). | 20 | 50 | 400 |
| Two additional lunches, estimated same as luncheon. | 36 | 32 | 184 |
| | 56 | 82 | 604 |
| Approximate average additional food daily, | 8 | 12 | 87 |

| | Proteid. | Fat. | Carbo- hydrate. |
|----------------------|----------|-------|--------------------|
| Breakfast, | 11 | 42 | 72 |
| Luncheon, | 18 | 16 | 92 |
| Dinner, | 25.5 | 43.5 | 125 |
| Extras, | 8 | 12 | 87 |
| Average daily total, | 62.5 | 113.5 | 376 |

| | |
|--|-------|
| Calories from proteid ingested, 4.9 x 306.25 — 10% allowed for non-absorption, | 275 |
| Calories from fat ingested, 9.3 x 1046.55 — 10% allowed for non-absorption, | 942 |
| Calories from carbohydrate, 4.1 x 1541.6 — 3% allowed for non-absorption, | 1,495 |
| Total calories, | 2,712 |

The statement made in the beginning of the article that the writer had no idea before making the arithmetical computations how the dietary would correspond with standards, is true in an absolute sense, but it would leave a false impression to allow the implication that a preconceived notion did not exist. As this notion was incorrect in almost every detail, it seems worth while to state it. The writer supposed that, while eating less heartily than previously, and less heartily than many other men and women, he was still considerably above Voit's standard of 118 gm. of proteid, 56 of fat and well up to the standard of 500 gm. of carbohydrate for a man at moderate work. Instead of this, he was very close to the low standard of Chittenden of 0.7 gm. of proteid and 30 calories per kilogram of body weight (about 80 kg. or 176 pounds, height 5 feet 9 inches) for professional men, and actually within Chittenden's standard of 0.8 and 35, respectively, for men at light work.

The writer also supposed that he was eating very little fat, on account of an antipathy to fat meat, and very limited use of gravy and butter. The rather free use of cream explains this discrepancy. It may be worth while to point out that the ordinary small ball or parallelopipedon of butter served at hotels and restaurants weighs about 10 gm. and that two of these are used by the majority of persons. Some persons habitually use 100 gm. or more of butter daily, not to mention fat meat, gravy, etc.

The writer also supposed, as did his friends, that he was using relatively large amounts of carbohydrate, but the inverse relation of the

appetite for sugars and starches was a greater compensating factor than had been supposed. Of the 376 gm. of carbohydrate, 221 were in the form of sugar, and mainly cane sugar. This is considerably in excess of the average, although, in an estimate of the consumption of sugar by about 40 persons, a few years ago, the writer found it to be 130 gm. per capita, less economic waste and plus that contained in candy and fruit outside of meal times. In this connection, it may also be stated that the writer has never been able to demonstrate more than a very doubtful trace of sugar in the urine, after the indulgence in a pound of candy in an evening, after a dinner containing the usual amount of carbohydrates. Generally speaking, the appetite and ability to care for sugars seems to be reciprocal to that for starches and, to a less degree, fats. A consumption of 250 gm. of potato at dinner, containing 50 gm. of starch, is considered a reasonable allowance by many persons, not engaged in hard labor.

A very important basis for clinical dietetic study is the ability to gauge the amount ingested by the eye. Obviously, for metabolism experiments, accurate analyses of the immediate food supply is necessary. But this cannot be done unless the food is specially prepared in homogeneous form. Meats, in particular, must be hashed and thoroughly mixed. Even in some metabolism experiments, this precaution has not been followed, but similar slices of bread, meat, etc., have been cut and analyzed. For ordinary clinical use, the error arising from the reliance upon accurate average tables of composition of food is probably less than would occur from the attempt to analyze "similar" samples of viands not reduced to a state of homogeneity, and, certainly, is sufficiently accurate for practical purposes when the variety of diet is not restricted to a very marked degree. The individual errors, indeed, tend to neutralize one another.

The writer knows of no royal road to a knowledge of the weights of food substances. Actual weighing is the only means of accomplishing the end. Many ingredients of the diet occur in the form of units which do not vary much from an average. For instance, ordinary lumps of sugar average 6 gm.; small round "Jersey" crackers, 5 gm.; standard soda crackers, 23 gm.; a fair-sized lamb chop weighs 60 gm. gross; the round muscle 20 gm., and other available muscle 10 gm. An ordinary cut of prime rib roast of beef with the bone removed, weighs about 25 gm. and two of these are equivalent to an ordinary serving of almost any meat. Much larger portions are served *à la carte* at first-rate restaurants. Shredded wheat biscuit, the ordinary serving of other cereals, an ordinary slice of bread and the half of a hard roll amount to 30 gm. each. When it is necessary to keep close account of the nutrition of a patient, it is well to reserve for him a loaf of bread, a special sugar bowl, a package of cereal, etc., and to obtain the amount used in a certain period by subtraction.

Clinical Department.

AN EXPERIENCE WITH CASCARA.

BY RICHARD F. CHASE, M.D., BOSTON.

IN a recent case of gastric ulcer I prescribed Ext. Cascara Sag. Fl. (P. D. & Co.), directing the patient to take 15 to 20 drops before each meal and to diminish the dose as the bowels became regulated. At the next visit the patient reported that the medicine had not materially influenced the actions of the bowels, that even teaspoonful doses had caused only slight evacuations, moreover, she said the medicine was not as bitter as I had given her to understand. My suspicions were aroused as to the product she was using, so requested her to bring to me the bottle and its remaining contents. On its receipt, I at once discovered by the taste and odor that the preparation was not the one I had prescribed. I had the same prescription filled at another druggist's and the desired result was obtained. Assuring myself in so far as possible, that substitution had been practiced in the case of the original prescription, I wrote the pharmacist accusing him of substitution. He at once denied the accusation and brought to my office the stock bottle from which the prescription had been filled. The bottle bore the proper label, but by comparing its contents with samples of the true product the druggist was soon convinced that something was wrong. Assuring him that his preparation was practically an inert one he left the bottle with me.

With the assistance of a representative of P. D. & Co., it was discovered by the number on the label, that the bottle of fluid extract of cascara had been put up by his firm in 1888, eighteen years previously. What preparation of cascara the bottle contained at this time could not be learned, but as cascara does not deteriorate with age, as I understand, the most natural conclusion is that sometime in the past another than the original product had been poured into the bottle. The mutual understanding between the druggist and me is that he unintentionally substituted.

This experience explains how in an unusual way an inferior product may be substituted for a good preparation.

My experience with and confidence in the preparation prescribed has led me twice in the past two years to the detection of practically worthless preparations of cascara. I have often heard physicians state that they do not obtain results with this drug (that many more that they do); the reason I have found at times is that either a good fluid extract was not used or else the drug was not properly administered. In the cases in which a laxative is indicated and the number is far less than is generally supposed if other measures are properly carried out, I have found no drug so generally beneficial as a good fluid extract of cascara, when given in small doses three times a day before meals. The same amount given in less frequent doses will not produce the same results.

Medical Progress.

REPORT ON THE PROGRESS OF SURGERY.

BY HERBERT E. BURRILL, M.D., BOSTON, AND H. W. CUSHING, M.D., BOSTON.

(Continued from No. 18, p. 500.)

THE MANAGEMENT OF CERTAIN CRITICAL CASES OF INTESTINAL OBSTRUCTION, WITH REPORT OF CASES.

JOHN W. ELLIOT,¹⁰ in a very interesting paper on this subject, read before the American Surgical Association in July, 1905, gives the following summary:

(1) We find the prevalent method of enterectomy with immediate suture in cases of intestinal obstruction attended with a high mortality, due to the changed condition of the distended bowel.

(2) Enterostomy with later enterectomy is to be reserved for the cases unable to bear primary enterectomy.

(3) Enterectomy with a temporary artificial anus should be the operation of choice in all critical cases of intestinal obstruction, where there is an opportunity for resection, whether it involves the large or the small intestine.

(4) The suggested improvements in the technique are as follows:

The upper distended bowel should not be opened until the peritoneal cavity is completely closed. (This is already the practice of several surgeons.)

The open ends of the bowel should be stitched together on their mesenteric side before they are fastened into the parietal wound. This will greatly facilitate the later closing of the artificial anus.

When the artificial anus is in the small intestine, the partially digested discharge from the upper opening should be collected and injected into the efferent opening.

(5) The closing of the artificial anus is a safe operation, and hardly disturbs the convalescence.

(6) Up to the present time not enough cases have been done by this method to estimate its relative mortality, but the cases here reported with those referred to suggest the probability of better results than have been obtained by enterectomy with immediate suture.

THE TREATMENT OF DIFFUSE SUPPURATIVE PERITONITIS.

Le Conte¹¹ after a brief experience with the method advocated by Murphy in the treatment of diffuse peritonitis is impressed with its value. He states that Murphy's technique may be ranged under six headings, as follows:

(1) The rapid elimination of the contents of the peritoneum, whether it be a perforation of the bowel, a cecocolic appendix, a ruptured peptic ulcer, etc. This must be done in the least possible handling of the peritoneal cavity.

(2) Drainage by tube of the lower portion

¹⁰ *Ann. of Surgery*, N. Y., vol. 41, p. 100, 1905.
¹¹ *Ibid.*, February, 1906, p. 211.

of the pelvis through a suprapubic opening, and free drainage through the operative incision.

"(3) The elimination of all time-consuming procedures at the time of the operation.

"(4) The semi-sitting position of the patient after operation, the so-called Fowler posture.

"(5) The absorption of large quantities of water through the rectum, which reverses the current in the lymphatics of the peritoneum, making the surface of that membrane a secreting instead of an absorbing one, and also markedly increasing the secretion of urine.

"(6) The prevention of peristaltic movements of the intestines by withholding all food or liquids by mouth, and, perhaps, by the administration of opium."

AN EXPERIMENTAL STUDY OF THE LOCAL EFFECTS OF PERITONEAL DRAINAGE.

Dr. John L. Yates¹² has contributed a valuable article, to which was accorded the Senn medal in 1905, by the Surgical Section of the American Medical Association. The conclusions that he reaches are of interest and are as follows:

Drainage of the general peritoneal cavity is physically and physiologically impossible.

The relative encapsulation of the drain is immediate.

The absolute encapsulation occurs early (less than six hours in dogs), and can be retarded, but not prevented.

The serous external discharge is an exudate due to the irritation of contiguous peritoneum by the drain.

There is a similar inward current from the potential into the general cavity.

This external exudate diminishes remarkably with the formation of encapsulating adhesions.

These adhesions, under approximately normal conditions, form about any foreign body.

Their extent and density depend on the degree and the duration of the irritation of this body.

Primarily fibrinous, these adhesions become organized in a few days (three days in dogs).

If the irritation persists, they become progressively more mature fibrous tissue.

After irritation ceases, their disappearance depends principally upon a mechanical factor,—the ability of the involved surfaces to pull themselves or to be pulled loose.

Drains should be the least irritating, and should be gradually and finally removed as soon as possible.

Irrigation through drains is futile to prevent adhesions, and dangerous.

After a drain is inserted, all intra-abdominal movements should be reduced to a minimum.

As soon as the drain is removed, intra-abdominal activity should be stimulated, to aid in the disappearance of the remaining adhesions.

Peritonitis, if not too severe, possibly aids in the rapidity of the encapsulation of the drain.

A drain in the presence of infection is deleterious to peritoneal resistance, and should only be introduced to exclude more malign influences.

Postural methods, unless destined to facilitate encapsulation, are both futile and harmful, as far as drainage is concerned.

Peritoneal drainage must be local, and unless there is something to be gained by rendering an area extraperitoneal or by making from such an area a safe path of least resistance leading outside the body, there is, aside from hemostasis, no justification for its use.

SUBPHRENIC ABSCESS.

F. Perutz,¹³ in an exhaustive article on this subject, has reviewed 158 different articles on the same subject. He has collected 214 cases. Inflammatory processes in the neighborhood of the stomach and appendix are the most frequent cause of a subphrenic abscess. The symptoms may be either acute or very insidiously chronic in character. Usually the organs in the vicinity are pushed forward and outward as the fluid collects beneath the diaphragm. There is limitation of movement of the side of the thorax which is in contact with the effusion, and not infrequently extension of the inflammation through the diaphragm constituting, when gas is present, a subphrenic pyopneumothorax. This extension to the pleura is accounted for by the extensive lymphatic communication between the two places.

THE SURGICAL TREATMENT OF TUBERCULOUS GLANDS IN THE MESENTERY.

This very interesting subject has not received the attention which it demands. Corner¹⁴ states: "Tuberculosis of mesenteric glands is found most frequently in adults affecting the lymphatic glands which drain the appendix or the ileo-cecal region. Though I have no intention of quoting specific examples, this class of cases must be referred to. In my lectures delivered at the Royal College of Surgeons of England in 1904, it was pointed out that the cecum was the second place of rest for food in the alimentary canal, the stomach being the first. Moreover, the cecum is the situation which a hundred- or thousand-fold contains more micro-organisms than any other part of the intestinal tract. These two points, the delay in the passage of food and the presence of organisms, lead to the presence of lymphoid tissue in the cecal region as a protective measure, and of its inflammation, appendicitis. Thus there are three reasons why the lymphatic glands in this situation should be those most frequently affected; namely, the delay in the passage of the food material, the presence of organisms, and the presence of inflammation. In operating on the appendix enlarged glands have been frequently found, either in the mesenterium itself or at the ileo-cecal junction, which have turned out to be caseous or partially cretified. It is a most curious fact that suppuration is very uncommon in the mesenteric glands. Even in a septic disease like acute appendicitis with abscess, suppuration is exceedingly rarely

¹³ Centralblatt f. d. Grenzgebiete d. Med. u. Chir., Jena, vol. viii, No. 10.

¹⁴ The Lancet, Dec. 23, 1905, p. 1825.

¹² Surgery, Gynecology, and Obstetrics, December, 1905.

seen. The most probable explanation seems to be that the abdominal lymphatic glands which drain the intestinal tract become tolerant and inured to the products of bacterial action, so that they are very rarely excited to the pitch of suppuration."

Mr. Corner then gives the histories of four cases of tuberculous glands of the mesentery where he operated. He considers that there is a very close relationship between tuberculous peritonitis and tuberculous of the mesentery glands. The tuberculous mesenteric glands are the result, as he clearly states, of tuberculous enteritis, not of peritonitis.

THE REVERSAL OF THE CIRCULATION IN A LIMB.

Carrel and Guthrie, from the Hull Physiological Laboratory, University of Chicago,¹³ contribute a very interesting study. The object of this experimentation is given as follows:

"These experiments have been undertaken with the view, both physiological and surgical, of studying the changes of the circulation of the limb after reversal; and of finding a method of preventing gangrene, when the arteries of a limb become unable to carry the red blood to the capillaries."

The writers state: "The reversion may be brought about by cutting the main artery and vein of a limb and uniting the central end of the artery to the peripheral end of the vein and the peripheral end of the artery to the central end of the vein. Then, from a functional point of view, the vein becomes an artery, and the artery a vein. The capillary circulation is also reversed."

Experiments were done on dogs and the writers state that they demonstrate that:

"(a) The valves present, at first, the reversion of the circulation in the veins

"(b) After a short time, the valves gradually give way and the red blood flows through the veins as far as the capillaries

"(c) Finally, it passes through the capillaries, and the arteries are filled with dark blood. Probably dark blood returns from the capillaries towards the heart through some veins.

"(d) Practically complete reversal of the circulation is established about three hours after the operation"

Their conclusions are as follows:

"(1) The reversal of the circulation in a limb of a dog is possible.

"(2) It can be established by an end-to-end arteriovenous anastomosis.

"(3) Under the same conditions, the lateral anastomosis does not establish the reversal of the circulation.

"The permanent results of these operations—a series of which are being performed under aseptic technique in this laboratory—will be published later. If normal nutrition of the limb were possible, and the results of the end-to-end anastomosis permanent, the operation would, perhaps, be proposed for the preventive treatment of gangrene following obliteration of the arteries."

ON PRESERVATION OF THE NERVE SUPPLY TO THE BROW, IN THE OPERATIVE APPROACH TO THE GASSERIAN GANGLION.

The paralysis of the occipito-frontalis muscle due to the severance of the upper twig of the facial nerve constitutes a deformity following the incisions that are necessary to expose and remove a gasserian ganglion. Dr. Harvey Cushing¹⁴ has recognized that it would be desirable, if possible, to avoid this deformity. He states: "In my last five operations I have again turned my attention to the question of preserving this nerve, and have found, contrary to my expectations, that the incision and approach to the skull could be so altered as to avoid injuring it without adding particular difficulties to, or modifying in any great respect, the subsequent steps of the operation. Four of these cases have been total extirpations for major neuralgia; in the fifth I had to be satisfied with simple division of the sensory root of the trigeminus, a case in which an inoperable sarcoma had grown up through the base of the skull under the ganglion, causing severe trigeminal pain. The malignant nature of the disease from which this patient was suffering rendered the question of cosmetic result far less important than in the neuralgia cases; and consequently the zygomatic arch was not removed, but in other respects the method of approaching the ganglion has been the same in each of the five cases." He gives photographs of one of his patients.

The operation he states is as follows: "The incision has been made within the hair margin, not for the purpose of concealing the scar, because these cicatrices are almost invisible after the operation, but, as has been stated, in order to avoid division of the nerve. The posterior limb of the incision is carried down to the zygoma over the temporal vessels, which usually must be ligated. The skin flap is then reflected downward and forward by blunt dissection, the handle of the scalpel sufficing for this purpose. The temporal fascia, thus exposed, is incised in a line concentric with the skin incision and likewise reflected. The zygoma, which has thus been brought into view at the lower angle of the wound, is then shelled out of its periosteal sheath, not as formerly described by making an incision along its external surface, but by crowding forward its coverings *en masse*. The exposed fibers of the temporal may then be divided as usual by a horseshoe-shaped incision and the muscle scraped away with a periosteal elevator as far down as the base of the skull. In order to satisfactorily expose the skull, a little deeper retraction of the flap is necessary than by the older method, the ordinary small appendix retractor being used for the purpose of holding down the cutaneous and fascial part of the flap as well as the muscle. From this point on the operation is conducted as heretofore described."

This is one of the refinements in technique that are so necessary to secure the best results from operative procedure.

A NEW METHOD OF EXCISION OF THE KNEE WITHOUT OPENING THE JOINT.

Flint¹⁷ recognizes that tuberculous material smeared over the surface of the wound is a source of danger from secondary infection. He has planned an operation which he believes has certain advantages. It is as follows:

"The skin incision should be rectangular, the two vertical cuts being well back at the sides of the leg, extending from a little above the level of the upper limit of the subcutaneous bursa to one inch below the joint line. These two vertical incisions are connected across the front of the tibia by a transverse incision. This rectangular skin flap with the subcutaneous tissue is reflected upward.

"The next incision is curved, the concavity upward. It starts in the vastus internus a little above the upper limit of the subcutaneous bursa and is carried down and outward in the direction of the muscle fibres to the tendons of the quadriceps extensor one-half inch above the patella, and from here upward and outward in the direction of the fibers of the vastus externus to a point corresponding to the beginning on the inner side. The muscle with the tendon is completely divided and burned upward, thus exposing to view the subcutaneous bursa. We next make two small incisions on either side of the femur, starting on each side of the patella in the incision just described, and carried downward and backward to the joint line. The one on the inner side divides the tendinous expansion of the quadriceps, the one on the outer side the tendinous expansion and part of the iliotibial band. After completing these incisions the subcutaneous bursa is separated from the femur with the knife and turned down, tilting the patella when not adherent. The last incision in front is carried transversely across the front of the tibia down to bone just below the joint line.

"On the inner side the sartorius and gracilis are pushed back: on the outer side the biceps and peroneal nerve.

"A flat retractor about one inch wide is now introduced on the inner side behind the head of the tibia close to the joint line. It is first introduced vertically between the gracilis and sartorius on one side, and the tibia on the other. These muscles are pried off and the retractor brought to a horizontal plane, the apex passing behind the tibia. This retractor is now pushed outward, always close to the bone until it emerges at the outer side. All soft parts are thus held back.

"The next step is to saw through the tibia as close to the joint as circumference seems to warrant, the leg being still flat on the table; the retractor being in place protects the soft parts.

"The saw-cut through the head of the tibia is used as a joint. The femur is flexed on the body, the leg on the femur, and with a large knife the soft parts are quickly separated from the posterior structures of the joint. By a little downward traction on the leg, combined with the pull of its own weight, injury to the vessels is easily avoided.

This seems to be much more easily accomplished in this manner than by the operation which attacks the posterior structures of the joint from the anterior aspect. One has at least a better sense of security because one is perfectly sure of the relation of the vessels to the knife.

"As soon as the posterior region of the condyles is exposed the femur is sawn through from behind forward and slightly downward at a level sufficient to clear the cartilage behind. This saw-cut is carried forward until it reaches the margin of the cartilage on the anterior surface of the femur, and the saw then withdrawn. The direction of this cut should be downward and forward so as to lose as little as possible of the femur and obtain the desired slightly flexed position of the bones subsequently. It is easy to be deceived as to the exact position of the cartilage behind. One's examination should be particularly careful at this stage of the operation, otherwise the saw-cut in the femur will be too high up.

"After withdrawing the saw from the femur the leg is once more placed in a horizontal position. The saw is introduced behind the subcutaneous bursa at the upper margin of the articular cartilage on the front of the femur and a cut made which will meet the anterior limit of the horizontal saw-cut made from behind. This last cut is almost vertical, in the coronal plane, and allows the articular portion of the femur, which extends upward in front, to be removed with the joint.

"This is the last step of the incision proper, for it is now possible to lift out the joint with the patella and subcutaneous bursa, the articular surfaces of femur and tibia, all complete without having opened the joint. Up to this point a tourniquet is used, but inasmuch as this part of the operation takes but little time, in fact about ten minutes, and, in easy cases, six minutes, we do not see the disadvantageous effects of longer use, such as would be necessary to obtain complete hemostasis in an operation which opens the joint transversely or dissects off the structures little by little. On removal of the tourniquet the bleeding points can be quickly clamped and tied, thereby reducing hemorrhage to a minimum.

"The subsequent steps of the operation differ in no way from those hitherto customary."

A STUDY OF INFECTION OF THE KNEE JOINT BASED UPON AN ANALYSIS OF 310 CASES.

Carleton P. Flint, in an article on this subject,¹⁸ summarizes as follows:

Non-penetrating injuries, penetrating injuries, traumatic or operative, and knees independent of any injury in the course of some other infectious process or not, may present signs and symptoms not to be distinguished in the absence of bacteriological examination from the cardinal signs and symptoms of infection.

Certain of these cases are undoubtedly infected, but the data at our command do not allow us to distinguish these from such as may be due to

¹⁷ Annals of Surgery, March, 1906, p. 426.

¹⁸ Annals of Surgery, October, 1905, p. 570.

trauma and those possibly due to toxins secondary to infection elsewhere.

The knee joint has certain germicidal powers.

One out of every 22 operations upon clean knees becomes sufficiently infected to demand operation (4.5%).

One out of every 9 operations for recent (five days) traumatic non-penetrating injury becomes sufficiently infected to demand operation (11%).

One out of every 35 operations for pathological conditions other than traumatic injuries more than five days old becomes sufficiently infected to demand operation and draining the joint (2.9%).

One out of every 22 operations for simple fracture of the patella becomes sufficiently infected to demand operation (4.5%).

One out of every 71 operations for fracture of the patella done after the fifth day becomes sufficiently infected to demand operation (1.2%).

One out of every 9 to 10 operations for fracture of the patella done before the fifth day becomes sufficiently infected to demand operation (10.5%).

Three out of every 5 cases of penetrating injury to the knee joint become sufficiently infected to demand operation (60%).

Of compound fractures of the patella, 7 out of 9 become sufficiently infected to demand operation (78%).

Certain knees subjected to non-penetrating injury and not operated become sufficiently infected to demand operation (10% of the operated septic cases).

Certain knees become sufficiently infected to demand operation where no history of trauma exists or other evident septic focus in the body (13% of the operated septic cases).

Certain knees become sufficiently infected to demand opening and draining the joint in the course of some evident focus of infection elsewhere in the body (11% of the operated septic cases).

One out of every 9 infected knees which have been opened and drained dies (11%, some after previous amputation).

One out of every 15 infected knees which have been opened and drained comes to amputation before recovery (6.6%).

One out of every 31 infected knees which have been opened and drained is resected (3.2%).

Most knee joints which have been infected, opened, drained and recovered show varying degrees of functional disability, from slight limitation of motion to complete ankylosis with or without subluxation.

The average stay in the hospital of an operated infected knee joint is between two and three months.

When it is once determined to open and drain a knee joint, the operation should be as radical as possible at the start.

The position of the leg should be that giving the best mechanical drainage, i. e. the patient should be face down.

The risk of infection is greatest in penetrating wounds of the knee (60%).

The risk of infection is least in operations upon clean knees and where there has been no recent trauma (3 to 4%).

SURGICAL TREATMENT OF INTRASPINAL TUMORS.

Richard H. Harte¹⁹ reviewed the literature of this very interesting subject and reports two cases, one a paraplegia from Pott's disease, in which laminectomy was done with great improvement; the second case, a dermoid cyst of the spinal canal with operation and recovery. He has found 87 cases in which the situation of the tumor in reference to the dura is stated. Fifty of these were extradural and 36 intradural. The average duration of the symptoms before operation was two years to three months. In 6 cases the symptoms had existed for periods varying from four to eighteen years. The writer gives an excellent account of the technique of the operation.

INTRAPLEURAL LIPOMA, ACUTE PERICARDITIS, PERICARDIAL EXPLORATION.

R. H. Fitz²⁰ has called attention to this condition which must be rare. He reports a case of subpleural lipoma which was more or less the shape of a pear, the small extremity being attached most firmly to the external surface of the pericardial sac along a line extending from the anterior mediastinum in the region of the pulmonary artery (where it seemed to be continuous with the fat tissue of the pericardium) downward on the left side toward the posterior mediastinum. The mass of fat tissue appeared to be covered in places by a thin, shiny layer resembling the pleura. The condition was confounded with an exudative pericarditis.

The pericardium was tapped in the fifth interspace near the left border of the sternum, and again in the left fourth interspace some two inches from the sternal edge. The cannula entered at least one and one-half inches in each place. Later an exploratory trocar and cannula were inserted through the sixth left interspace in the axillary line. The instrument entered two or three inches, the tip was moved freely, but no fluid escaped. A bit of tissue removed by the cannula was found on microscopic examination to consist of fat. Other cases of intrapleural lipoma are referred to.

Fitz recommends that operation be carried out through the left xiphocostal space, and that if aspiration is not successful incision should be used since it gives ample room for resection of the costal cartilage if necessary, is free from risk to the pleura and peritoneum, and enables injury of the internal mammary vessels to be avoided or controlled. In critical cases when aspiration causes no outflow of fluid and the tip of the instrument can be moved about within the pericardium, exploratory incisions should speedily follow.

SURVIVALS AFTER INTERSCAPULO-THORACIC AMPUTATION.

Jeanbrau and Riche²¹ have analyzed the records of the mortality of this operation for malignant growths and state that since 1887 the mortality has dropped from 29.16% to 7.84%. Patients usually survived three years. The number of cases where the diagnosis was established histologically is 125; absolute cure has occurred in 24 cases where patients have lived more than five years.

FRACTURES OF THE OLECRANON TREATED BY SUBCUTANEOUS EXARTICULAR WIRING.

Murphy²² states: "Considering that coaptation of fragments in fractures of the olecranon is not easily obtained by manipulation, the maintenance of the fragments is frequently an impossibility, and the treatment by splints or casts is frequently followed by ankylosis or impairment of motion. I have come to the conclusion that operative treatment is the most advisable. On the other hand, the exposure of the elbow joint appears to me to be dangerous. The open treatment that Lord Lister applied to fractures of the patella, and which is practiced to a great extent to-day in England, does not appeal to me in the case of fractures of the olecranon. I have always feared to open a joint, even under the greatest aseptic precautions, for we all know that the liabilities of infections in a joint are greater than those in the peritoneum. Therefore, the subcutaneous and exarticular wiring of the olecranon seemed to me the most advisable and the simplest procedure. As far as I have been able to learn from the literature, subcutaneous wiring of the olecranon has not been resorted to by any one else. It is such a simple and practical procedure that I have felt that its publication might be beneficial to the general practitioner and surgeon, who undoubtedly have had unpleasant experiences with such fractures."

The operation is apparently an effective one, but we cannot agree with the conclusions reached by the writer for we never have seen an instance of any marked disability following a fracture of the olecranon.

A NEW METHOD OF ARTHROTOMY FOR OLD DISLOCATIONS OF THE SHOULDER, BASED ON EXPERIENCE IN THE RADICAL BREAST REMOVAL.

E. Wyllys Andrews,²³ in an article on this subject, gives the steps of the arthrotomy as follows:

(1) Incision from clavicle downward across front of shoulder into axilla. The cut is large, 50% longer than by the older methods. Never trust a short incision here.

(2) Section of the pectoralis major near its insertion, leaving about one centimeter attached to bone. This muscle, being cut transversely, is laid over with the skin flap, thus exposing the axillary vein and brachial plexus. The pectoralis

minor is not cut, unless the head of the humerus and vessels have been forced under it.

(3) Careful examination of the vessels, if they cross the tuberosity or head of the humerus, is now made. The artery cannot readily be seen, except by drawing aside the vein. On account of this deep position, it is more often involved in the adhesions, and has been the vessel usually torn. Great care and plenty of time are needed to separate these vessels when they or their large branches, *e. g.*, subscapular or circumflex, are found adherent. No efforts at reduction should be made until the vessels and large nerve trunks are isolated and pulled aside. Bear in mind that some of the reported injuries of the vessels are due to projecting fragments or spicula on the humerus.

(4) The forearm should now be flexed on the arm as a lever, and an assistant should rotate, inward and outward, with a rocking motion, and make traction, when the fibers of the adhesions will be seen and heard to tear gradually, so that the range of motion increases. The operator, while this is going on, should clear the socket of any granulations and cut and nick such bands as refuse to yield after hard stretching. He should search for the lumen of the shrunken capsule. The head and glenoid cavity soon approach each other, the operator tilting the scapula towards the head of the humerus, and giving directions simultaneously as to flexing, extending, abducting, and rotating the limb, as he sees fit. At the last moment the head is apt to take a subglenoid position and refuse to ride over the lower rim of the socket. Before cutting the ligaments or sclerosed muscles more widely, as one is tempted to do, if a blunt hook or retractor be made to pull the upper end of the humerus straight away from the body, the head can sometimes be dragged over the lip of the socket by a smart pull at the critical turn of the manipulation.

(5) The pectoralis major, and, if cut, the minor, should now be reunited by the Harris tendon suture method, and the skin closed with separate suture. Drainage should rarely be dispensed with. This operation is invariably a bloody one, if the dislocation is of long standing and the adhesions firm. Good drainage for a few days prevents infection, which can easily take place with large joint surfaces bathed in wound secretion.

His conclusions are as follows:

(1) It must be considered established that great force is never justifiable in old shoulder dislocations.

(2) Few cases can be left unreduced, on account of pain and pressure symptoms on the brachial plexus.

(3) Resection is more satisfactory, but not ideal or wholly safe.

(4) Arthrotomy by the old incisions is tedious, and never has been widely practiced, but has shown good results.

(5) Arthrotomy by the author's method is simplified and made quicker, as well as safer; it would possibly be as safe as resection, and much more ideal in results.

Reports of Societies.

THE SOCIETY OF CLINICAL SURGERY.

The sixth meeting of the Society of Clinical Surgery was held in Baltimore on April 13 and 14, and proved as interesting as any of its predecessors. All of these meetings have been remarkably successful, owing largely to the novel methods pursued; and members have come to feel that the results attained and the information conveyed are more striking and important than in the case with any other surgical meetings which they attend. After an experience of three years, it is to be hoped that organizations with similar purposes and methods may multiply. It is not only that men come to learn intimately and at first-hand the accomplishments of their associates, but there is established a familiarity and a delightful give-and-take relationship which adds greatly to the enjoyment of such professional gatherings.

Members met at the Hotel Belvedere and proceeded at once to the Johns Hopkins Hospital where they gathered in the Gynecological Operating room.

Dr. H. A. KELLY, by invitation, opened the proceedings by performing his operation for suspension of movable kidney, approaching the organ posteriorly through the superior lumbar triangle. He anchors the kidney low without displacing it through the abdominal wall, passing one stitch about the twelfth rib and securing the kidney further by three additional stitches. He does not split the capsule. Dr. Kelly then discussed renal prosthesis and referred especially to certain vague points, not immediately referable to the kidney, of which patients complain, pain suggesting appendicitis, lumbar aches, or inguinal hernia. If the kidney be suspected, the diagnosis is made sure by injecting a sterile fluid through the ureter into the renal pelvis, when promptly the patient will exclaim "That's the old pain." Dr. Kelly demonstrated this maneuver successfully on a patient before the Society, illustrating by artificial hydroureteritis the condition actually present.

Mr. MAX BLOOMER, by invitation, then gave an extremely interesting address, with sketches and illustrations, on the development of the kidney, dwelling especially upon the arrangement of the calyces and their relation to the renal pelvis, blood supply, and ureter.

Members then adjourned to the general operating rooms of the hospital where Dr. HARVEY CUSHING showed an infant, operated upon five days previously for craniotomy for birth pressure paralysis, from subdural hemorrhage. Improvement was already evident and the wound was healed. Dr. Cushing pointed out that these cerebral lesions from hemorrhage at birth are probably far more common than is supposed, and that even with absorption of the clot, and partial or complete subsidence of the paralysis, a cyst or scar may remain giving rise subsequently to focal epilepsy. Dr. Cushing also showed a number of patients illustrating admirably the good results obtained by his present method of removing the Gasserian ganglion. He spoke also of his operation for decompression, removing a large bone tumor from brain, emphasizing the point secured when the tumor is not benevolently. He then operated upon an adult patient, thus giving of Jacksonian epilepsy.

Dr. J. V. BLOOMER then demonstrated a case of double inguinal hernia his present method of treating that condition, consisting especially upon the simplicity of his technique, with nontransplantation of the cord and the use of the internal oblique muscle

instead of the rectus for closing in large hernial openings. Dr. Bloodgood then showed a large series of interesting cases demonstrating successful end-results, giant cell sarcoma, enucleated from the tibia three years ago, the patient now well and walking about; a case of giant cell sarcoma removed from the radius by resection of the growth one year ago, the patient now well with a useful hand and arm; a case similar to the tibia case, well twelve years after operation; a patient illustrating a good result after Finney's pyloroplasty; a case of gastric disease presented for diagnosis, the long-standing symptoms having suggested ulcer with pyloric obstruction, the patient being now well after one week of medical treatment; a case of dislocation and fracture of the internal condyle of the humerus with an excellent result after partial resection; a case of cancer high in the rectum, now well, nine months after removal of the growth through the abdomen; a case of Pan's disease with very large spleen, now well nine months after exposing and packing the spleen; a case of bone cyst of the humerus cured by curetting and drainage; two cases of cancer of the breast, both well fourteen years after removal of the tumors, and another similar case well after five years; a case operated upon for the rare condition, double thyroid cyst, now well; a child vigorous and well after the operative and fresh air treatment for tuberculous peritonitis.

Dr. J. M. T. FINNEY then showed an extremely interesting case, a vigorous man of seventy, the victim for some months of aneurism of the right subclavian artery. Dr. Finney had operated upon the man three months previously, tying the innominate which was involved, and tying the subclavian beyond the aneurism. The man now appears perfectly well with good use of his arm. Dr. Finney also showed a case of fracture of the lower end of the humerus from which he had been obliged to excise fragments just above the joint. Function was excellent. Dr. Finney then operated for cancer of the sigmoid flexure without apparent metastasis.

After lunching in the Surgical Building, members repaired to the Laboratory of Surgical Pathology where Dr. Bloodgood gave an interesting demonstration of his methods of teaching surgical pathology, and dwelt especially upon the nature and results of operating in case of various forms of tumor. Members then met in the Anatomical Laboratory where Dr. R. G. HARRISON, by invitation, gave a demonstration of his method of the study of experimental embryology, showing how the young embryos of certain animals may be grafted and partially transplanted in a variety of ways. He spoke especially of the method of transplanting the limbs and torso from one piece of frog's embryo to another, and showed a specimen of the developed hybrid tadpole, and frogs. This demonstration, in addition to the experience of practical surgeons, was a truly extremely suggestive lecture, as well known to our bodies as to the same to open up new avenues of research and point to the solution of many obscure problems.

Dr. S. S. SUTHERLAND, of half an hour, then showed the after-effects of the removal of a large cancer of the rectum and sigmoid, together with a large cystic structure in the urinary bladder, the case of

Dr. S. S. SUTHERLAND, of half an hour, then showed the after-effects of the removal of a large cancer of the rectum and sigmoid, together with a large cystic structure in the urinary bladder, the case of General S. S. SUTHERLAND, of half an hour, then showed the after-effects of the removal of a large cancer of the rectum and sigmoid, together with a large cystic structure in the urinary bladder, the case of

which had been operated upon in his service, with seven deaths; and he called attention to the fact that about 13% of these enlarged prostates are malignant. In nearly all cases he advocates operation by the perineal route, according to his well-known method, and in order to distinguish malignant cases he made the following points in diagnosis: early and persistent induration, rapidity of development, small size of the growth, infrequency of hematuria until late, the constant and somewhat indefinite pain which may be in the hips or sacral region, and the early involvement of the seminal vesicles. These symptoms, combined with examination by the cystoscope, will establish the diagnosis. The speaker then spoke of his perineal operation for removal of the malignant prostate: rectangular incision, section of the bulbous urethra and freeing of the prostate with the vessels and trigone, removal of the whole invaded area, anterior to the urethral openings, closure of the bladder wound and reuniting of one angle of the bladder wound with the distal urethral stump. This description was illustrated with admirable drawings. Dr. Young then conducted the Society to his operating room where he performed for them in a brilliant manner the operation of perineal prostatectomy for non-malignant disease.

Members then adjourned to the Anatomical Building where Dr. FLORENCE SABIN (by invitation) gave an interesting address on the development of the Lymphatic System, showing how she began work by using young pig embryos, injecting aniline blue beneath the skin. The earliest development of lymphatics was in the region of the hip and the next in the neck. Later the lymphatics, which are true vessels and not mere tissue spaces, spread over the body radiating especially from a deep sac in the neck which Dr. Sabin has named the Lymph Heart. The speaker showed a number of illuminating preparations and corrosion, showing how the lymph vessels follow the course of the veins especially and form the thoracic duct. She also spoke of the formation of lymph nodes from the lymph heart, as well as in other parts of the anatomy.

Dr. JOSEPH ERLANGER (by invitation) then addressed the Society describing the condition known as heart-block, and its relation to Stokes-Adams disease, illustrating the condition by producing artificial heart-block on the dog. Dr. W. H. HOWELL (by invitation) in the Physiological Laboratory, then demonstrated on the dog the heart, isolated by the method of Martin, Porter and others, with its nutrition maintained through irrigation of the coronary arteries with Ringer's solution; and he showed the action of the accelerator nerves on such a heart, which by these processes may be revived and stimulated to a normal rhythmicity several hours after death.

Dr. W. H. WELCH (by invitation) then favored the Society with a delightful address dealing with certain problems of immunity, and their relation to surgical operations. He prefaced his remarks by showing and commenting upon three interesting microscopic specimens; an appendix enlarged through excessive connective tissue thickening, suggesting a new growth, but without involvement of the mucosa; tissue sections containing numerous examples of the *Spiracheta pallida* of syphilis, abounding especially in the sweat glands, and two interesting specimens from Ehrlich's Laboratory, illustrating mouse cancer undergoing transformation into sarcoma. Speaking of surgical operations in disease Dr. Welch further took as his text the fact that when we operate we deal generally with abnormal conditions against which the normal physiological processes of the organism are already striving, so that we have as our allies these

natural processes, inflammations and the like, our effort being to remove the source of disease and trust to nature to combat and remove its secondary manifestations. Nature has a perfect mechanism for dealing with physiological problems; her method of dealing with pathological problems is imperfect.

After lunching in the Physiological Building the Society visited the Hunterian Laboratory where Dr. W. HALSTED (by invitation) demonstrated on dogs his suggestive experiments for the partial occlusion of arteries by metallic bands, noting how these bands constrict the vessels, burying themselves in the adventitia but not necessarily damaging seriously the nutrition of the distal parts. Dr. Halsted also showed a method of performing end-to-end intestinal suture, a modification of Maunsel's method, but obtaining his traction by sutures passed through the wall of the gut instead of by lateral section and opening of the gut.

Dr. HARVEY CUSHING then gave a demonstration of his methods of teaching students in surgery through practice in operative technique and operations upon dogs. Among other interesting details of this animal clinic he showed how two of his students, Mr. Heuer and Miss Henry, were producing experimental cardiac valvular lesions, and demonstrated dogs in whom such lesions had been produced.

The Society then adjourned to meet in Philadelphia next October.

Recent Literature.

Outlines of Medical Diagnosis. Prepared for the Use of Students, at the Harvard Medical School, Boston. Fourth edition. Boston: F. H. Thomas Co. 1906.

The scope of this small volume is indicated by its title. It serves its purpose well in directing the attention of the student to the important lines of investigation in the study of individual cases, as well as in indicating the main chemical tests which have become an essential part of the physician's equipment. We commend the book as a most accurate and valuable epitome of modern diagnostic method. Its serviceableness reaches far beyond the undergraduate student.

Clinical Methods. A Guide to the Practical Study of Medicine. By ROBERT HUTCHISON, M.D., F.R.C.P., Assistant Physician to the London Hospital, and to the Hospital for Sick Children, Great Ormond Street, and HARRY RAINY, M.A., F.R.C.P. [Edin.], F.R.S.E., Examiner in Medicine and Clinical Medicine, St. Andrew's University, formerly University Tutor in Clinical Medicine, Royal Infirmary, Edinburgh. Ninth edition. Illustrated. Chicago: W. T. Keener & Co. 1905.

This small volume appears in its ninth edition, rewritten in part. The chapter on clinical bacteriology has been revised and in places wholly rewritten by Dr. James Beattie, who brings a peculiar fitness to the task. The book is well arranged for ready reference, is profusely illustrated, and is as complete in its details as one could expect from so small a volume.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MAY 10, 1906.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS. \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico. \$6.75 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (Incorporated),
27 AND 29 BROMFIELD STREET, BOSTON, MASS.

THE SIGNIFICANCE OF HABIT.

THE recognition of the simple fact that habit has much potency both for good and evil in the education of the child and in the production of various conditions later known as disease or health, is coming to be more generally accepted. It is apparent that in many senses the child is the father of the man and that the early months and years are all-important in determining the efficiency or failure of the later years. This general principle has long been acknowledged and more or less vaguely acted upon, but a definite tendency is now apparent to study, on the basis of habit, many processes which have come to be called diseases, with most admirable therapeutic results. It is not to be doubted that much of the so-called nervous disturbance of later years is directly dependent upon errors and false starts in early life. Apparently, of late, a considerable degree of the training of children, using that term in its broad sense, is falling to the lot of physicians, a function formerly in great measure usurped by the clergy. However this may be, we can no longer evade the fact that from a strictly medical standpoint the training of children has the greatest importance, and that the prevention of the modern diseases of civilization should be comitated early and not late, if such conditions are ultimately to be eradicated.

In this connection we note with interest a paper from the pen of Dr. G. Eric Campbell Pritchard, of London, which appears in a recent edition of the *Lancet*. Dr. Pritchard emphasizes his communication "The Training of Nerve Centers in Children," and discusses in a most readable and convincing way the necessity of

"rehabilitating an old friend in new vestments." He concerns himself with the application of the principle of education to the lower nerve centers controlling organic function, and directs his remarks not only to defective children, but also to those of superior intelligence who suffer from initial disabilities. It is in general undesirable, he points out, to distinguish sharply between so-called functional and organic varieties of disease. It is particularly unfortunate that our attention should be so concentrated upon certain local pathological processes that we fail to recognize the ultimate influence and authority of the central nervous system in carrying on nutritional and vegetative functions. As an example of this principle, which is too often forgotten, the change in our conception of fatigue is quoted. Formerly, in the training of an athlete the muscular elements were supposed to be responsible for the sense of fatigue. Now, we realize that the cell bodies which preside over muscular movement are the more essential element, and that the general nervous condition of the athlete is also of the highest importance if his feat is to be successfully performed. In general, it is very properly pointed out that in spite of the apparent automatic character of organic function, neural habits are being formed which must ultimately have results either good or bad.

Dr. Pritchard discusses with much acumen the intimate relation and the practical significance of the nervous system and other organs of the body, and insists on the importance of habit in the perpetuation of what we are accustomed to speak of as normal functions. From this as a basis he proceeds to show in a way which must be convincing that much of our organic life is simply a question of habit, and what is more important, from the medical standpoint, that much of our weakness and inefficiency, whether due to so-called disease of certain organs or of an incapable nervous system, is directly traceable to the same source. It is not our present purpose to enter into detail regarding the various habits which are, on the one hand, productive of good, and on the other, of ill effects. We desire merely to emphasize the fact, which possibly because of its somewhat self-evident character has been curiously overlooked, that a recognition of habit is a positive curative factor of many abnormal conditions, is essential to a proper understanding of their cause. Dr. Pritchard's statement is one which may well be read by all those to whom the importance of this principle has not spread.

BENJAMIN FRANKLIN'S CONTRIBUTION
TO MEDICINE.

SUITABLE exercises, commemorative of the two hundredth anniversary of the birth of Benjamin Franklin, were recently held in Philadelphia. Franklin's versatility has often been the subject of comment, but it may not be generally known that he had and expressed certain ideas on medical subjects which were far in advance of his time. To this fact President Eliot called attention in an address made on the occasion of the commemorative exercises on the subject "Franklin as Printer and Philosopher."

As a natural philosopher Franklin was justly distinguished, and he appears to have had, what is always valuable, an active scientific imagination. Printing was but one of his many interests. He was the first to give accurate information on the origin of certain storms, on the usefulness of certain types of fireplace and on many applications of electricity apart from those for which he is chiefly renowned. President Eliot also draws attention to the sagacity of Franklin's scientific inquiries, as illustrated by his theories of colds and their causes. He combated, it seems, the idea that colds arise either from dampness or exposure. He pointed out the fact that savages and sailors are not liable to colds, and that those persons who are careless regarding draughts and exposure usually enjoy a like freedom. From these and similar observations he concluded that colds and so-called influenzas are the result of contagion, and that the affection is transmitted through personal contact or association rather than by means of the causes which were then almost universally, and still are to a considerable degree, attributed as sufficient.

It is not to be questioned that such an attitude showed a remarkable degree of scientific acumen, which later research has in large measure confirmed. We sometimes think, however, that the pendulum has swung rather too far on the side of infection and taken too little into account those essential predispositions which make infection possible. No doubt the draught and the exposure still play their part in a perfectly physiological way in rendering mucous membranes susceptible to the inroads of the organisms which produce the final result. The matter still remains difficult of explanation, but this in no sense detracts from what must have been regarded one hundred and fifty years ago as a most radical and heretical doctrine. It illustrates again the principle that scientific discoveries of moment are frequently foreshadowed long before they have

attained the dignity of scientific demonstration. This Franklin accomplished in many lines of investigation.

REPORT OF THE NEW YORK STATE CHARITIES
AND AID ASSOCIATION.

THE thirteenth annual report of this most useful association to the New York State Commission in Lunacy is in our hands and gives one an excellent idea of the work which this organization is accomplishing and the influence it is bringing to bear for the betterment of certain social conditions. It is suggestive of the tact which has been exercised that six of the association visitors have been appointed by the governor as managers of the institutions which they formerly visited for purposes of criticism and advice. There are at present forty-eight legally appointed visitors to state hospitals who have presented reports to the main society. The recommendations made in these reports are by no means unanimously indorsed, but they serve to show what impression the institutions make upon intelligent men and women, and hence are of distinct value.

Considerable important recent legislation affecting the insane has been enacted during the last year. A new law, for example, re-establishes boards of managers for the state hospitals which acts in such a way that the position of the superintendents is greatly strengthened, and the boards of managers are given actual control over internal affairs, whereas the State Commission in Lunacy retains complete financial control, as it has since 1893.

It is gratifying to note that for the first time in several years the state hospitals closed their fiscal year without a deficiency. This is regarded as being due to several causes, among which are the unusually high recovery rate of patients admitted, and the smaller number of persons becoming insane. These facts are of special interest in view of the widely heralded increase in insanity. The report contains much further information of interest to the psychiatrist and to those interested in the broader problems concerning the support of the dependent insane. It bears evidence, also, to the unquestioned fact that mental disease is coming to be studied like other ills to which flesh is heir, and that public interest is awakening to the necessities of the situation both on the humanitarian and scientific side.

MEDICAL NOTES.

GIFT TO THE MEDICAL DEPARTMENT OF WASHINGTON UNIVERSITY. — It is announced that a gift of \$50,000 has been made by Mr. Robert S. Bookings and Mr. Adolphus Busch to the Medical Department of Washington University, St. Louis.

THE INTERNATIONAL CONFERENCE OF SOCIETIES OF THE RED CROSS. — The announcement is made that the International Conference of Societies of the Red Cross will be held in London in June of next year. This conference is held every five years, and this is the first in England.

THE NEW SERIES OF AMERICAN MEDICINE. — The previously announced appearance of *American Medicine* in the form of a monthly has occurred with the April issue. The page is reduced in size, but still retains the double column form, and the arrangement of the subject matter bears evidence of the continuance of the policy which has characterized its predecessor. A new feature is a summary of the editorial comment of other journals.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, May 9, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 31, scarlatina 25, typhoid fever 11, measles 79, tuberculosis 57, smallpox 0.

The death-rate of the reported deaths for the week ending May 9, 1906, was 20.24.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, May 5, 1906, was 226, against 233 the corresponding week of last year, showing a decrease of 7 deaths and making the death-rate for the week 19.80. Of this number 113 were males and 113 were females; 216 were white and 10 colored; 131 were born in the United States, 90 in foreign countries and 5 unknown; 51 were of American parentage, 118 of foreign parentage and 27 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 36 cases and 2 deaths; scarlatina, 42 cases, 1 death; typhoid fever, 9 cases and 2 deaths; measles, 86 cases and 6 deaths; tuberculosis, 43 cases and 14 deaths; smallpox, 1 case and no deaths. The deaths from pneumonia were 38, whooping cough 1, heart disease 21, bronchitis 5, and marasmus 7. There were 8 deaths from violent causes. The number of children who

died under one year was 43; the number under five years, 62. The number of persons who died over sixty years of age was 46. The deaths in public institutions were 66.

There were 5 cases and 3 deaths reported from cerebrospinal meningitis during the week.

THE BOSTON MEDICAL ASSOCIATION. — At the recent centennial of the Boston Medical Association, held at the Boston Medical Library, Dr. John Baptist Blake read a suitable poem commemorative of the occasion.

NEW ENGLAND ASSOCIATION FOR THE EDUCATION OF NURSES. — We call attention in another place to the meeting of the recently organized New England Association for the Education of Nurses. This meeting should be well attended. Much recent discussion on the subject has demonstrated that the whole nursing problem is passing through a critical stage, and that the utmost deliberation is required in looking toward the future. This meeting should give opportunity for the freest and most candid discussion of the various aspects of a difficult question.

NEW YORK.

CEREBROSPINAL MENINGITIS ON AN ITALIAN STEAMER. — On the steamer *Il Piemonte* of the Italian line, which arrived at quarantine on May 3 with more than twelve hundred immigrants, three persons died from cerebrospinal meningitis during the voyage from Palermo. At the time of her arrival, five other of the steerage passengers were ill with the disease, and these were removed to the hospital on Swinburne Island, where one of them, a woman, died on the following day.

A SEASIDE PARK. Mayor McClellan has signed the Seaside Park bill recently passed by the Legislature, which permits the city to expend \$2,500,000 for the purchase of a tract of land at or near the seashore for a public park. The park, when established, is to be under the control of the Park Department, but will be for the use also of the Health and Charities Departments and of the trustees of Bellevue and Allied Hospitals, in the way of convalescent homes and fresh-air facilities. Charitable societies may also lease space in the park.

PASSAGE OF STEVENS WAINWRIGHT BILL. The Stevens Wainwright bill, which requires all medicinal preparations containing alcohol and various other narcotic or potent drugs to

be so labelled as to state the presence and the percentage of such ingredients, has passed the Senate at Albany by a vote of 30 to 15. This admirable measure was introduced in the Legislature by the New York State General Committee for Safeguarding the Sale of Narcotics, of which Dr. A. Jacobi is vice-chairman and which is composed of a number of prominent physicians, clergymen and other citizens.

DEATH-RATE. — The condensed quarterly report of the Health Department's bureau of records for the quarter ending Dec. 31, 1905, which has just been issued, shows that the death-rate was 16.43, as against 17.23 for the corresponding quarters of the preceding five years. Comparing the figures of the principal causes of death with those of the quinquennial averages of the corresponding quarters, corrected to correspond with the increase in population, the following decreases are found: All causes, 773; under one year, 212; under five years, 590; typhoid fever, 109; malarial fevers, 34; small-pox, 9; measles, 1; scarlet fever, 59; whooping-cough, 18; diphtheria and croup, 194; influenza, 18; pulmonary tuberculosis, 4; other tubercular diseases, 54; apoplexy, 47; heart diseases, 10; acute bronchitis, 141; pneumonia, 113; Bright's disease and nephritis, 39; old age, 89. The few causes showing increases are as follows: cancer, 58; cerebrospinal meningitis, 66; violent deaths, 119.

OFFICERS OF THE AMERICAN THERAPEUTIC SOCIETY. — At the annual meeting of the American Therapeutic Society, which was held in New York May 3-5, the following officers were elected for the ensuing year: President, Dr. Robert Reyburn, Washington; first vice-president, Dr. J. E. Janvrin, New York; second vice-president, Dr. Frederic H. Gerrish, Portland, Me.; third vice-president, Dr. Howard Van Rensselaer, Albany, N. Y.; secretary, Dr. Noble P. Barnes, Washington; treasurer, Dr. John S. McLain, Washington. Washington, D. C., was fixed upon as the next place of meeting. A banquet was given to the Society by the New York members at the Waldorf-Astoria on the evening of May 4. Dr. Edward D. Fisher, chairman of the committee of arrangements, acted as toastmaster, and after-dinner speeches were made by Dr. Carl Beck, the president, Drs. Satterthwaite and Wilcox of New York and O. T. Osborne of New Haven, ex-presidents, Dr. Robert Reyburn of Washington, president-elect, and by Drs. Pottenger of Los Angeles, who was attending the meeting of the

California State Medical Society in San Francisco at the time of the earthquake, Gerrish of Portland, Me., Henderson of Toronto, Canada, J. Madison Taylor of Philadelphia and William J. Morton of New York.

Obituary.

JAMES WINCHELL COLEMAN ELY, M.D.

Dr. JAMES W. C. ELY died May 7 in Providence, R. I., at the age of eighty-six years, one of the oldest and most respected of the physicians of his city. Dr. Ely was born in Windsor, Vt., Oct. 2, 1820, and traced his descent back to Nathaniel Ely, who came to this country from England in 1633. He was graduated from Brown University in 1842, and studied medicine in Boston, receiving his degree from Harvard University in 1846. He returned to Providence and remained there throughout his long and active professional career. He at once became a member of the Rhode Island Medical Society, which he served as secretary, treasurer and president, and also as censor. He later became physician to the Providence Dispensary and city physician, a position which he held for sixteen years. He was also an attending physician at the Rhode Island Hospital in 1868 until 1874, when he became a consulting physician. He was likewise associated with the Butler Hospital for the Insane as consulting physician and held many offices in associations not strictly medical. Among his other appointments he served on the consulting staff of the Providence Lying-In Hospital and founded the Providence Medical Association. His career throughout was a most honorable one in which he served his profession as well as the city of his adoption faithfully and well. He is survived by his wife and one son.

A report is given elsewhere of a social celebration which was given in his honor only ten days before his death.

Miscellany.

IN HONOR OF DR. J. W. C. ELY'S SIXTY YEARS OF ACTIVE PRACTICE.

ONE hundred and thirty members of the medical profession in Rhode Island, with distinguished representatives from Boston and elsewhere, met in Providence on Friday evening, April 27, to attend a dinner given in honor of Dr. James Winchell Coleman Ely, the dean of the Rhode Island physicians, which had for its object the recognition of the sixtieth anniversary of Dr. Ely's entrance upon the practice of his profession in Providence. Dr. G. Alden Blumer presided. A loving cup of massive form and impressive workmanship was presented to the guest of honor with the following inscription: "Presented to James Winchell Coleman Ely, A.B., Brown University, 1842; M.D., Harvard

University, 1846, by the medical profession of Rhode Island, as a token of affection and esteem and in commemoration of his sixtieth anniversary as a practicing physician in the city of Providence, April 27, 1906.

Dr. Blumer on presenting the loving cup made a brief but touching and eloquent address, the closing part of which, referring to Dr. Ely's advanced age, was as follows:

"Much has been said of late, as the result of a grave misunderstanding of the words of the witty medical philosopher, whose charming letter from Oxford has just been read to you, to lead one to believe that the young of our day and generation are so wise that they can set aside the experience of their elders in impudent reversal of the proverb, 'With the ancient is wisdom, and in length of days understanding.' The life of our honored guest refutes that erroneous notion if ever life did, and there are others present at this banquet who can lay emphatic claim to a proportionate share in that living refutation. Surely one cannot adopt that view without flying in the face of the history of every age and every country. Even as Michael Angelo drew designs for St. Peter's in his eighty-second year, so do our own Rhode Island octogenarians do things that show us younger and often less active men that the freshness of youth may survive in old age. It is a trite saying that a man is as old as his arteries, and, thank Heaven, Dr. Ely has many of them in his brain, whatever their condition may be elsewhere, that are still soft. This is not the place for a disquisition on the philosophy of old age, still less its pathology, though one may admit in passing that with some, while faculties wane, self-confidence, even in good men, waxes apace. But our guest is one of those who has never lost for a moment the power of self-adjustment, and of recognizing new conditions as they arise. If times have changed he has always changed with the times. Never for a moment has he viewed with jealous eye the rise into prominence of younger men, or suffered his own authority, well-earned as it is, to stand in the way of progress. 'While I live,' said Victor Hugo, 'it is my duty to produce.' It is the duty of the world to select, from what I produce, that which is worth keeping. The world will discharge its duty. I shall discharge mine.' I have never heard Dr. Ely (for he is a more modest man than Victor Hugo) use grandiloquent language like that, but that mental attitude I conceive to reflect our friend's outlook upon life. And nothing embitters old age more than the thought that we grudge it even that which it is capable of doing well, or even better than ourselves. If I were asked to name the characteristic which more than any other has endeared Dr. Ely to his fellowmen, I should say that it is his absolute honesty—honesty to himself, honesty to his brethren, honesty to his patients, a character which stands four square to all the world. The late Col. Alex. Biddle, a manager of the Pennsylvania Hospital, once informed a friend of mine that at the close of the Battle of Gettysburg, hav-

ing had command of a brigade, he was directed to make a report. He sat for some time before his blank sheets and then simply wrote in the few words I am now using, that he proceeded to the point to which he had been ordered and there remained with his command until the close of the battle. In that terse report we have the glorious summing up of such lives as that of Dr. Ely."

Dr. Blumer had previously read the following letter from Dr. William Osler, regretting his inability to be present:

"Allow me to join in the joy of your colleagues of Rhode Island that you have been spared so long to grace the profession which we love and in which you have been so devoted a worker. The life you have lived is an encouragement to us all. Setting at naught both the psalmist and the preacher, you have taught us that the strength of old age may be neither labor nor sorrow when the golden bowl remains unbroken and the silver cord retains its tenseness. What a satisfaction it must be to have reached the rare reward, vouchsafed to so few—the frosty yet kindly old age and all that should accompany it, with at the same time a mental and bodily vigor that makes you a still notable figure in our midst. I call it a reward, and yet is it not rather a legitimate interest which many more should earn? As I read it, the great lesson of your life is that you have had the art to grow old gracefully, a lesson so hard to learn and so often a bitter mistake. Lear was right. 'Age is unnecessary'—not an inevitable and grievous burden which death alone unloads. You had the good sense to recognize early that life is a progressive evolution, that the times change, and that if we do not change with them the stream leaves us on the banks with no one to lament our fate but a querulous old man sighing for the days that are no more. And so it has been granted to you to escape that tragedy so often seen and so vividly depicted by Matthew Arnold in 'Empedocles on Etna':

'But he whose youth fell on a different world
From that on which his exiled life is thrown,
Whose mind was fed on other food, was train'd
By other rules than are in vogue to-day.
Whose habit of thought is hatched, who will not
change
But in a world he loves not must subsist
In ceaseless opposition.'

"You met the coming generation with a helpful smile, not with a scowl, knowing well that the problems it had to face differed from those with which you battled, and, grasping this truth, it was given you the rare privilege of retaining a sympathetic interest in all the phases of life. The young man has found in you a trusty guide, the middle-aged a philosopher and the aged a true friend. The beauty of your life has been in its freshness, in the keenness with which you have entered into the work of our profession and the readiness with which you have accepted responsibilities too often shirked by men who reach a certain stage and age. I can conceive of no more

enviable position in a community than that which you have reached.

"You remember one evening at dinner that I taxed you with having written sonnets. It was my dullness that made me suggest it. I should have known better. You have written man's best poem — the epic of a life full of human spirit, a poem which your friends know by heart and which will remain as a precious memory long after you have crossed the bar."

Dr. C. T. Gardner responded for the medical profession at large, Dr. F. C. Shattuck for the Harvard Medical School, President W. H. P. Faunce for Brown University, Charles A. Catlin for the trustees of the Rhode Island Hospital and Rathbone Gardner for the trustees of the Butler Hospital.

a long time under such circumstances. My wife and I each grabbed a child and ran downstairs ready to get into the street. Our house was not seriously damaged, but the chimneys went, as they did all over town. Gas and water pipes broke and electric wires were torn away.

The damage from the earthquake alone would have been immaterial, but the breaking of water mains was fatal. For a time no one realized the danger from fire. I was all over town in a machine, and beyond a few buildings down, everything seemed as usual until eight or nine, the earthquake having been at 5.15. Fires started in many places and soon made headway in the parts of the town without water. By noon we knew all the business section and a great part of the southern portion of the city was doomed. Up to nightfall it seemed certain that destruction would not advance beyond the square on which you were when out here. A sudden change came, however, by midnight, and the fire swooped over Sutter Street, on which my office used to be. I had time to save a microscope and some records, but lost everything else. I could have saved more, but all night my machine was

OPENING EXERCISES, BY THE KING AND QUEEN OF PORTUGAL, OF THE INTERNATIONAL MEDICAL CONGRESS AT LISBON, APRIL 19, 1906.

Dr. Costa Almeida, President of the Congress, sitting on right of the Queen.

The Queen. The King.

Professor Bombarda, Secretary General, reading the Inaugural Statement.

LETTERS FROM SAN FRANCISCO.

THE following letter, which is of interest in connection with the recent earthquake, has been received in Boston from a prominent medical practitioner in San Francisco. It is an individual statement by a competent eye-witness, and all such testimony in regard to such an event has its value.

OAKLAND, April 28, 1906.

We have had a rush of experiences these last few days, and letters can do little justice to them. The earthquake was terrifying, one felt so absolutely helpless, and the twisting and rocking of the house seemed beyond the power of any material to resist. Forty-five seconds seems

busy getting people out of the threatened districts. Next morning early, my wife and the children came over to my father's, where they now are. That day and night the fire swept across and up the city and was stopped two squares away from our home.

You have no idea of the destruction by reading of it; we are just beginning to realize it ourselves. The people have been wonderful, and the spirit abroad is a brave one. I have charge of the medical wards at the Presidio General Hospital, as the regular men are on other duty. It is like being back in the interne days again. The camps outside are getting into shape and there is yet no serious trouble. No one knows what the future will bring. The banks and insurance men will not pass judgment for some weeks, and it will at best take years to build up the town. The big buildings were not damaged by the earthquake, and the spirit in the air says they shall rise again from the fire. Of course, it knocks my plans on the head. My father

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING MAY 5, 1906.

C. H. T. LOWNDEN, surgeon. Detached from the "Texas," and ordered to the "Virginia," April 27.

S. G. EVANS, surgeon. Detached from the Naval Recruiting Station, Denver, Col., and ordered to the "Louisiana," April 27.

L. MORRIS, surgeon. Detached from the "Iowa," and ordered home to wait orders, April 27.

M. K. JOHNSON, surgeon. Detached from the "Maine," and ordered to the "Iowa," April 27.

R. B. WILLIAMS, passed surgeon. Detached from the "West Virginia," and ordered to the "Maine," April 27.

J. R. DYKES, assistant surgeon. Ordered to the Navy Yard, New York, April 27.

F. W. S. DEAN, assistant surgeon. Ordered to the Naval Recruiting Station, Denver, Col., April 27.

P. R. STALNAKER, assistant surgeon. Ordered to the "West Virginia," April 27.

J. B. MEARS, assistant surgeon. Ordered to the "Minneapolis," May 1.

J. S. K. REEVES, assistant surgeon. Detached from the "Minneapolis," and ordered home to wait orders, May 1.

E. C. White, assistant surgeon, ordered to the "Virginia," May 1.

J. P. HAYNES, assistant surgeon. Appointed assistant surgeon with rank of lieutenant, junior grade, from April 16, 1906, May 2.

W. G. STEADMAN, Jr., acting assistant surgeon. Appointed acting assistant surgeon, from April 27, 1906, May 2.

SOCIETY NOTICES.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY.—The regular meeting of the New England Hospital Medical Society will be held at Hotel Bristol, Copley Square, Thursday, May 17, 1906, 7:30 P.M. Section of General Medicine, Dr. Blanche A. Denig, Chairman.

Reports of cases treated with Mechanical Vibration Stimulation, with illustration of the technique, by Drs. Dexter, Bond, Stevens and Denig.

BLANCHE A. DENIG, M.D., Secretary.

NEW ENGLAND ASSOCIATION FOR THE EDUCATION OF NURSES.—There will be a meeting at Huntington Hall, Massachusetts Institute of Technology, Boylston Street, on Friday,

May 11, 1906, at 4 and at 8 P.M. Paper for afternoon: "What proportion of a nurse's training should be spent in district nursing?" Miss Annette Fisher. Discussion. "The present curriculum from the point of view of the nurse." Dr. Hugh Cabot. Discussion.

S.P.M.: "Are the applications for admission to training schools diminishing in number?" Statistics read by Dr. G. Wolcott. Discussion. "The advantages of separate organization for training schools for nurses from that of the hospital." Dr. Alfred Worcester. Discussion: Dr. G. H. M. Rowe, Dr. Edward Cowles, Dr. Herbert B. Howard, Mrs. W. W. Vaughn, Dr. F. W. Patch. A cordial invitation to be present is extended to those interested.

MISS EMMA A. ANDERSON, Secretary.

DR. RICHARD C. CABOT, President.

RESIGNATION.

HENRY P. BOWDITCH, M.D., George Higginson Professor of Physiology in the Medical School of Harvard University, has resigned, the resignation to take effect at the end of the current academic year.

RECENT DEATHS.

DR. HOWARD GRAHAM WETMORE, of New York, died on April 27, at High View, Sullivan County, N. Y. He was born in New York, and was graduated from the College of Physicians and Surgeons, in 1879.

DR. D. H. MANX, of Brooklyn, N. Y., died on May 2. He was a native of Delhi, Delaware County, N. Y., and seventy years of age. At the time of his death he was Grand Chief Templar of the International Order of Good Templars, in the State of New York.

THOMAS JAMES GARRIGAN, M.D., M.M.S.S., died in North Brookfield, April 20, 1906, aged fifty-one years.

BOOKS AND PAMPHLETS RECEIVED.

Lippincott's New Medical Series. Edited by Francis R. Packard, M.D. The Medical Diseases of Infancy and Childhood, with Points on the Anatomy, Physiology and Hygiene peculiar to the Developing Period. By Alfred Cleveland Cotton, A.M., M.D. Illustrated. Philadelphia and London: J. B. Lippincott Co. 1906.

Annual Report of the Surgeon-General of the Public Health and Marine-Hospital Service of the United States for the Fiscal Year 1905. Washington, 1906.

TREATMENT OF CHRONIC DISEASES OF THE
HEART BY THE NAEUHEIM METHODS;
ITS INDICATIONS AND CONTRA-
INDICATIONS.*

BY FRANCIS P. KINSBUTT, M.D.,

*Professor of Clinical Medicine, College of Physicians and Surgeons,
Medical Department of Columbia University, New York; Physician
to the Presbyterian Hospital, New York.*

SEVERAL months ago I was honored by an invitation from Dr. R. C. Cabot to read a paper before the Boston branch of the Massachusetts Medical Society on the Nauheim treatment of chronic cardiovascular diseases. It gave me much pleasure to accept the invitation, but in accepting I was conscious that much of the material of a paper on this subject would be very familiar to the members of this society. For this I ask your indulgence.

The opportunity has been afforded me of studying the Nauheim treatment under especially advantageous conditions during the past two years. I took a five weeks' course of treatment in Nauheim in the summer of 1901 and again in 1905. During these visits, besides my personal experience of the treatment, I was granted courteous and full opportunity by Professors Theodore Schott, Heinemann and Groedel to see their most interesting cases and to examine the patients to whatever degree and with whatever frequency I desired. As the result I have been able to form a reasonable opinion of the effects to be expected in cases suitable for what is known as the Schott method of treatment, which is the combination of resistance exercises and baths, and of the contra-indications for its application.

Before considering the effects of the baths and the resistance exercises from a clinical standpoint, and their physiologic action, I shall refer briefly to the composition of the Nauheim waters and to the technique of both the baths and the exercises.

It may be of interest here to recall that the efficacy of the Nauheim baths in the treatment of many forms of rheumatism had been generally recognized in the early part of the last century. It was the unexpected improvement which was seen to occur in the often associated organic disease of the heart that led Boneke in 1860 to call attention to the therapeutic value of the Nauheim baths in cardiac disease.

The springs which are used for bathing purposes are three in number. Their chief constituents are: (1) chloride of sodium; (2) chloride of calcium; (3) carbonic acid gas, free and in combination.

They vary somewhat in their saline and carbon dioxide content. The range in the chloride of sodium strength is between 2½% and 3%, in the chloride of calcium between ½% and 1%. The free carbonic acid gas content varies between 1.0074 and 2.3764 parts per 1,000 gm., equalling

respectively 571 cc. and 1216.6 cc. In other terms, each liter of the spring richest in carbonic acid gas contains 1216.6 cc. of the gas. The range of the natural temperatures of the different springs is between 31.2° Celsius (88.16° F.) and 35.3° Celsius (95.54° F.).

A system has been elaborated which permits of a wide variation in the saline and carbon-dioxide strength of the baths, and as they vary in their different constituents they are known as:

(1) The ordinary brine bath (*gewöhnliches Soolbad*), free from carbonic acid but rich in salines.

(2) The thermal brine bath (*Thermalbad*), rich in salines and containing a considerable amount of carbonic acid in combination.

(3) The thermal effervescent bath (*Thermal Sprudel*), holding an intermediate position between the thermal and the bath next to be described.

(4) The effervescent bath (*Sprudelbad*), which receives its waters direct from the subterranean springs, with the full saline and carbonic acid content and with only a very slight diminution in their natural temperature.

(5) The current thermal brine bath and current effervescent bath (*Strombad* and *Sprudelstrombad*). These baths also receive the water as it leaves the springs. The water forcibly enters at the lowest level of the bathtub, and by means of overflow pipes at the top leaves it throughout the entire period of immersion. The saline strength of the various baths can be increased at will by the addition of the crystallizable waste product, motherlye (*Mutterlauge*), of the neighboring salt works.

The course of baths usually begins with the brine or the thermal brine bath, strengthened after a few immersions by the addition of gradually increasing quantities of motherlye. After several days the thermal sprudel and again after a similar period, usually a fortnight from the beginning of treatment, the effervescent sprudel baths are substituted. The effervescent current baths are reserved for the final days of treatment and often are not given. The duration of the baths at the beginning of treatment is not longer than six to ten minutes, gradually lengthened to twenty minutes; the latter time is rarely exceeded. The temperature of the first baths is generally from 92° to 95° F. It is reduced with succeeding baths. Temperatures lower than 84° F. rarely are used. Usually not more than two or three successive baths are permitted in as many days, when a day of interval is prescribed. The patient on emerging from the bath is wrapped in heated towels and quickly dried by the attendant. Rest for at least an hour in the recumbent position is imposed after the bath. The number of baths varies from 20 to 35. The system described generally prevails but many variations are and should be made, in our judgment, to adapt both the bath and the exercises directly to be described to the individual case.

* Read at a Library Meeting of the Suffolk District Medical Society, Medical Section, March 28, 1906.

In healthy subjects the immediate effects of

immersion in the baths is a notable diminution in the frequency of the pulse and a distinct increase in its volume. Usually there is also a slight increase in the depth of the respirations with a corresponding decrease in their number. A vaso-dilatation of the superficial vessels, as indicated by the uniform reddening of the surface of the body, is noticeable. This is especially marked in the effervescent Sprudel bath. The blood pressure has a short initial rise followed by a depression to or below the original level, succeeded by a renewed rise to its former height.

A series of very careful observations in regard to the effect of the bath upon the pulse were made by me in my own person during my visit in 1904 and confirmed in the summer of 1905.

The pulse was taken before undressing, and any increase in frequency during the act was allowed to subside before immersion. After one and one-half to two minutes of immersion, either in the simple brine or in the effervescent brine baths, the frequency was invariably reduced from 8 to 10 beats, if the pulse was 76 or more before immersion, and its volume was notably increased; if under 70 before immersion, the reduction did not exceed 6 beats. The pulse-rate is usually accepted as a guide for the length of the bath. Its duration invariably should be within the limits of causing any increase in the frequency of the pulse. In my own case, at the beginning of treatment, the pulse-rate began to quicken after ten minutes; later in the treatment an increase in frequency occurred only at the end of a twenty-minute immersion. The reduction in the pulse-rate was fully maintained during the subsequent period of rest.

The evidence of vaso-dilatation of the surface vessels was always well marked, and with it there was a sensation of general and very agreeable warmth following the first sensation of coolness.

The exercises, known as the Schott resistance exercises, used in connection with the baths, a combination to which I have applied the name of the Schott Treatment, were introduced by the late Dr. August Schott and his brother, Dr. Theodore Schott, as the result of elaborate and prolonged experiment. In their words, as quoted by Bezly Thorne,¹ "they consist of movements designed to bring into successive and regulated action almost every collective system of voluntary muscles comprised in the human frame. They consist of slowly conducted flexion, extension, adduction, abduction and rotation, in orderly succession, of the arms, trunk and lower extremities. Each succeeding movement is resisted by an attendant to such an extent as to oppose without arresting it. Each movement must be slowly and evenly made with a definite and uniform effort on the part of the patient. The office of the attendant is not limited to resisting the movements with equally uniform but slightly inferior force, but it is his duty to impose a short interval of rest after each movement, to

enjoin slow and regular breathing and more especially, by observing the rate of the breathing and its force as indicated by the *ala nasi*, to insure that no undue strain is placed on heart or lungs."

The attendant must bear upon but never grasp or constrict the patient's limbs, lest the movement of groups of muscles be impeded or arbitrarily promoted. The resistance, always slight at first, is gradually increased with progressive treatment. The respirations and pulse should largely be the guide for the degree of resistance and the number of movements given. If either increases in frequency, the exercises should be modified or discontinued. The duration of the single treatment is, as a rule, fifteen to thirty minutes, including the intervals of rest. There are nineteen different exercises, of the simplest character, and they are fully described, with illustrations, in Bezly Thorne's book. The description of a single one will illustrate the technique. The patient extends his hands in front of him at the level of the shoulders, the palms touching. The attendant, standing in front of him, places his hands on the outer surface of the patient's wrists, which rest in the hollow between his thumb and forefinger. The patient then slowly and steadily carries his arms outward until in a line with the shoulders, the attendant gently and slowly resisting. The arms and hands are then brought to their original position with a similar resistance upon the part of the attendant, whose hands have been slipped to the palmar surface of the patient's wrists. Schott usually advises the daily administration of the exercises but both the frequency and the number given on a single occasion are properly subject to many variations.

The first exact observations on the effect of exercise, of the contraction of a muscle or a group of muscles, upon the circulation in healthy subjects, were made by Ludwig and his pupils Sezelkow, Sadler and Gaskell. Further investigations were undertaken later by Mosso Chauveau Kaufman, Morey, Oertel, von Basch, Comte, Bloch, Moritz, Masing and others. Lauder Brunton and Tunncliffe² were led by the somewhat conflicting results obtained by the earlier observers to undertake another series of investigations on the effect of resistance exercise upon the local and general circulation in man. Their experiments were conducted with every precaution against error and the results suggest that an explanation of the conflicting statements made by previous investigators is to be found in the difference in strength of the exercises employed.

In gentle resistance exercises Lauder Brunton and Tunncliffe constantly observed:

Coincident with the beginning of the exercises a diminution in the pulse frequency (3 to 4 beats) and a rise in blood pressure (10 mm.). During the second half of the movements the blood pressure fell to its original level, the pulse frequency was unaltered. With the cessation of the exercises (thirty minutes' duration) the blood

¹ "The Schott Methods of Treatment of Chronic Diseases of the Heart," W. Bezly Thorne, fourth edition, London, 1905.

² British Medical Journal, 1897, ii, p. 1073.

pressure further fell (10 mm.) during thirty minutes, and the pulse rate 7 beats in five minutes, at which point both were maintained. After forty-five minutes the blood pressure had risen to its normal level but the reduction in the pulse frequency persisted. The number of respirations remained the same throughout the exercises. The sphygmogram showed a marked increase in the volume of the pulse during the exercises, the pulsations being nearly double their former size.

Edgcombe's and Bain's² experiments on the effect of resistance exercises upon the circulation are confirmatory of Lauder Brunton's. Both series of investigations showed that if the exercises were of sufficient strength to increase the frequency of the pulse the blood pressure was increased throughout their employment.

The physiologic effects of gentle resistance exercises in the healthy subject are, therefore, similar to those produced by the baths, *viz.*, a diminution in the frequency and an increase in the energy of the cardiac systole, an increase in the volume of the pulse and a diminution in peripheral resistance. The effect upon blood pressure apparently depends upon the relative degree of the increased cardiac energy and output and the peripheral vessel dilatation. If the energy and output, or both, are in excess of the dilatation, a rise in pressure results. If the inverse order obtains, the blood pressure after a short initial rise falls to its original level.

If the physiologic effects of the baths and exercises are such as have been described, their employment in many forms of cardiac inadequacy, a term expressive of a disproportion between the demand upon the heart and its ability to meet it by whatever cause produced, rests upon a scientific basis and should constitute a potent therapeutic.

Clinical experience indicates that such expectations are in a greater or less degree fulfilled. The degree of success in their employment will depend, as Bezly Thorne³ expresses it, upon:

(1) The responsive capacity in the individual case of the nervous mechanism to peripheral stimulation (cutaneous and muscular, the effect of the baths and exercises respectively); (2) the responsive capacity of the vascular tissues; (3) the degree of integrity of the myocardium, and finally, I may add upon (4) a sound clinical judgment and experience in determining these conditions.

The effects of the baths and Schott exercises may now be considered from the clinical standpoint.

In cases of cardiac dilatation suitable for this treatment one of the immediate effects of both the baths and exercises, in many instances, is a shrinkage in the outline of the cardiac area and the movement inward and sometimes slightly upward of the apex impulse. In the case of the exercises, this observation was originally made by August and Theodore Schott, and their interpretation of it, that it represented an actual diminution in the size of the heart, was at first

doubted. Radiographic studies have apparently confirmed their view and it is generally accepted at the present time by clinicians. The extent of the shrinkage, as estimated by percussion, varies. I have repeatedly observed in my clinical work a shrinkage of a half inch in the left cardiac and an equal one in the right outline after single resistance exercises of twenty minutes' duration, including the intervals of rest.

The diminution in size thus obtained after a single exercise is of very temporary duration, but it is claimed by Schott that with the continued employment of the method a more permanent diminution is effected. My own experience is in accord with this view. In cases of dilated heart without organic valvular disease, to which I shall refer later, the normal size not only is attained but may remain permanent.

The immediate effect upon the heart is presumably the result of strong reflex influences excited by peripheral muscular stimulation and acting simultaneously upon the cardiac regulator nerves and the vasomotor centers. The response is a more energetic systole (an increased driving power on the part of the heart) and dilatation of the peripheral arterioles respectively. The dilated heart chambers are more completely emptied and there is an increased transfer of blood from the venous to the arterial system. If these temporary effects can be sustained, as I believe they are by successive applications of the exercises over a considerable period of time, the purpose of all therapeutics in dilated hearts with loss of compensation is effected.

In the relief of venous hyperemia the effect of diminished venous stasis in the veins of the heart walls is sometimes lost sight of. It is the first and most potent factor in the establishment of an improved myocardial nutrition. The view which I have expressed in regard to the mode of action of the exercises I would apply also to the baths. The peripheral stimulation differs in kind but the response is similar.

In attempting to formulate the varieties of cardiac inadequacy suitable for the employment of the methods described, I shall be guided by the experience of those most familiar with this treatment and by my personal observations.

The most numerous and brilliant successes in my experience are obtained in cases of enfeebled, relaxed, dilated hearts, with or without a murmur of muscular or relative mitral incompetence, following prolonged and exhausting diseases, the various acute infectious diseases, and also associated with anemia of varied causation. In some of these cases it is difficult to speak positively of the changes which have occurred in the heart. Possibly there is no more than a loss of tone and relaxation of muscle. In others, especially those following the acute infectious diseases, there undoubtedly exists a parenchymatous myocarditis, granular or fatty, of varied severity. In the anemias, primary (chlorosis) and secondary, judging from the extreme fatty changes found in the heart muscle in the grave forms, a less severe grade of fatty degeneration is probably

² Lancet, London, 1899, i, p. 1552.

present. In all these cases there are symptoms of cardiac inadequacy. Such cases are often rebellious to the ordinary methods of treatment. Rest in the strict sense of the term is distinctly harmful. Digitalis, general tonics and a favorable climatic environment are far less efficient and rapid in their action than the combined use of the baths and resistance exercises.

Under the above head may also be included the cardiac inadequacy, which not infrequently follows severe muscular effort, the "heart strain" of many authors. In many instances a very considerable dilatation is present. Rest in these cases is certainly indicated in the beginning of treatment, but a little later the improvement is more rapid under a judicious use of the baths and exercises. The forms of cardiac affections described all come under the head of curable diseases of the heart. Unfortunately the laity is unable and the medical adviser occasionally fails to differentiate the incurable from the curable forms, and patients flock to Nauheim, with or without the advice of a physician, in the hope and often full expectation of a permanent cure of incurable organic disease of the heart.

In incurable organic disease the best results should be obtained in mitral insufficiency with dilatation, and such is unquestionably the case. Where the compensation is maintained with difficulty, and in the early stages of failure, very striking results are secured. Compensation is restored, which is often maintained indefinitely with intelligent care on the part of the patient.

Schott expects much more than this, and I must admit that I have seen extraordinary improvement where a very serious loss of compensation existed. The relief of dyspnea, of passive congestion of the various organs, the amelioration of irregular action and coincidently a diminution in the size of the heart, have been more rapid than I have seen by other methods of treatment. Groedel believes that less satisfactory results obtain where mitral stenosis is associated with insufficiency. Broadbent, on the contrary, expects good results in such cases. In aortic insufficiency the consensus of opinion is that little good may be expected from the treatment. Where dilatation is marked, with a corresponding loss of compensation, the treatment may be potent for evil. Broadbent thinks that with the *inception* of mitral incompetence in these cases some benefit may be expected.

Of the indications for the Nauheim treatment in angina pectoris one must speak with caution. Defining angina pectoris as a syndrome or symptom group, the clinical pathology of which may differ in different cases and which has to be determined in each individual instance, which may or may not be associated with gross anatomical lesion, it must be admitted that cases presenting all the symptoms of angina major are sometimes benefited by the Nauheim treatment. Several noteworthy instances have come under my observation. Many of these cases certainly belong either to the functional (hysterical) or

vasomotor type, or at least are not due to organic coronary disease. The cases which I personally studied were associated with organic disease of the heart, but certain clinical signs suggested the absence of organic coronary disease. In one of the cases a mitral lesion, which is extremely rare in angina associated with coronary lesion, was present, and the aortic valves were sound; the blood pressure was about normal (150 mm. Riva Rocci) for the age of the patient (sixty-two). My observations lead me to believe that benefit may be derived from the Nauheim treatment in cases of angina pectoris, presumably of the functional or vasomotor type, and which have not yielded to other therapeutic measures. The absence of aortic insufficiency or stenosis, of a constant arterial hypertension, and of the evidence of a probable *general* arteriosclerosis, should be useful guides in advising this treatment. In its employment much care is indicated; the baths should be warm, weak and short, and only slowly strengthened.

Is the presence of a general arteriosclerosis a contra-indication for the employment of the Nauheim treatment? A mere palpability of the accessible vessels, if unattended with arterial hypertension disproportionate to the age of the patient, certainly should not be regarded.

Groedel regards cases with a blood pressure of 150 mm. (systolic pressure Riva Rocci) as appropriate for treatment. Pressures above 170 mm. he believes to be unsuitable.

A decision on the advisability of the baths and exercises in myocarditis, other than the forms previously described, is a difficult one. The signs and symptoms of even grave forms are notoriously doubtful. A marked cardiac inadequacy, however, in the absence of evidence of valvular disease and noteworthy dilatation, especially if associated with arteriosclerosis, may reasonably be regarded as a sign of a grave impairment of myocardial integrity, and constitutes in my opinion a *positive* contra-indication for treatment.

In cases of general emphysema with its permanent increased pulmonic pressure, a positive contra-indication also exists.

It is unnecessary to more than mention the contra-indication in suspected aneurism.

Aside from general contra-indications for the employment of the baths and exercises, there are equally positive indications for the modification of both in individual cases suitable for treatment. In the case of the baths such an indication is the failure of the usual reaction during and after immersion. In these cases the evidence of at least cutaneous vaso-dilatation is lacking; the patient experiences a sensation of cold throughout the bath and subsequently, and there is often yawning and occasionally slight nervous rigors. Such a failure of reaction does not necessarily indicate that the treatment is inapplicable; it is often remedied by increasing the saline content of the bath.

In the employment of the exercises, indications for their modification consist in any increase in

the frequency of the pulse, of the respirations, of the slightest dyspnea, and of fatigue on the part of the patient. These symptoms may indicate merely that there is a slight disproportion between "demand" (degree of exercise) and "supply" (cardiac energy) and one easily to be corrected.

Indications of the *unsuitability* of both baths and exercises are a marked fall in blood pressure and an increase in the area of cardiac dullness during their administration. The latter sign has recently been observed by me in my wards in the Presbyterian Hospital in a single instance, during the use of exercises of the gentlest form. The case was one of organic mitral incompetence with dilatation and an almost complete loss of compensation.

I have occasionally observed in my use of the exercises a very slight increase in the area of cardiac dullness, without appreciable change in the blood pressure. It has been in cases of suspected myocarditis without valvular disease. If a modification of the exercises has corrected this sign, I have not regarded the treatment as inapplicable.

I would add a final word on the administration of the exercises. To be efficient they must be attended with "little exertion and no fatigue." A certain amount of training of the patient and a careful selection and instruction of the operator is necessary. To secure the proper conditions, the patient must be taught not to hold his breath or his body rigid (a common tendency), which involves increased conscious effort, to make the movements slowly and very steadily, and to recognize the degree of resistance advised by the physician. The operator should be light of hand, intelligent and trained in the observation of ordinary symptoms. The use of too great resistance, sometimes at the demand of the patient, is the most common fault of the operator and the most difficult to correct. I have found. At the beginning of treatment I am in the habit of demonstrating the degree of resistance I wish employed in the individual case. In so adapting the treatment it is needless to say that the pulse rate, the blood pressure, the site of the apex impulse and the outline of the heart, must be noted before and after the first employment of the exercises, and from time to time throughout their use.

I have had convincing proofs in my personal practice of the great benefit to be derived from the use of the resistance exercises *alone* in many forms of cardiac inadequacy. That discrimination and judicious care are required in their application, I have endeavored to show. Schott advises their employment with "self-imposed resistance" as an after treatment in many cases. It is within the competence of any one who has become thoroughly familiar with the different movements and involves little risk of injury through over-exertion.

It is to the credit of Schott that he has always maintained that the efficiency of artificial Nauheim baths is similar to that of the natural

ones, and there is abundant clinical evidence to this effect. There is equal evidence that results are attainable where the treatment is conducted under the conditions which obtain at well-ordered spas and in institutions which are not seen in cases treated at home.

I was impressed with the mental atmosphere at Nauheim. It was one of hope and cheerful expectation, the stimulus of which must ever be regarded in our therapeutics.

Purposely I have omitted the recital of cases in the present paper. I have chosen rather to give my general conclusions based upon a personal and careful study of these cases.

THE TREATMENT OF ORGANIC HEART DISEASE BY THE PNEUMATIC CABINET.*

BY CHARLES F. QUIMBY, A.M., M.D., NEW YORK, N.Y.

If the teachings of history alone were not sufficient clearly to define the difficulties which one must encounter who ventures to ask recognition of any new measure that is a radical departure from accepted methods, certainly fourteen years' experience in the struggle to gain such recognition leaves nothing further to be desired in that line of instruction. I am now the happy possessor of such an experience.

While perfectly conscious, therefore, of my position to-night, I nevertheless count myself most fortunate in the full assurance that, from such an audience, in this center of American learning and culture, my propositions and claims whether accepted or not at least will not meet that "A priori" condemnation, which is the outcome of ignorant conceit. No one can appreciate more keenly than myself the profound significance of the fundamental proposition, which it is the purpose of this paper to demonstrate and defend; that, of all available measures for the treatment of organic heart disease, the pneumatic cabinet is the most potent and valuable; and, from the standpoint of our present knowledge of cardiac pathology, provides a scientifically ideal method of treatment. No one can be more surprised in recognizing the truth of that statement than was I. Begun in a hope, born of affection, that it might give transient relief to the distress of a very dear friend, its use was continued for nearly a year before I awoke to a consciousness of what was being done. From that time each year has added unvarying proof of its incomparable value.

The difficulty which every one finds in following a technical presentation of an unfamiliar subject is my excuse for the very familiar form of this paper.

Four things are necessary for a demonstration of the value of the pneumatic cabinet in the treatment of cardiac disease. First, a review of the mechanics of the circulation; second, an explanation of the physical principles involved in the action of the cabinet; third, the applica-

*Read at a Library Meeting of the Suffolk District Medical Society, Medical Section, March 28, 1906.

tion of this action to the pathic conditions of heart disease; and, fourth, clinical evidence of the accuracy of the previous demonstration.

First, the circulation. It is sufficiently accurate for our present purpose to say that the sole function of the vascular system is mechanical, and consists simply in keeping up a flow of blood through the vessels. This flow depends upon push from behind and obstruction in front. The amount of flow is determined by the difference between pressure behind and resistance in front; or, as both of these are manifest by blood pressure, by the difference of blood pressure in heart and arteries. This difference of pressure upon which blood flow depends we shall speak of hereafter simply as differential pressure. Making this statement general we say that all circulation of the blood is determined by differential blood pressure, or tension, and is always in the direction of the lower pressure. Just here comes the point which has special bearing on the cabinet action. Since blood flow is purely mechanical, and dependent solely on difference of pressure, the result will be the same whether this difference be gained by increase in one, or decrease in the other pressure; *i.e.*, it makes no difference, so far as blood flow is concerned, whether we increase ventricular, or decrease arterial pressure. It does make a very great difference in another way, however, as we shall see later. It is evident that a single, permanent differential pressure could not maintain a circulation in which blood must be returned to keep up the supply in the heart. Therefore, this differential pressure, in which the high pressure is in the heart and the low in the arteries, lasts for only half the cardiac cycle, and in the other half there is a reversal of the pressure difference, with the low in the heart and the high in the arteries. Thus the mechanics of the circulation is seen to consist of an alternating differential pressure, first in favor of the arteries and then of the heart. A single word here as to the mechanism of the circulation. The heart and arteries are made to do their work under an established blood pressure. Their ability to maintain their nutrition, and hence power, under increased blood pressure is limited. Every permanent increase of blood pressure above normal demands an increased force expenditure, which requires increased nutritive supply. And cardiac degeneration, failure and death are inevitable results when nutritive repair of the vascular mechanism fails to keep pace with the demand for force expenditure. Therefore, increase of blood pressure as compared with tissue repair is the fundamental cause of death in all forms of organic heart disease. Since all valvular lesions cause an absolute increase of pressure in one or another heart cavity, while primary muscular degenerations cause an increase of pressure as compared with heart power, we now see why it does make a very great difference to the patient and in the duration of his life, whether that differential blood pressure which maintains his circulation is gained by a reduction or increase of pressure.

From the foregoing mechanics of the circulation we have, therefore, the following propositions:

1. The circulation depends upon an alternation of differential blood pressures, and its amount is determined solely by the difference, not by the absolute amount of such pressures.
2. The integrity of the vascular mechanism and, hence, duration of life depend directly upon the maintenance of the absolute amount of blood pressure below a fixed limit; or below an established ratio to heart power.
3. Every cardiac lesion causes an immediate and progressive increase of blood pressure, either absolute or relative, and such increased pressure is the essential cause of death. Therefore,
4. The ideal treatment of organic heart disease is to maintain the circulation under low blood pressure; or to hold any inevitable increase of pressure within the limits of possible compensation.

To what degree, then, does the pneumatic cabinet make possible this ideal treatment?

The apparatus itself is a box of sufficient size to contain a single patient, which can be closed air-tight. (Fig. 1.) On the top is a bellows by

Fig. 1.—Interior view of cabinet, showing ozone generator through glass front.

means of which the air within the cabinet can be rarefied, the degree of rarefaction being shown by a mercurial gage on the front. Passing through the front is a stop-cock, and the patient is provided with a tube, to be attached to this cock on the inside, through which he can breathe from the outside, as he takes the tube in his mouth and the cock is opened. There is always, however, sufficient air in the cabinet so that the patient can breathe when desired, under the lower pressure of the rarefaction. With a patient enclosed in such a cabinet it is evident that respiration may take place under three different conditions of atmospheric pressure.

First, barometric pressure within the cabinet, and, hence, upon both the pulmonary and cutaneous surfaces. Second, rarefaction, or

lowered pressure on both those surfaces. (Fig. 2.) Third, barometric pressure on the pulmonary and a lower pressure on the cutaneous surface (Fig. 3.) To obtain this, the patient takes the

FIG. 2

breathing tube in his mouth with the lips tightly closed about it, the stopcock is opened, thereby connecting the lungs with the outside air, and rarefaction made within the cabinet. What, now, will be the effect of these different atmospheric pressures on the circulation? The last is the only absolute differential pressure, and we take that first. (Fig. 3.) Let us assume that the rarefaction in the cabinet is, say, one inch of mercury. This represents essentially a diminution of pressure over the entire cutaneous surface of one-half pound to the square inch. Thus, the patient, breathing through the tube from the outside, has normal or barometric pressure within the thorax, on the pulmonary vessels and on the outside of the heart, while that on the systemic circulation is one-half pound to the square inch less, or about five hundred pounds less in a foot. In other words, we have applied one huge drop to the entire systemic circulation, that is, one-half pound to the inch. It is obvious that the effect must be exactly that of a small one only manifested generally instead of locally. There will be therefore dilatation of vessels, lowering of blood pressure, and suction of the blood from the lung into the systemic vessels, thus giving hastened circulation, with less work on the part of the heart. The result is pulmonary anemia and systemic plethora, of a degree determined by the amount of differential pressure and the length of its continuance. With a rarefaction of two inches, three minutes' breathing

under these conditions will give the strongest man distressing dyspnea. The most striking illustration, however, of the power of this motion of the cabinet is in the almost immediate arrest of pulmonary hemorrhage. This motion may be used either with low rarefaction for two or three minutes, the patient breathing in and out through the tube; or with high rarefaction very briefly. For our present illustration we assume the latter, with a rarefaction of one inch of mercury. With this rarefaction the differential is maintained only while the patient takes a long, slow inspiration and a second or two after the inspiration ceases. This represents from six to ten heart beats, and in that time pulmonary hyperemia will be relieved and the systemic vessels filled, under lowered pressure. Now, at the end of such an inspiration, with mild pulmonary anemia and systemic plethora, the patient suddenly drops the breathing tube as the cock is closed, preventing any rush of air from without. The result is an immediate drop of pressure on the pulmonary surfaces from barometric to that within the cabinet. (Fig. 2.) This sudden change makes the absolute pressure on the two circulations the same; but, by reason of the weaker anatomical supports of the pulmonary vessels, it practically makes a differential pressure in favor of the lung, thus reversing the previous differential, and sucking the blood from the full systemic vessels back into the lung.

I always find this point the hardest to make clear: that lowered atmospheric pressure is the

FIG. 3

only value of differential pressure in favor of the pulmonary circulation. Every one recognizes the effect of extreme rarefaction, manifested at very low altitudes. Every one admits that

the dyspnea, palpitation, bronchial and nasal hemorrhage caused by such altitudes are the result of vascular dilatation and intense pulmonary congestion. In view of this it is difficult to understand failure to recognize that the effect of milder rarefactions must be the same in kind if not in degree. It is obvious that the extreme vascular disturbance resulting from high rarefactions must be started with the first reduction of atmospheric pressure; and, indeed, it is a well-known fact that in ascending mountains one appreciates a gradually increasing oppression. It should, therefore, require but a moment's reflection to see that the slight rarefaction of the cabinet air is, so far as concerns the circulation, essentially a mild differential pressure in favor of the pulmonary circulation, which acts to draw the blood from the systemic vessels in precisely the same way that the previous absolute differential drew it from the lung into the general circulation.

We thus have the round of the circulation complete, with an alternation of differential pressures,—one drawing the blood out during inspiration, and the other drawing it back during expiration. The blood flow is thus maintained by mechanical forces acting in precisely the same manner as the physiological; which, at the same time, lower blood pressure and give rest to the heart and arterial muscles.

Let us now make the application to conditions of disease; and for this purpose I shall take a case of aortic incompetency as the simplest. With this lesion the first pathic increase of tension is in the ventricle during diastole, and its degree depends, so far as any controllable factors are concerned, upon the tension in the arteries. And these two tensions react to increase each other. Arterial tension driving the blood back during diastole causes ventricular dilatation; and the consequent increased amount of blood thrown into the arteries with systole produces a progressive increase of arterial tension, to continue the process of dilatation with each succeeding diastole. Now let us place a patient with this lesion in the cabinet and see the effect. As the cabinet is closed with the breathing cock open, the patient takes the tube in his mouth, and at once the cabinet air is rarefied. This gives the absolute differential pressure (Fig. 2), in favor of the systemic circulation, with these results: the vessels are dilated, arterial tension lowered, obstruction to heart action diminished, the work of the heart lessened, the force and amount of diastolic dilating reflux decreased, and, best of all, excessive ventricular tension removed, whereby the heart has opportunity to regain its tone and elasticity, and to restore its failing nutrition. If this differential be held only through a long, slow inspiration, pulmonary congestion will be relieved and the systemic vessels well filled. Then the tube is dropped and the cock closed. (Fig. 1.) At once we reverse the differential and with expiration suck the blood back to the lung. Thus the blood is hastened in its flow while arterial tension, aortic reflux, and both cardiac

and arterial strain have all been lessened. A regular treatment consists simply in repetition of these motions; and no patient suffering from this lesion can take a dozen such breaths and not be conscious of relief. This motion, under which the patient, sitting in a rarefied air, inspires from without air at barometric pressure, *i.e.*, under a differential pressure favoring the systemic circulation, and expires into the rarefied air of the cabinet, I have termed "forced inspiration." It is the most powerful motion and may be used with rarefactions of from one to one and a half inches. It is liable, however, at first, to increase the distress of extreme pulmonary congestion with failing right heart. For such cases the proper beginning treatment is what I have termed "differential respiration." In this motion the patient both inspires and expires through the tube, thus maintaining barometric pressure on the lung, while only a slight rarefaction is made in the cabinet air, of from one fourth to one half inch. (Fig. 2.) The patient makes from six to a dozen or more respirations under this mild absolute differential, according to his strength; and then, to avoid the suction effect of rarefaction in increasing pulmonary congestion, as he drops the tube the cock is left open and barometric pressure is at once restored in the cabinet. In this way we gain all the cupping effect in relieving pulmonary congestion and lowering systemic tension and avoid increasing pulmonary congestion by not aiding the return blood flow.

The application of these two motions in the treatment of mitral insufficiency, aortic obstruction, and the various forms of cardiac degeneration should be obvious from what has already been said. It is equally plain that the cabinet is not adapted to the treatment of mitral obstruction. As much relief may be gained by its use even in that condition as from the Neuheim method, but it requires some special skill to avoid doing harm.

The natural criticism which comes at this point is this: Granting all that has been said to be true, a patient cannot spend his life in the cabinet, and the amount of relief which can be gained by any reasonable length or frequency of treatment can hardly be sufficiently great, or enduring, to make the treatment practicable. To this I should reply, "That is precisely what I thought at first." But even the most skeptical must agree that, whatever the nature of the cabinet action may be theoretically, its therapeutic value will be decided by the clinical results. It may help, however, to a fuller comprehension of those results if we recall for a moment the conditions under which the heart does its work and maintains its nutrition. While the heart is made to take up nutrition in very brief intervals of rest, the ability to take that nutrition depends upon the condition of the muscle cells themselves; and although these cells are made to endure rapidly repeated strains yet, if a certain limit is exceeded, they suffer what might be called nutritive paralysis; a paralysis analogous to that

of a voluntary muscle which has been kept constantly contracted for a long time. Now, we know that such a muscle, if allowed complete relaxation for even a short period, may be made to contract again for a considerable time. If

Pl. 6

such short rest does so much to restore nutrition in a voluntary muscle, which requires long periods of rest for full repair, is it not fair to assume that twenty minutes' complete relief to heart strain is practically a very prolonged rest for a muscle that regularly gets its nutrition in such brief periods?

In support of the foregoing claims as to the value of this treatment, I desire to present first a few sphygmographic tracings. They are intended to show only the effects of the cabinet upon arterial tension.

In Plate T the first two tracings show the effect of the cabinet, which was not very marked or persistent, in a case of pure arterial fibrosis. The last three show a very decided effect, which was essentially permanent, in a case of mild arterial disease with moderate mitral reflux. Plate G, from a case of pure mitral incompetency, shows the effect of the cabinet in reducing the pulse rate at the first treatment, from 120 to 96

Pl. C

and the effect upon the amplitude of the pulse of five days' treatment. Plates C' and C'' are from a case of aortic regurgitation with slight chronic renal trouble. Their significance will be appreciated after reading the record on the

tracings of the time and manner in which they were taken. Plates H and B' are from cases 3 and 4 reported below. The first three tracings of Plate B' are especially significant and valuable showing, as they do, the immediate reduction of tension by the cabinet (tracing 2 compared with 1), and the effect upon the heart in enabling it to take up work after this brief complete rest. (Tracing 3 compared with 1.)

I shall report but four cases, and those as briefly as possible. They have been selected with the view of showing the failures of the cabinet, as well as the successes, so far as there is failure.

Jan. 10, 1906. Mrs. B., thirty-seven. Has had trouble with heart for eleven years since birth of only child. Two years ago became worse, and for past year has been very ill, suffering from the regular results of mitral leaking, with the back pressure on the abdominal circulation and liver. Large doses of digitals gave some relief, but is still in great distress

Pl. G'

and can hardly walk across the room. E. and I have been taking 20 drops tri. Dig. every six hours, but has constant angina and severe pain in left leg. Examination shows thin, anemic woman, moderate edema of feet, considerable ascites, and large pulsating liver. These symptoms of back pressure are out of proportion to the dyspnea as respirations are only 24. Dyspnea is quickly increased, however, by the least exertion. Heart beats are 98 to the minute and some irregular. Pulse at wrist 114, and forearm 104 for tracing. There is about a 25% mitral regurgitation.

Digitals were continued and five or six small doses of chloral. Patient was kept at office, and given three treatments. The day after the third treatment, Mrs. B. could walk to the office for purpose with very low resistance, and the temperature was broken by two periods of rest. The patient was entirely relieved by the first of these treatments, and the respiratory trouble. At end of day patient said she felt better than for a long time.

Treatment was continued six weeks. On third day pulse began to show regular rhythm, and at end of third week it was constant and very regular, and was the only way restored by rest. In four days swelling of feet, all gone, but some abdominal enlargement. At end of third week there was no longer any abdominal ascites, and at the treatment the angina and heart debility had been cured.

decreased nearly three inches; but liver still pulsated. During third week patient gave up coming to office in carriage and walked to and from her room, a distance of nearly two blocks. Family reasons caused discontinuance of treatment. Soon after returning to her home in New Jersey she began to go backward, and has now lost about all she had gained. Cases like the above, in which the symptoms of back pressure in the abdomen are out of proportion to those in the lung, I regard as the most unfavorable for any treatment. Yet here, the cabinet gave immediate and progressive relief when all medication had failed. And such a case, if I understand it aright, is not fitted for the Neuheim treatment.

Pl. B"

The second case is quite different. Mr. M., age forty-two. Has had an aortic lesion since he was twenty-four. It caused him no great trouble until the spring of 1904, when, following severe muscular strain, he developed an intermittently persistent angina, of rather mild degree, which was associated with palpitation and much general discomfort. He consulted a justly prominent New York physician who diagnosed a double aortic murmur, put him on digitalis and told him that he would have to continue its use the rest of his life. The digitalis gave rather uncertain relief and did not prevent the anginal attacks, or much affect the general discomfort.

Examination, a year later (April 12, 1905) confirms the diagnosis as to the aortic lesion. Digitalis was stopped and patient put under cabinet treatment, which was given twenty minutes daily for a month. Result, entire relief, and the patient returned to his home in the Berkshires to live the life of country gentleman. In the year since, he has been in town three times for three or four days at a time and has then come in each day for a treatment. Beyond this he has done nothing and has been entirely well.

Case III is an extreme illustration of success and final failure through no fault of the treatment.

F. M., age thirty-five, was admitted to my service at the City Hospital on Dec. 13, 1904. The following is a brief abstract of his history: Fourteen years ago was in bed eight weeks with inflammatory rheumatism. Since then gradually increasing trouble from disturbed sleep, palpitation, shortness of breath, pains in limbs and swelling of feet. Was treated in Bellevue six years ago for heart trouble with all the above symptoms. Four weeks ago had acute attack at night; obviously an acute dilatation, with intense dyspnea

and angina. Feet swelled rapidly and all symptoms grew worse up to time of admission. Examination gives all the signs of extreme cardiac dilatation, with double aortic and double mitral murmurs, and a presystolic thrill. Patient can breathe only in sitting position, and any noise or disturbance in the ward starts an attack of angina and most distressing dyspnea. No medication affords relief except morphia, and this has to be given in frequent doses. The history notes, "Dec. 16, three doses of $\frac{1}{2}$. Dec. 21 to 28, $\frac{1}{4}$ every four hours. Dec. 29, $\frac{3}{4}$ gr. was required to relieve an attack. Dec. 30, small amount of fluid in abdomen; liver 5 cm. below ribs and tender; respirations 44; patient complains of great precordial distress; apex in sixth space past axillary line." The history continues unchanged with constant use of morphia, to Jan. 19, when a still further dilatation occurred, and every one thought the end had come. But he lived, and improved slightly until Jan. 25, when I had a cabinet in the hospital ready for use. On that date patient was taken to the treatment room and given fifteen minutes' treatment in short pieces. The effect on the circulation is shown in the tracings of Plate H. The pulse was reduced from 98 to 92; the systolic blood pressure raised from 140 to 150; and the diastolic from 60 to 110. The precordial pain and dyspnea were much relieved. Owing to inexperience of the staff and my inability to be at the hospital every day, treatment was not given daily, but every treatment gave obvious relief. Morphia was still required at times for the relief of angina, largely because the staff did not dare use the cabinet for that purpose. As they became accustomed to its use I directed that they should do so, and this note appears in the history for Feb. 5: "Patient found in very severe pain, with pronounced dyspnea; pulse rapid, tension high; with each spasm of pain the systolic sound at apex distinctly changed in pitch, becoming higher. Patient was taken to cabinet on stretcher. For the first five respirations the pain and dyspnea were very evident, and it was with great difficulty that patient could properly use the tube. After five respirations patient became suddenly better. Was given two sittings of five minutes each and was returned to the ward with the dyspnea entirely gone, the pain much relieved."

This experience was repeated several times until, owing to frequent disturbances in the ward, on Feb. 18 the patient was taken to a private room. From that time until his discharge on March 9, there was no medication except iron pills and the cabinet. He had no further attacks of angina or dyspnea, and, on leaving the hospital, said he felt better than he had in six years. This patient promised to call at my office for continuance of treatment. He did so the day after leaving the hospital, but from that time all trace of him has been lost, although persistent search was made at the address given. The history as given, however, is sufficiently striking and convincing as to what may be done with the cabinet.

The last case which I shall report is the first case of organic heart disease ever treated by the cabinet. In 1885 W. B., then twenty-eight years of age, suffered a severe attack of endocarditis and aortitis. Such recovery as he made was gained only after nine months' absolute rest, most of the time in bed, and left him with an extensive aortic insufficiency, but poorly compensated. He attempted to resume his business as a lawyer, but the frequent interruptions, incident to recurring attacks of acute dilatation soon compelled him to retire to the country, where he became interested in what has proven to be an immense enterprise. This he was able to carry, at first, because the work could be made to await his ability to do it. As the

demands on his strength increased, and became more imperative, however, the attacks of heart failure returned with increasing frequency and severity until, just as he was preparing to give up he was prostrated by an unusually severe attack and I was called to see him. This was seven years after his first attack, during which time he had been under the most competent medical supervision. He presented all the symptoms of extreme acute dilatation, following aortic insufficiency. The pulse was intermittent, irregular and uneven to an extreme degree. The heart gave loud double aortic and systolic mitral murmurs. He could not lie down, and even in the erect position angina was intense, while the throbbing in the head was almost worse. He had learned by sad experience that digitalis only increased the former as did glonoin the latter. My mental prognosis was speedy death, but in about two weeks he was able to walk slowly without exciting serious increase of cardiac irregularity. A few days later he received his first treatment by pneumatic differentiation, on Dec. 23, 1892. This was given daily for some two months and then daily when he happened to be in town, which varied from two days to two weeks at a time, with intervals extending up to a month when he had no treatment. In six weeks from the first treatment he resumed his business, which he continued despite constantly increasing burdens, for thirteen years, to the summer of 1905, with but a single relapse. For three years he took no vacation, but in the spring of 1896, after a winter of unusual strain, he asked permission to go abroad, to which reluctant consent was given. Although the voyage was smooth, by the time he reached London he felt the warning headache and called a physician who took him through a mild attack of dilatation. On recovery he consulted Dr. A. E. Sanson. By permission I quote from letters of Dr. Sanson and the attending physician, Dr. Edwards. The latter says, "Mr. B. came under my care April 26. He had a very threatening attack of heart failure, with intermittent systole at frequent intervals, often every third or fourth beat. Obvious evidence of aortic and mitral disease with constant regurgitation at the mitral and regurgitation at all kinds of pressure on the aortic valves. He has, of course, a heart which is permanently infirm and will at all times be gravely worsened by anxiety, worry or over work." Dr. Sanson says: "May 19, 1896. I have to-day examined your patient. I find evidence of hypertrophied left ventricle, some dilatation and hypertrophy of the right chambers, a fusiform dilatation of the aorta and abundant signs of obstruction and incompetency at the aortic valve orifice. The left ventricle has dilated to the production of the systolic murmur of mitral incompetency." Both physicians advised the patient to devote the remainder of his life to the study of botany. He reached New York the last of May. Within a week he resumed business, taking treatment constantly. The first of September he went to the country for a vacation, where he was under treatment, and by the end of the month his only murmur was the original aortic regurgitation, which had been the only murmur up to the time of his trip abroad. The disappearance of both systolic murmurs when treatment began in 1892 had similarly shown that they were purely dilatation murmurs.

Soon after this the patient made his permanent home in the country and installed a cabinet in his own house. At that time in reckoning up, he found that he was a director in 15 companies, secretary and treasurer of 5, all involving very large investments, and that, during the previous year he had spent, on the average, one night in every four on a railroad train. For the

next eight years he continued the same active life without any discomfort until the fall of 1901, when, at my regular fall examination, a new murmur was discovered, which, however, had caused no discomfort. It was a mitral systolic of entirely new character, which I believed was due to eccentric hypertrophy of the left ventricle, and of most serious import. Despite all warnings the patient neglected himself and insisted on marrying. This he did in February, 1905, and from that time until his death Sept. 30, the heart failure was steadily progressive. The only gross change in the heart, which weighed 23 oz., aside from the original aortic lesion, was hypertrophy, apparently limited absolutely to the left ventricle. This hypertrophy the pathologist of the City Hospital considered remarkable for the absence of all signs of inflammatory change.

If this were the only case I had to report, I feel that it would justify my claims as to the value of the cabinet treatment. For, while I am well aware that cases of aortic regurgitation often surprise us by their continuance, I do not believe that any such case, after a progressively downward course of seven years to the point of death, suddenly turns in six weeks under any other known method of treatment, and continues for thirteen years an uninterrupted course of health under increasing strain.

In conclusion and in summary permit me to say:

1. The pneumatic cabinet does not cure incurable organic heart lesions.
2. After nearly thirty years' observation and reasonably careful study of the results obtained by other methods, in the hands of acknowledged authorities, and fourteen years' personal experience in the use of the cabinet, I am firmly convinced that it affords more immediate, extensive, and lasting relief than any other known measure.
3. That its use is based upon such strictly scientific principles, and the results are so plainly determined by established physical laws, as to justify its description as the nearest approach to the ideal method of treatment in organic cardiac disease.

DEPLETION IN HEART DISEASE.*

BY FRED C. BRADLEY, M.D.

Jackson Professor of Clinical Medicine in Harvard University

ANSWER rest of the heart spells death. It must work. Rest is for it a relative term. Moreover, its work feeds itself as well as the rest of the organism. The treatment of a diseased myocardium, therefore, whether the disease is primary in the muscle or secondary to either a block at one or more of the valvular orifices or to impeded coronary circulation, falls into two main divisions, economy of work and efficiency of work.

It is my duty this evening to speak briefly on the first of these divisions: economy, which indirectly may be of great value, nay, indispensable, to efficiency, the direct means of securing which will be discussed by Dr. Pfaff. Economy

*Read at a Library Meeting of the Suffolk District Medical Society, Medical Section, March 28, 1906.

of work means such reduction in the demand for work as the particular case at a particular time requires — rest; it means also the removal of such conditions, mechanical or other, as impede the action of the heart. Of these conditions one of the most potent and frequent is dropsy, primarily a direct result of myocardial weakness and liable to be the cause of further weakness. At first and for a short time it is conceivable that the external dropsy, at least, should relieve the heart somewhat through the reduction of the volume of the blood. But such effect, if existent, can be, I think, only transient, the swelling of the tissues obstructing the return of blood through the thin-walled veins and capillaries while the supply of arterial blood is far less affected.

Cardiac dropsy, of course, never occurs until the right ventricle fails to meet the call upon it, and implies an overaccumulation of blood in the venous as compared with the arterial system. Certain it is that we always hail the diminution of cardiac dropsy as an indication of some gain in heart power, while we are careful not to mistake a mere shifting of the edema, due to gravity or other cause, for its real diminution.

Dropsy, then, indicating an overtaxed right ventricle and a surplus of blood on the venous side of the heart, such measures as tend mechanically to ease the right ventricle are clearly called for. These come under the broad term "depletion." Of these the most rapid and direct is the abstraction of blood, either by venesection or leeching or wet cups. There are cases in which blood letting, and that alone, can turn the scale. No one who has seen it can forget the effect — the gain in color and in breathing power with prompt increase in the urine and corresponding decrease in the dropsy — which may follow the abstraction of half a pint to a quart of blood. It may be wise to take more: but I have been struck by the apparent disproportion between the amount of blood taken and the relief given.

If leeches are used the hepatic region is a convenient place, and it is usually well to increase the bleeding by a poultice over the bites.

Next to bleeding comes purging and, outside of a hospital, usually preferable if there is time. Copious watery discharges are what is needed, and it has seemed to me usually worth while to explain to the patient that the drain does not weaken him save in so far as the necessary exertion may be tiring. The freedom of the purgation should, in the main, be proportional to the degree of dropsy. The serum drained from the blood through the bowel, is of course, promptly replaced from the tissues. One is far more apt to purge too little than too much. The choice of the agent is of less consequence than the production of the effect desired.

An ounce or two of Epsom salts in saturated solution in black coffee is often serviceable if the stomach will stand it. In some cases comp. jalap powder, elaterium or Croton oil is preferable.

Sweating may help in getting rid of the dropsy. It is best carried out in a cabinet, the patient

sitting up, as he cannot ordinarily lie down flat or long enough for the purpose.

The serous cavities can be tapped, often with great advantage, if they contain fluid in notable amount and other measures are not promptly efficient.

If edema of the legs be hard and brawny I have found Southey's tubes, modified, as to be presently described, helpful. A thoroughly sterilized aspirator needle or trocar of fair caliber can be thrust an inch or more upward into the subcutaneous tissue of the outer aspect of each lower leg or of the thigh, the skin having been previously carefully cleaned. The needle should then be packed around with sterile cotton or gauze in order to keep the skin as dry as is possible, and should be connected by rubber tubes with a bottle hung under the bed. I have thus drawn off 144 oz. of serum in twenty-four hours from one needle in each leg. The fine needles originally suggested by Southey seem to me to be too small.

The old practice of scarification I regard as dangerous having seen intense dermatitis and sloughing ensue from the constant maceration of the skin and the impossibility of adequate cleanliness. A physician should regard it as a reproach on the part of nature if he allows the legs to burst.

In dropsy in general, but above all in cardiac dropsies, diuresis is a result of action on the heart rather than directly on the kidneys. This certainly applies to the digitalis group. It seems to me that it also applies to diuretin which I have never seen of avail in purely renal dropsies, but which often greatly increases the flow of urine in cardiac dropsies. It has, indeed, seemed to me that the action or failure to act of diuretin on the urine in cardio-renal cases may determine the predominance of the heart or the kidney element at a given time.

Perhaps I do not use caffeine aright, but I have never got such results from it as the French report.

Apocynum cannabinum, on the other hand, has rendered me good service when other things have failed.

Calomel I give as a diuretic in doses of three grains every four hours for two or three days, usually uncombined with opium, special attention being given to the mouth to prevent salivation. I do not use calomel either as a purgative or diuretic unless I feel pretty clear that the kidneys are suffering from nothing more than passive congestion. As a rule, it does no harm; but, like arsenic and lead, mercury is largely excreted by and is an irritant to these organs. I have seen a single dose of calomel cause extreme salivation in nephritis and am, therefore, rather afraid of it. There are, moreover, other agents equally good for the purpose and more free from danger. Squills and calomel may enhance the effect of digitalis.

Finally, plain common sense dictates that the diet of a patient whom we are trying to relieve of cardiac dropsy by depletion should be as dry as

the features of the particular case permit. The blood mass is already larger than the weakened myocardium can manage and limitation of liquids is an important means of lightening the load.

THE USE AND ABUSE OF DIGITALIS.*

BY FRANK FAYE, M.D., BOSTON.

We owe most of our knowledge of the use of digitalis to English physicians living at the end of the eighteenth century.

William Withering introduced digitalis as a remedy into medical practice. He had heard that quacks used this plant in consumption and in dropsical conditions, and that repeatedly the latter were relieved by digitalis in their hands when regular medical treatment had failed. Withering decided to study the effects of digitalis preparations on his patients. In very carefully conducted experiments he came to the conclusion that digitalis was a powerful diuretic medicine, which often proved of greater value than other diuretics known at that time. He already knew that the strength of the different digitalis preparations differed according to the manner of compounding the same, and the season when the plant was collected. Withering, in his book, "An Account of the Foxglove, and some of its Medical Uses," gives us minute directions for preparing digitalis compounds and advises in what conditions they could be useful. He warned against their use in heroic doses, a warning based upon his own experiences and those of other English physicians, who had, in the hope of improving Withering's results, increased his doses manifold. On page 119 of his book we find the first case of digitalis poisoning described, which ended fatally. This description is the more interesting as it gives us a correct picture of the action of digitalis on the pulse in medicinal and toxic doses. In this special case the patient was treated by a physician in the Edinburgh Infirmary. In the beginning of the treatment digitalis was given according to Withering's teachings. "The urine began to flow freely on the second day, and on the third day the swelling of which the patient suffered began to subside. The dose was then increased more than quadruple. The pulse sunk to 50, but the urine increased in quantity. Still larger doses of the infusion of digitalis were ordered. The pulse sunk to 41, and at length to 35 in a minute. The patient gradually sunk and died, but previous to his death, for two or three days his pulse rose to near 100."

Withering knew only of the diuretic effect produced by digitalis; he was not aware of its pulse-reducing properties.

This action of digitalis was clearly demonstrated and expounded by John Ferriar in his "Essay on the medical properties of the digitalis purpurea." Ferriar says on page 299, "While it [digitalis] lessens the frequency and quickness of arterial contraction, it often increases at the

same time the secretion in the kidneys." "The diuretic power of digitalis does not appear to be a constant and essential quality of the plant; the power of reducing the pulse is its true characteristic."

Ferriar was the first physician who taught that the main action of digitalis was its characteristic one upon the circulation. It is true he was very much puzzled that digitalis could act as a sedative to the pulse, and at the same time as a stimulant to the urinary secretion, and he acknowledged frankly his inability to explain this phenomenon.

Ferriar laid great stress upon the importance of watching closely patients under digitalis treatment, and according to him "the patient's pulse must be examined from hour to hour." As to the dose of digitalis he very appropriately writes, "Let me observe once for all, that nothing is less accurately fixed in medicine than one of its most important objects, the doses of remedies. The proper dose of a medicine is undoubtedly that quantity which produces the effect required, whatever be its numerical denomination. A full dose of foxglove is, therefore, merely a relative term."

Withering and Ferriar and their associates studied digitalis experimentally on their patients. They experimented in most cases very carefully and taught us how and when to use this powerful remedy. In criticising their experimental results and deductions we must not forget that they lived before the time of auscultation and percussion and, further, when we consider their limited means of observing and controlling the results of their experimental work on their patients, we must regard their work as classical. An especially fine observer and sharp critic was John Ferriar who, besides his excellent empirical knowledge, was a very witty humorist in things medical.

These excellent empiricists could not, however, explain how digitalis acted and how it produced its effects; they saw only the results and did not understand how they were effected. It is interesting and at the same time instructive to hear Ferriar cry: "If any person were inclined to write a satire on medical evidence, the different testimonies respecting the properties of this single plant would furnish abundant material." "It is a diuretic," says one physician. "It has no diuretic power," says another. "It is a stimulant," says a third. "It is a sedative," cries another. "It has no properties at all," exclaims a fifth. What should the public believe?"

Ferriar's lamentation ought to ring in the ears of many a medical expert who is giving expert testimony. "What should the public believe?"

The action of digitalis, and its *modus operandi*, could only be found out with the advent of experimental research on animals. The results of these researches have explained the clinical observations made empirically by the English physicians; they make clear why in certain cases

* Read at a Library Meeting of the Suffolk District Medical Society, Medical Section, March 28, 1909.

of hydrops digitalis acted as a diuretic, and why in other apparently similar cases no increase of urinary secretions followed the use of this same remedy. The knowledge of the action of digitalis gives us a rational indication for its practical application, of its legitimate uses, and at the same time enables us to avoid abuses of this powerful remedy. Speaking of digitalis action I would like to add that the same remarks hold good for similar acting drugs, like scillain, strophanthin, convallamarin, etc. The main results obtained in experiments on cold and warm blooded animals or on the isolated heart of these animals showed that digitalis stimulates directly the heart muscle and the inhibitory apparatus of the heart in its central and peripheral parts. The result of this action is an increase of blood pressure, with an increase of pulse volume and a decrease in the pulse rate. With large (toxic) doses of digitalis we still see an increased blood pressure, but the pulse rate now rises. Later the pulse beats become irregular, and with fatal doses the circulation becomes finally paralyzed.

This is the usual way in which digitalis acts also on human beings.

The therapeutic effects of digitalis we seek in the practice of medicine are an increase of blood pressure with an increase of pulse volume, and a decrease in the pulse rate.

As soon as the pulse rate becomes increased it is a manifestation that we are getting the dangerous effect of overstimulation. Nevertheless, as with every drug, we may find in some patients deviations from the normal action. The knowledge of these abnormal occurrences will also prevent an abuse of this drug. In some people the vagus nerve does not respond to stimulation by digitalis and we see no reduction in the pulse-rate. The counting of the pulse alone will, therefore, give no light as to whether digitalis acts in such cases. In other instances the decrease in pulse rate may counterbalance the increased blood pressure, and the total work of the heart done in the time unit may be less than in ordinary cases. However, in other instances the heart's action may be already toxically influenced, the heart beat may be much increased in number and the pulse waves follow each other so rapidly that they have no time to reach the radial artery. A pulse count alone, if not controlled by auscultation of the heart, may lead to a misconception of the situation, and a new dose of digitalis may bring about paralysis of the circulation, before an increased pulse rate gives the signal of danger. As the main action of digitalis is to increase the blood pressure and so better to fill the arterial system, the rational indications for its use are clearly indicated. Digitalis may be used in all cases of abnormally low blood pressure and in all such pathological conditions in which some symptoms of the disease may be traced to an incomplete filling or emptying of the circulatory system. In the first place are, of course, to be mentioned all valvular diseases of the heart with failing compensation. To give digitalis in valvular disease of the heart

in which compensation is perfectly established by a corresponding hypertrophy of the heart muscle, is a gross abuse, but often practised.

The best results of the action of digitalis are, as a rule, to be seen in mitral and in aortic insufficiency. To get a good effect in aortic valvular diseases the quantity of the drug to be used has to be usually larger than in mitral diseases. In mitral stenosis and in recent valvular diseases, the effect of digitalis is generally not so marked. In myocarditis, dilatation of the heart, palpitation and pericarditis, digitalis may be used, but always with caution and close observation of the patient. Ferriar already advised the use of digitalis in palpitation of the heart, if the condition was not caused by dyspepsia or general nervous debility.

Recent experimental research on an isolated heart with irregular beats showed that if blood contained digitalis and was perfused through the coronary artery, the heart was made to beat regularly again, thus proving Ferriar's deduction.

The use of digitalis for diuretic purposes is, of course, only indicated when the lack of diuresis can be traced to circulatory disturbances. Other diseases in which digitalis may be indicated are especially furnished by disturbances in the lungs, hypostatic conditions, emphysema, pneumonia, etc., all cases in which the symptoms may be traceable to some impairment in the circulation. Knowing the action of digitalis, we know its use and can and must prevent its abuse, lest the patient suffer.

The old English physicians taught the use of digitalis; modern experimental science explained its action, and so taught a prevention of its abuse.

A BIOGRAPHIC CLINIC ON TCHAIKOVSKY.

BY GEORGE M. GOULD, M.D., PHILADELPHIA.

(Concluded from No. 19, p. 517.)

In the majority of cases of severe eyestrain, past or present, the discerning oculist finds a curious result that may be too easily and thoughtlessly passed over. It is the inhibition of thought and normal mental action which comes from the derouted and morbid ocular reflex. How frequently it is found that the sufferer sits staring with blank loss of power to concentrate his mind upon the task or the writing before him? There is a mysterious loss of imagination, an inability either to think or to execute. The intellect and creative faculty seem palsied. Tchaikovsky re-illustrates this inhibiting effect of ever-attempted but impossible ocular function:

I often sit for hours pen in hand, and have no idea how to begin my articles. I think I shall never hammer anything out; and afterwards people praise the fluency and ease of the writing! Remember what pains Zarembo's exercises cost me. Do you forget how in the summer of 1866 I worked my nerves to pieces over my First Symphony? And even now I often gnaw my nails to the quick, smoke any number of cigarettes and pace up and down my room for

long before I can evolve a particular motive or theme. (35.)

I am very well pleased with my musical work. As regards the literary side of it, I believe it will cost me some days of my life. I cannot describe how it exhausts me. How many penholders I gnaw to pieces before a few lines grow perfect! How often I jump up in sheer despair because I cannot find a rhyme, or the meter goes wrong, or because I have absolutely no notion what this or that character would say at a particular moment. (39.)

I no longer compose anything — a sure indication of an agitated mind. (41.)

From November, 1880, until September, 1881, Tchaikovsky wrote nothing. (Biog. 41.)

Inspiration will not come; every day I begin something and lose heart. Then, instead of waiting for inspiration, I begin to be afraid lest I am played out, with the result that I am thoroughly dissatisfied with myself. And yet the conditions of life are satisfactory: wonderful scenery and the society of those I love. (43.)

I notice that the older I grow, the more trouble my orchestration gives me. I judge myself more severely, more critical with regard to light and shade. In such a case the country is a real boon. (47.)

I have been sitting all day over two pages, yet they will not come out as I wish. (53.)

Not only will the individual or special task "not get itself done," as Carlyle said, but any work whatsoever, and the life-work itself, is inhibited and frozen in the attempt, and the loss of inspiration is here, as frequently elsewhere, painfully deplored.

But work will not come back to me. Rome and Roman life are too characteristic, too exciting and full of variety, to permit of my sticking to my writing-table. However, I hope the power of work will gradually return. (39.)

Oh, my God, if I could only find strength and gladness of heart for new works! Just now I can only go on patching up the old ones. (37.)

I believe I shall never write anything good again. I am no longer in a condition to compose. (41.)

If I were young, this aversion from composition might be explained by the fact that I was gathering my forces, and would suddenly strike out some new path of my own making. But, alas! the years are beginning to tell. To write in a naive way, as the bird sings, is no longer possible, and I lack energy to invent something new. I do not tell you this because I hope for your encouraging denial, but simply as a fact. I do not regret it. I have worked much in my time, in a desultory way, and now I am tired. It is time to rest. (42.)

Formerly I wrote as easily, and as much in obedience to the law of nature, as a fish swims in water or a bird flies. Now I am like a man who carries a precious but heavy burden, and who must bear it to the last at any cost. I, too, shall bear mine to the end, but sometimes I fear my strength is broken and I shall be forced to cry halt! (42.)

Annoyed with my failures. Very dissatisfied because everything that comes into my head is so commonplace. Am I played out? (41.)

No impulse for creative work. What does this mean? Have I written myself out? No ideas, no inclination? Still I am hoping gradually to collect material for a symphony. (48.)

Am I done for and dried up? Perhaps there is yet some subject which could inspire me; but I ought to

compose no more absolute music, symphony or chamber works. To live without work would weary me. What am I to do? Fold my hands as far as composition is concerned and try to forget it? It is difficult to decide. I think, and think, and do not know how to settle the question. In any case, the outlook has not been cheerful the last three days. (52.)

When he should have been at the acme of his creative power, he gave his best energies and care to a work which was at once recognized as without inspiration. He had hammered it out of a weary and inhibited and morbid brain, and he could not himself understand the reason of its ill success:

From the press I have encountered such hatred and hostility, that, even now, I cannot account for it. On no other opera have I expended so much labor as sacrifice; yet never before have I been so persecuted by the critics. (47.)

It is an undoubted *fiasco*. This failure has wounded me in my inmost soul, for I never worked with greater ardor than at *The Enchantress*. (47.)

The reason for the failure of *The Enchantress* must be sought elsewhere; possibly in the defective interpretation of both the chief parts; but more probably in the qualities of the music, which still awaits its just evaluation at the hands of a competent critic. (Biog. 47.)

In cases of severe eyestrain, whether in private practice, or as gleaned from the biographies of men and women of genius, one of the most appalling symptoms frequently found is hopelessness, despair, intense mental suffering, an irresistible feeling that life is worthless, and, although young, soon to come to an end. In Tchaikovsky's case, as was true in that of many others, it once reached the suicidal impulse. There are few minds than can sanely and successfully resist the lifelong insistence and maddening tendencies of continuous agonizing and mysterious disease. Note the age at which this despair occurs:

I cannot shake off the conviction that I shall not live long, and shall leave my symphony unfinished. (26.)

I am already very tired of life. (27.)

Tchaikovsky never gives the true reason for his yearning after solitude and a life of "heavenly quiet and serenity," but it certainly did not proceed from "misanthropy," "indolence" or weariness of life. (Biog. 27.)

What comes of it all? I am old and can enjoy nothing more. I live on my memories and my hopes. But what is there to hope for? (32.)

Boredom consumes us all, and the reason is that we are growing old. Yes, it is useless to conceal that every moment brings us nearer to the grave. (32.)

Misanthropic feeling comes over me, which has often hap-
pened before. It comes partly from my nerves, which sometimes get out of gear for no particular reason, and partly from the rather uncertain fate of my compositions. (32.)

The things which once seemed to him new and interesting now appeared more and more wearisome and unprofitable, and his moods of depression became more frequent, more intense, and of longer duration. (Biog. 33.)

You write of being out of spirits. Believe me, I am the same. (35.)

I am overcome by a sense of loneliness, of desolation. (35.)

In my life, too, there are days, hours, weeks, nay, and months, in which everything looks black, when I am tormented by the thought that I am forsaken, that no one cares for me. Indeed, my life is of little worth to anyone. Were I to vanish from the face of the earth to-day, it would be no great loss to Russian music, and would certainly cause no one great unhappiness. (36.)

In March and April he began to suffer again from mental depression. (37.)

The fact that we both suffer from the same malady would alone suffice to draw us together. This malady is misanthropy; but a peculiar form of misanthropy, which certainly does not spring from hatred or contempt for mankind. (37.)

At my age when one has nothing more to hope in the future. (44.)

After convalescence, which had lasted seven years, Tchaikovsky returned to all these activities with vigor and enjoyment, although after a time his courage flagged and all his strength of will had to be requisitioned to enable him to "keep up this sort of existence." Enthusiasm waned and there succeeded — in his own words — "a life-weariness, and at times an insane depression; something hopeless, despairing and final — and (as in every *finale*) a sense of triviality." (Biog. 44.)

Overcome with insane depression. (46.)

I sit at home full of remorse. The cause of my remorse is this: life is passing away and draws near to its end, and yet I have not fathomed it. (47.)

My absent-mindedness is becoming almost unbearable, and is a sign of advancing age. However, every one was surprised to learn that I was only fifty-one yesterday. Carnegie especially was very much astonished. They all thought, except those who knew something of my life, that I was much older. Probably I have aged very much in the last few years. I feel I have lost vitality. (51.)

I must confess to a morbid fear and horror, as though I were entering the kingdom of the dead and the world of those who had long since vanished. (52.)

... He says that had he remained a day longer in Moscow he should have drowned himself, and it is said that he did go so far, in his terrible depression, as to stand up to his chest in the river one frosty September night, "in the hope of literally catching his death of cold, and getting rid of his trouble without scandal." (Mason.)

Readers of the clinical biographies of other eyestrain sufferers have noticed the repeated occurrence of the fact that these so often have been compelled to work at a "white heat," with an intensity of emotion and recklessness of result that was itself morbid, and a certain indication of an underlying morbid cause. It was only thus that the nervous mechanism could be whipped and spurred to overcome the resistances and inhibitions of the balking mechanism of eye and brain. Again the case of Tchaikovsky illustrates:

I should feel quite happy and contented here, were it not for the morbid, restless need of hurrying on my work, which tires me dreadfully, without being in the least necessary. (43.)

In any case my mental condition has been very gloomy of late. The composition of the *Manfred* Symphony — a work highly tragic in character —

is so difficult and complicated that at times I myself become a Manfred. All the same, I am consumed with the desire to finish it as soon as possible, and am straining every nerve; result, — extreme exhaustion. This is the eternal *cercle vicieux* in which I am forever turning without finding an issue. If I have no work, I worry and bore myself; when I have it, I work far beyond my strength. (45.)

There are times when it seems to me it would be wise to cease from composing for a while; to travel and rest. But an unconquerable desire for work gains the upper hand and chains me to my desk and piano. (45.)

I cannot live without work, but why do circumstances always compel me to be in a hurry, to have to overtax my strength? (47.)

In the old — not the modern — text-books on "migraine," and in the case of every patient who has long endured this disease, it is noticed that there is a seeming contradiction of health and happiness almost synchronously, or quickly alternating, with the deepest agony and dejection. The following excerpts show the symptom reappearing in Tchaikovsky's case:

I have suffered all the winter, but my physical health is not in the least impaired. (35.)

More and more misanthropical. Imagine, now-days, I am often drawn towards my monastic life, or something similar. Do not fancy I am physically out of health. I am quite well, sleep well, eat even better. (35.)

Forgive me, dear friend, for boring you with these continual complaints about my health, which are out of place, for in reality I am a perfectly sound man, and the little ailments about which I grumble are not serious. (38.)

A splitting headache, and spent a wretched night. I recovered during the return journey to Petersburg, and to-day I feel quite refreshed. (39.)

My health is better. I have gone through such a terrible attack of nervous headache, I thought I must have died. I fell asleep so worn out, I had not even strength to undress. When I awoke I was well. (43.)

He was no longer a misanthropist, rather he sought those to whom he was dear, not only as a man, but as a personage. (44.)

When I am quite well — as I am at present — I am seized with a feverish thirst for work, but the thought of the shortness of human life paralyzes all my energy. (46.)

I was ill again after my last letter to you. This time I was so bad that I decided to send for the doctor. It seemed to me that I was about to have a strange illness. Suddenly I received a telegram saying that I must be at the rehearsal. I answered that the rehearsal was not to be thought of, for I could not travel. But at the end of half an hour I suddenly felt so well that — in spite of terrible disinclination — I went to Moscow. Every trace of headache, which for ten days had so affected me, vanished. Is not this a curious pathological case? (46.)

Complete success. Great enjoyment — but still, why this drop of gall in my honey-pot. (47.)

In this question lie the germs of that weariness and suffering which had their growth in Tchaikovsky's soul simultaneously with his pursuit of fame, and reached their greatest intensity in the moment of the composer's greatest triumphs. (Biog. 47.)

The work went easily, and his health was good. (51.) Increasing nostalgia and depression of spirits. (52.) I was taken so ill in the carriage that I frightened

my fellow-passengers by becoming delirious, and had to stop at Khar'ov. After taking my usual remedies and a long sleep, I awoke quite well in the morning. (52.)

This year, 1893, opened with a period of serene content, for which the creation of his Sixth, or so-called "Pathetic," Symphony was mainly accountable. The composition of this work seems to have been an act of exorcism, whereby he cast out all the dark spirits which had possessed him in the preceding years. (Biog. 52.)

At this time he suffered from a terrible attack of headache, which never left him, and threatened to become a chronic ailment. It departed, however, with extraordinary suddenness on the fourteenth day after the first paroxysm. (52.)

In spite of the discomforting news which met him in all directions, from the time of his return from England to the end of his life, Tchaikovsky was as serene and cheerful as at any period in his existence. (Biog. 53.)

I was very ill. (53.)

Just lately I have been dreadfully bored and misanthropical. I do not know why. I sit in my room and see no one but the waiter. I long for home, work and my normal existence. (53.)

He had never felt better or happier in his life. (Kashkin, 53.)

That the case of Tchaikovsky may in most of its phases illustrate the clinical picture of "migraine," as described by the careful observers of a past (not present) generation, one must add the frequently observed symptom of partial paralysis, or paresis:

At this time he was suffering from a nervous affection of the right hand, which made conducting a matter of considerable difficulty. (Biog. 51.)

In America the news that I could not go, because my right hand was disabled, reached them by cable, and they were very much upset. Now they are awaiting an answer — yes or no. (51.)

Yesterday I suffered so much that I could neither sleep nor eat, which is very unusual for me. I suffer not only from torments which cannot be put into words (there is one place in my new symphony, the Sixth — where they seem to me adequately expressed), but from a dislike to strangers and an indefinite terror — though of what the devil only knows. This state makes itself felt by internal pains and loss of power in my legs. However, it is for the last time in my life. (53.)

There is also found the usual phenomenon that the eyes, the original source of the entire train of reflex symptoms, only rarely show painful signs of the disease, and these but temporarily.

Another unpleasant experience took the form of an obstinate affection of the eyes, which hindered him from working regularly. (25.)

In spite of his eyes being affected and his constant change of quarters. (25.)

My health is good, only one thing troubles me a little — my eyesight, which is tried by my work. It is so much weaker than formerly that I have been obliged to get a pair of eyeglasses, which I am told are very becoming to me. (32.)

There are ninety-nine cases of atypical "migraine" to one that some writers call "typical." I have omitted many references and others have

been given in previous pages, to the complaint of headaches, neuralgia, neuralgic headaches, etc., scattered through the letters and life of Tchaikovsky. Severe eyestrain will usually result in some form of cerebral disorder or ache, or in "bad digestion," "dyspepsia," "catarrh of the stomach," etc. The latter class of disorders are persistently complained of by Tchaikovsky. For instance:

Suffering from a form of dyspepsia. (37.)

I wish some one could explain to me the origin of that curious exhaustion which comes upon me almost every evening, about which I have already written to you. I cannot say it is altogether disagreeable, because it usually ends in a heavy, almost lethargic sleep, and such repose is bliss. Nevertheless the attacks are tiresome and unpleasant, because of the vague anxiety, the undefinable yearning, which take an inconceivably strong hold upon my spirit, and end in a positive longing for Nirvana — *la souffrance*. Probably the cause of this psychological phenomenon is of quite a prosaic nature; I think it is not so much a mental ailment as a result of bad digestion, a sequel of my catarrh of the stomach. Unluckily we cannot get over the fact that the material influences the spiritual! (38.)

In spite of the greatest care and moderation, I suffer from dyspepsia. It is not serious, and I have no doubt a cure at Vichy will completely set me up. (46.)

One wonders if a certain number of cases of alcoholic dissipation are not being constantly caused by the nervous disorders and irritations due to eyestrain. The note is not wanting in Tchaikovsky's case.

Since the day you left I have taken several glasses of brandy at night, and during the day I drink a good deal. I cannot do without it. I never feel calm except when I have taken a little too much. I have accustomed myself so much to this secret tipping that I feel a kind of joy at the sight of the bottle I keep near me. I can only write my letters after a nap. This is a proof that I am still out of health. (48.)

A careless or prejudiced critic might think that Tchaikovsky's melancholy and ill-health were largely due to his ill success in life and as a musician. The following excerpts will answer:

The people around me often wonder at my fortuitous and my apparent ill-temper, while actually I do not lead an unhappy existence. What more can a man want whose prospects are good, who is liked, and whose artistic work meets with appreciation? (27.)

I assert that life is beautiful in spite of everything! This "everything" includes the following items: illness, I am getting much too stout, and my nerves are all to pieces. (30.)

He realized his wild dreams of fame, and attained to such prosperity and universal honor as rarely fall to the lot of an artist during his lifetime. (Biog. 47.)

Physically neither better nor worse than in former years, possessing the unlimited affections of those whom he loved in return, — he was, to all appearance, an example of mortal happiness, yet in reality he was less happy than before. (Biog. 47.)

And the secret grew keener, as his weakness grew more intolerable. The more he accustomed his temperament to unsuitable occupation, the further he advanced his reputation, the more complete was his

disenchantment with the prize. Radiant and glittering as it had appeared from afar, seen closer, it proved insignificant and tarnished. Hence the profound disillusionment, "the insane depression," the something "hopeless and final" which make so dark a background to the picture of his brilliant success at home and abroad. (Biog. 47.)

That the nonsensical word, *hysteria*, may not be used, Tchaikovsky replied in advance:

To my regret, however, you seem to see what is good for me precisely where I — and several others — see what is inimical to my health; in the very thing which appears to me an unprofitable and aimless exertion. . . . All you have written to me, and also your manner of saying it, only proves *how little you know me*, as I have frequently observed on former occasions. Possibly you may be right, and I am only *putting it on*; but that is precisely the nature of my illness. (38.)

Another ancient and humorous superstition had also to be illustrated:

His first impressions of Vichy, whither he had been ordered by his physician, were far from favorable, but the local physician persuaded him to remain at least long enough for a "demi-cure," from which he derived great benefit. (35.)

Tchaikovsky now resembled those individuals who do not recognize the true cause of their sufferings, and, therefore, have recourse to the wrong treatment. (Biog. 35.)

The sole object of the journey mentioned in this letter was to take a cure at Vichy. The catarrh of the stomach from which he suffered had been a trouble to Tchaikovsky for the last twenty years.² Once, while staying with Kondratiev at Nizy, the local doctor had recommended him *Natron* water. From that time he could not exist without it, and took it in such quantities that he ended by acquiring a kind of taste for it. But it did not cure his complaint, which grew worse and worse, so that in 1876 he had to undergo a course of mineral waters. The catarrhal trouble was not entirely cured, however, but returned at intervals with more or less intensity. About the end of the eighties his condition grew worse. Once during the rehearsals for *Pique Dame*, while staying at the Hotel Rossiya, in St. Petersburg, he sent for his brother Modeste, and declared he "could not live through the night." This turned his thoughts more and more to the "hateful but health-giving Vichy." But the periods of rest after his various tours, and of work in his "hermit's cave," at Klin, were so dear to him that until 1892 he could not make up his mind to revisit this watering place. This year he only decided to go because the health of Vladimir Davidov equally demanded a cure at Vichy. He hoped in this congenial company to escape his usual homesickness, and that it might even prove a pleasure to take his nephew abroad. (Biog. 52.)

To complete the sketch these paragraphs may be added:

"I was shocked at his appearance," he writes, "for he had aged so much that I only recognized him by his wonderful blue eyes. A man old at fifty! His delicate constitution had suffered terribly from his incessant creative work." (Door, 51.)

² Who has not seen correction of errors of refraction relieve so-called bilious attacks, periodical vomiting, anorexia, indigestion and other gastric symptoms? Prof. John H. Musser, Jour. Am. Med. Assoc., Nov. 4, 1905.

But this was probably the fatal moment in his indisposition, for, while talking, he poured out a glass of water and drank a long draught. The water had not been boiled, and they were dismayed at his imprudence. But he was not in the least alarmed, and tried to calm their fears. He dreaded cholera less than any other illness. After this his condition grew worse, but he attributed all his discomfort to a copious dose of Hunyadi which he had taken earlier in the day, and still declined to send for his favorite doctor, Bertenson. (Biog. 53.)

Death occurred on Oct. 25 (Nov. 6), at the age of fifty-three.

And why this death at the age of fifty-three? It is not an explanation to say that it was due to cholera, even if one admits the correctness of the pretty evidently false diagnosis. This feeling is expressed by his brother, who wrote:

As at the beginning of the sixties, when he chose a musical career, and in 1885, when he resolved to "show himself in the eyes of the world," so also at this juncture, we are conscious of a feeling that *things could not have gone on much longer*. (Biog. 52.)

His death, which came to solve the problem, seemed fortuitous. Yet it is clear to me that it came at a moment *when things could not have gone on much longer*; nor can I shake off the impression that the years 1892 and 1893 were the dark harbingers of a new and serene epoch. (Biog. 52.)

Despite the smiles of the neurologists, or diagnosticians who care not for the forty years of functional disease which preceded anatomic pathology, or the irresistible impact of infectious disease, the explanation of Tchaikovsky's death lies in the lifelong preparation of the "soil" by eyestrain, doubled now by presbyopia. The lethal diseases are in truth often but the executioners of long precedent functional disorders. Imitating a foolish science, his biographer explains the life disorder by the ancient but still living superstition of "heredity":

His one certain inheritance seems to have been an abnormally neurotic tendency, which probably came to him through his grandfather Assier, who suffered from epilepsy.

His grandfather was an epileptic, and his own symptoms pointed to an inherited nervous irritability. (Mason.)

Tchaikovsky also echoed the nonsense that still spoofs about the professional and biographic mind:

My nerves are poor, but this cannot be helped, and is not of much consequence. Whose nerves are not disordered in our generation — especially among our artists? (32.)

If this theory seems to the unobservant to have some ground when applied to musicians and literary workers, it may be suggested that no sign of "nerves" and "migraine" is found in Brahms, Mozart, Verdi, Mendelssohn, Goethe, Mommsen, Gladstone, and thousands of others in similar callings. Then the sculptors and painters and actors are also "artists," and one will seek almost in vain for the symptoms of eyestrain in these three classes of men.

In the midst of the perplexity, mystery and pain of his life, like Parkman, Carlyle and the majority of such sufferers, Tchaikovsky was struck with the tormenting puzzle of the nature of his life ailment, and he wrote as follows:

Dear friend, leading such a life, amid all these beautiful impressions of nature and art, ought not a man to be happy? And yet a worm continually gnaws in secret at my heart. I sleep badly, and do not feel that courage and freshness which I might expect under the present conditions. Only for a moment can I conquer my mental depression. My God! What an incomprehensible and complicated machine the human organism is! We shall never solve the various phenomena of our spiritual and material existence. And how can we draw the line between the intellectual and physiological phenomena of our life? At times it seems to me as though I suffered from a mysterious but purely physical malady which influences my mental phases. Lately I have thought my heart was out of order; but then I remembered that last summer the doctor who examined it declared my heart to be absolutely sound. So I must lay the blame on my nerves—but what are nerves? Why, on one and the same day, without any apparent reason, do they act quite normally for a time, and then lose their elasticity and energy, and leave one incapable of work and insensible to artistic impressions? These are riddles. (10.)

This is a genuinely scientific questioning, and millions of other sufferers in the last and in the present generation might have found the easy and simple key to the mystery, an easy and now well-known solution of the "riddles," and the relief of their torments, if the medical profession had exhibited the same or a slightly better logical and clinical acumen.

Reports of Societies.

LIBRARY MEETING OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

MEDICAL SECTION, HELD MARCH 28, 1906.

CHAIRMAN, R. C. CROSBY, M.D.; SECRETARY, L. A. LOCKE, M.D.

THE USE AND ABUSE OF DRUGS.¹

DR. CHAS. E. QUIMBY, New York.

PNEUMATIC DIFFERENTIATION.²

DR. FRANCIS B. KINSIGHT, New York.

THE NAUPEIN TREATMENT.³

DISCUSSION.

DR. VINCENT Y. BOWDITCH. I shall confine myself in this discussion solely to Dr. Quimby's paper on pneumatic differentiation in disease of the heart. About twenty years ago, Dr. H. L. Williams introduced the pneumatic cabinet to the profession as a

means of making topical applications to the lungs in cases of pulmonary disease. At that time I investigated the subject and experimented with the cabinet in cases of phthisis. I soon came to the conclusion that as far as topical applications to the lungs was concerned the instrument was practically of little value, but I knew that as a means of pulmonary calisthenics it had decided merit and, to make a long story short, we have had two in use at the Sharon Sanatorium as a means of encouraging deep breathing, accompanied by the inhalation of some soothing vapor as a palliative for irritated throats and bronchial tubes. That the instrument is of decided benefit for such purposes we have no doubt. It should be said, however, that the method of using the cabinet has been, up to a comparatively recent date, somewhat different from that described by Dr. Quimby.

With its use in heart lesions I have had no personal experience, but in the past few years I have become much interested in his work and have been deeply impressed by the results in one case which I had the privilege of seeing and examining a few years ago when in New York.

This gentleman previous to his treatment by Dr. Quimby had been pronounced a hopeless invalid by at least two eminent specialists, one in England and another in America, and he was apparently doomed to a life in the country away from all excitement or active life. Not long after his treatments in the pneumatic cabinet were begun, he began to improve, and far from being a comparatively useless invalid he became the chief pillar of a great establishment at Niagara Falls, undergoing tremendous drains upon his time and strength without difficulty, apparently, just so long as he was able to take occasional treatments in the cabinet, which always gave him relief from the circulatory disturbance which occasionally appeared consequent upon failure of compensation in severe valvular disease of the heart. When I saw the gentleman, he was in the midst of active work a few years after his first treatments. Upon examination I found evidences of a greatly enlarged heart filled with tremendous murmurs, indicative of at least aortic and mitral regurgitation. He told me his history, and spoke most warmly of the relief he had experienced from the cabinet and of the fact that he always had one near him with a trained assistant who could give him the treatment when necessary. I was deeply impressed by that case, and have been following Dr. Quimby's work, in somewhat desultory fashion, I am sorry to say, but with great interest, believing that he has found a comparatively simple but most effective method of relieving some of the most distressing symptoms of valvular disease followed by lack of compensatory power.

Wishing to get the opinions of others who had investigated the subject recently, I have recently written to and received answers from three physicians who have followed Dr. Quimby's work and who have tested the merits of the cabinet. With your permission I will now read some short extracts from these letters, after I have given the testimony as of much weight.

MARSHALL S. A. J. HOSKIN,
WATKINS ISLAND, NEW YORK, U.S.A.

MARCH 11, 1906.

Dear Dr. Quimby:—When I was called to the Hospital at the University, I saw the first of the pneumatic cabinet, and after the series of treatments that I saw was given, I was pretty sure that it was a valuable means of treatment. I have since had a very fine examination of a patient who had an attack of valvular disease. A cabinet was used, and certainly

¹See p. 549.

²See p. 551.

³See p. 543.

⁴See p. 539.

striking, especially the effect on the intensity of the murmur; there were about thirty cardiac cases on the service, seven or eight of which were given treatment, three of which were continued over a fairly long period. . . . The blood pressure is taken before entering and after leaving the cabinet with a Janeway instrument. In several cases sphygmographic tracings were made from the radial pulse.

The treatment was used on cases of cardiac disease of the mitral or aortic valves either alone or both lesions present in the same case. Regurgitant lesions were the type of valve disease.

The most important results of the treatment were:

(1) The blood pressure was reduced, as a rule, to about 10 to 20 mm.

(2) The respirations became immediately more comfortable and less labored.

(3) The circulations were equalized.

(4) The precordial pain was almost instantly relieved and the oppression removed.

(5) The murmurs at first very loud and harsh—in the cabinet being easily heard at a distance of 8 to 10 feet—became softer and softer until in some cases they disappeared completely for a time.

One case I remember distinctly, who failed to respond to the usual therapy with bed rest, who had mitral and aortic regurgitant murmurs with immense dilatation, heart measuring at least 25 cm. from the right to left border, the man weighing about 130 pounds. He suffered most severe spasmodic precordial pain that morphine relieved very little, and progressively failed until he seemed only a few hours from death when the cabinet treatment was given.

Almost instantly his attacks of precordial pain ceased and his dilatation diminished rapidly and he was comfortable in twenty-four hours. He continued to do favorably, heart becoming smaller and smaller for the following month when he suffered from an acute dilatation as a result of a struggle with a neighboring patient who was alcoholic and suddenly became destructive. Before this time he received treatment for twenty minutes each day. After the acute dilatation his anginal attacks returned and he was given the cabinet whenever he had an attack of cardiac pain—in the night or in the day. The pain always subsided immediately on the administration of the treatment, his blood pressure was diminished, his circulation was equalized in the two circulations, the lesser and greater, he breathed more easily, and usually slept comfortably afterwards. From this attack he recovered in about ten days.

The patient was a young man, *chef* by occupation, arteries were soft and no other kidney disturbance than congestion.

The treatment was used in simple mitral and aortic regurgitant cases where the arteries were not seriously involved and the kidney was not markedly changed. Their recovery seemed to me to be more rapid than similar cases treated either with ordinary vaso-dilators or with a cardiac tonic (digitalis) and a vaso-dilator. Their comfort after the treatment, their easier respiration, their more gentle blood pressure, their murmur much diminished in intensity, at times disappearing for a few minutes to an hour or two, their relief from cardiac pain when morphine practically failed, were the points that impressed me favorably.

I did not find that it was of special use in cardiorenal disease where a valve leak occurred more or less accidentally, but in cases of cardiac disease with no kidney or arterial complications the results were impressive. I don't mean to say that the cardiac rest afforded by the cabinet would do the cardiorenal cases no good,

but they are very much more unfavorable cases and the beneficial results were very much more transitory.

It required a patient of rather above the usual charity hospital type to co-operate perfectly in the treatment, hence the cases were selected. I observed no ill effect in any case whatever and fail to see how any accident could occur if the treatment was carefully applied.

This idea of varying the pressure on the two circulations in cardiac valvular disease is original with Dr. Quimby, so far as I know. Crile has tried the same thing, though instead of reducing the peripheral pressure he increased the pulmonary pressure by supplying air under increased pressure by means of a rubber bag, a method varying much in pressure from time to time and being crude and uncomfortable in application. He experimented more with surgical cases, I believe, and did not observe whether or not variation in this manner of applying different pressures to the two circulations had any effect in cardiac disease.

ALBERT H. GARVIN, M.D.

CITY HOSPITAL, BLACKWELL'S ISLAND, N. Y.

Dear Dr. Bowditch: As regards my experience with the pneumatic cabinet, I can say I have found it to act favorably, almost magically, in aortic cases with associated severe anginas. I saw one patient in collapse from the severity of the angina pains, breathing laboriously, rapid, high tension pulse, who, when placed in the cabinet for ten minutes under one inch of mercury, came out free from all pain, breathing easily, and blood pressure reduced from 30 to 50 mm. On daily treatment, this man left the hospital in a month, apparently as well as ever.

In all cases of valvular disease with associated high tension, I have found the cabinet to act very favorably.

I have noted good results from its use in slowly resolving alcoholic pneumonia without an associated valvular lesion. It produces coughing, an expansion of the most dependent alveoli, with the result that expectoration becomes profuse and the condition clears up rapidly.

I have only seen one case that was apparently harmed by its use, and that only for a day. This was a case of aortic regurgitation, it being a question, however, whether this was a functional murmur or valvular, in which there was associated exophthalmic goitre. After one exposure of ten minutes, he was seized with tachycardia and in the next twenty-four hours had thirty-two distinct attacks, varying in duration from one to twenty minutes, with a pulse uncountable. Treatment by cabinet was discontinued and it did not recur.

I trust my small contribution may be of some value to you. I candidly think that there is more in the cabinet treatment of cardiac and lung diseases than the medical profession in general have to date admitted.

EDWARD F. CROFUTT, M.D.

NEWARK, N. J.

Dear Dr. Bowditch: . . . As to my case: A man forty-two years of age, who for fourteen years had suffered more or less constantly with disturbed compensation, with frequent pronounced failures requiring hospital treatment which consisted in, certainly, rest and, probably, digitalis and glonoin. Each of his recoveries required weeks of time, and compensation was never completely restored; cardiac sleep was short; edema of the ankles, dyspnea and palpitation on slight exertion remained. He entered the City Hospital

in a severe attack of broken compensation, the usual treatment as outlined above was established, but the patient's condition was such (marked hypertrophy and dilatation of both right and left heart; double aortic murmurs, presystolic and systolic mitral and pulmonary systolic; rapid arrhythmic and high tension pulse, orthopnea, marked edema of ankles, hydrothorax and angina) that no surprise was felt at his steady decline. No doubt of his early dissolution was felt; in fact, so certain of it was the junior assistant that he made out the blank form of consent to autopsy in anticipation of seeking relatives the next day.

But with an abiding faith in the adage, "Where there is life there is hope," active stimulation was begun and he responded, to be returned to a condition that was little better than the original, giving no relief to the patient. In the course of a few days he showed a slight improvement from very active stimulation, but we felt it was the question of but a very short time before the break.

Dr. Quimby was, I am sure, very doubtful of results, but he decided to try the cabinet. But from the first sitting the patient showed a steady improvement. I have carried him on a stretcher to the cabinet when he was suffering intense agony, angina and urgent dyspnea, which heroic doses of morphine and glonoin would not influence in the slightest, and when by great effort only he was able to use the tube; and the end of ten minutes' treatment would return him to his bed so absolutely transformed as to amaze his ward mates and attendants, and the apparent change was supported by sphygmographic record. Within three weeks he was sleeping prone, and within six weeks insisted that his improvement entitled him to leave the institution. We were not yet ready to discharge, but did so upon his promising to return to Dr. Quimby for office treatment. He declared upon leaving that no previous recovery had been so satisfactory to him. During the whole course of cabinet treatment his only medication was Bland's pills.

As compared with the ordinary drug treatment of such a condition the results attained required less time and were of a more satisfactory nature, and, according to the cases Dr. Quimby has been able to follow, more permanent. Such an advantage, it seems to me, is a valuable accession to therapy. As we approach the simple we draw near to the ideal. Certainly, no one could require a more beautiful theory than that which governs "pneumatic differentiation," applying as it does the simplest law of physics, and the theory has been sustained practically by numerous cases at Dr. Quimby's hands. At least, I have yet to hear an answer to the question I have put to skeptics. "Given a real and serious condition such as the cabinet is aimed to treat, no other treatment except rest in bed being used, — an every case I have seen was certainly beyond rest alone, — results actually brilliant follow, if the cabinet did not accomplish it, what did?"

I saw no bad results following its use. I can imagine none in a suitable case, the only contra-indicating condition, as I understood it, being mitral stenosis without dilatation. In my opinion two very important preliminary steps are first, the education of the patient to a thorough understanding as to what he shall do, second, assurance of the patient of the perfect safety of the apparatus, which to the lay eye is undoubtedly formidable, and a heart case particularly fears suffocation. The cabinet does look stuffy, and the bolts and bars probably make the uninitiated dubious as to his ready escape if necessary.

The only unsatisfactory cases we had were those whose stupidity made them unable to understand what they were to do and those who could not be

assured of their perfect safety. In both these classes of cases some harm may have been done, but probably only temporarily. In the first type their bungling efforts to use the tube resulted in fatigue and irregular action of pressure. The second counteracted any good that might have been done by their great excitement.

I greatly regret that I am unable to add anything more of evidence, but I feel very anxious to support that in which I have the greatest interest and confidence.

C. L. GAUSDE, M.D.

I should not be so foolish as to pretend to be anything of an expert on the physics of this method of treatment. I must leave that to others more competent. But in studying Dr. Quimby's papers on the subject his theories have seemed to me sound and founded upon simple laws. Had I not seen one case that was most impressive, and had I not had the testimony of competent witnesses in other cases, I should have felt, very possibly, the skepticism that we all feel to a greater or less degree when any new and surprising method of treatment is urged upon us. We all know, however, that the results of experimental and laboratory research are often strangely and disappointingly at variance with clinical experience.

In these cases, however, Dr. Quimby's theories and his clinical experience seem to go hand in hand. I do not doubt that he has made his mistakes, possibly; I think it perfectly possible that in some cases there may have been failure to accomplish all that was desired. I have yet to learn of any great harm coming from the use of the cabinet; but even if such an unfortunate occurrence should ever take place, should that deter us from its use, any more than we should decline to use morphine or sulphuric ether because of occasional unfortunate results from their use?

All I ask now is, that before judgment is given the matter may be investigated and not put aside, as too often happens from fear of disaster or upon theoretical grounds alone. I am glad to say that there are two of these instruments in the city, and I sincerely trust that some of us will feel sufficient interest to thoroughly study the theoretical and clinical aspects of the subject.

I personally feel grateful to Dr. Quimby for what he has taught us, and trust he will keep bravely at the work which, in my belief, he a great boon to sufferers from certain forms of heart disease.

Dr. QUIMBY. — I am very glad of the opportunity to say something of the treatment of heart disease outside my own subject. Unfortunately, those who are interested in any special form of treatment are too often given credit for knowing nothing about other methods. I would be the last to ignore other forms of treatment of heart disease. The cabinet does not preclude others, in fact they may give relief where the cabinet fails. In general I believe it to be applicable to all forms of cardiac diseases with the possible exception of tobacco heart. It is of the greatest value in the cardiac and circulatory disturbances of old age. In cases of anemia of the brain it may increase the sense of weariness and vertigo, but only temporarily.

Dr. KISSICUT. — Dr. Quimby is very familiar with my appreciation of his splendid work with the pneumatic cabinet in the treatment of heart disease. In many cases I have seen most gratifying results following its use, but I do not know of any other form of treatment it has not a universal application.

I am very glad to hear what Dr. Piffard has advised concerning the use of digitals, and especially his advice that it be given in cases of aortic regurgitation. It is my experience that in the failing compensation of aortic regurgitation digitals is of the greatest benefit.

Recent Literature.

Materia Medica and Therapeutics, an introduction to the Rational Treatment of Disease. By J. MITCHELL BRUCE, M.A., LL.D. (Hon.), Aberd., M.D. (London). Fellow of the Royal College of Physicians of London; Consulting Physician to Charing Cross Hospital and to the Hospital for Consumption, Brompton, etc. New and enlarged edition, revised throughout and containing the Indian and Colonial Addendum to the British Pharmacopœia. Forty-seventh thousand. Chicago: W. T. Keener & Co. 1905.

The book contains the usual statements concerning *Materia Medica*, but is chiefly therapeutic in its scope. The author has adopted a special arrangement in the description of special therapeutics in systematically tracing the action and uses of different drugs from their first contact with the body to their elimination in the secretions. Under General Therapeutics, the action and use of drugs are grouped under the physiological systems (digestive, respiratory, etc.). To the present edition has been added an account of the *Materia Medica* and Therapeutics of drugs in the Indian and Colonial Addendum to the British Pharmacopœia and greater detail in the chemical and pharmaceutical relations of individual drugs.

Because of lack of conformity to the United States Pharmacopœia, the book is less suitable for use in the United States. In general it is to be recommended as a reliable and useful manual.

Materia Medica for Nurses. By JOHN E. GROFF, Ph.G., Apothecary in the Rhode Island Hospital, Professor of *Materia Medica*, Botany and Pharmacognosy in the Rhode Island College of Pharmacy. Third edition revised, with an appendix giving list of questions for self examination. Based upon the eighth decennial revision of the United States Pharmacopœia. Philadelphia: P. Blakiston's Son & Co. 1905.

The book is well arranged, well written and contains the essential facts for the nurse concerning drugs and their uses.

The Detection of Poisons and Strong Drugs. By DR. WILHELM AUTEURIEU, translated from the third German edition, by WILLIAM H. WARREN, Ph.D. Pp. xii, 222. Philadelphia: P. Blakiston's Son & Co. 1905.

This very admirable laboratory handbook presents in sufficient detail the various methods of detecting all of the common and many of the less common poisons, and of determining quantitatively the important alkaloids and certain other active principles of drugs in common use. It is a most valuable contribution and cannot fail to be greatly appreciated, not only by students but by specialists in toxicological work.

Textbook of Insanity Based on Clinical Observations. For Practitioners and Students of Medicine. By Dr. R. VON KRAFFT-EBING, late Professor of Psychiatry and Nervous Diseases in the University of Vienna. Authorized translation from the latest German edition by Charles Gilbert Chaddock, M.D., Professor of Diseases of the Nervous System in the Marion-Sims-Beaumont College of Medicine, St. Louis, Mo., etc., etc. With an Introduction by Frederick Peterson, M.D., of New York. Pp. xvi, 638. Philadelphia: F. A. Davis Company.

Although this translation of Krafft-Ebing's once famous work is a posthumous one, no student of psychiatry, however wedded he may be to the latest doctrines in mental disease, can fail to find much of the teaching of this master-mind instructive and altogether profitable. His extraordinary insight put him in advance of his time in knowledge of the subject and enabled him to expose some of the traditional fallacies regarding mental disease, its mechanism, etc. His handling of cases is thorough and eminently practical, and his account of them shows the close observer, original thinker, and resourceful physician — the highest type of clinician. The absence of the more recent tenets as to disease-processes, etc., which have done so much to simplify our understanding of insanity, deprives the work of full value to the student of to-day as an up-to-date textbook, but it should, nevertheless, be most helpful for collateral reading and reference on account of the author's minute analysis of the various mental states and his sound and original views on a variety of points in a most comprehensive study of the subject.

The translation, though a trifle involved in style here and there, is, on the whole, excellent.

Hygiene and Public Health. By B. ARTHUR WHITELEGGE, C.B., M.D., B.Sc. Lond., F.R.C.P., D.P.H., and GEORGE NEWMAN, M.D., D.P.H., F.R.S.E. Tenth edition, revised, enlarged and in great part rewritten. Pp. 636. Chicago: W. T. Keener & Co. 1905.

Although this little book has reached its tenth edition and shows evidence of revision, in that it contains fairly numerous references to recent discoveries, it is hardly suited to the needs of American students, practitioners and health officers. It is constructed on purely British lines and includes, therefore, the usual exposition of the public health acts and by-laws, for the multiplicity and impossibility of practical enforcement of which Great Britain is justly celebrated. The chapters on Air and Meteorology are fairly satisfactory, but those on Water, Soils and Foods not only are accorded insufficient space but contain many statements which are not in agreement with ideas generally accepted as sound and authoritative. In general, it may be said that important subjects receive very inadequate treatment and unimportant ones undue consideration. The work can hardly be regarded as worthy of the traditional place on the specialist's table.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MAY 17, 1906.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned

Subscription Terms: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

**OPENING OF LABORATORIES OF THE
ROCKEFELLER INSTITUTE.**

At the formal opening of the laboratories of the Rockefeller Institute, on May 11, the previously announced program was carried out. Dr. Holt, the secretary of the Board of Directors, gave a sketch of the preparatory work accomplished and the plans for the development of the Institute in the future. He said that many applications had been received from England, France and Germany for staff places, but that it had been decided to train Americans for such positions. Resident fellowships and scholarships would provide the requisite material. At present the working staff would consist of fourteen members, divided among the various departments, while the laboratories would provide facilities for fifty students. In time a hospital on the grounds would be indispensable, in order that the researches carried on might attain their highest usefulness, and it was also the design of the Institute to co-operate with the New York Health Department and all other active agencies for the suppression of disease. "We hope to have the money and the men of science," he said, "to cope with all emergencies threatening the public health."

The president of the Board, Dr. William H. Welch of Johns Hopkins University, in his brief but admirable address, expressed the opinion that the Institute would place America high in rank with France, Germany and Great Britain as regards research work in scientific medicine. President Eliot, of Harvard, and President But-

ler, of Columbia University, also spoke. Mr. Rockefeller was not present, but was represented by his son, John D. Rockefeller, Jr.

President Eliot devoted himself to the scientific investigator. In his opinion, however it might be in theology, in science there is no such thing as final truth. The scientific investigator is a law unto himself. The institution in which he works merely supplies him with facilities and he does the rest. His work is secret, but the results are made public and mankind gets the benefit. More than that of any other man his labor is for the public welfare, for the cure and prevention of disease.

President Butler referred to the significant fact that the Institute was situated in the midst of a dense population of a kind which would receive the greatest benefits from its work. Institutions like the Rockefeller would foster in the public mind the respect for science. Pasteur believed that the neglect of science and scientific work lay at the bottom of the defeat of France by Germany in 1871. The conduct of the recent war against Russia by the Japanese was to his mind a plain proof of the value of scientific training. The value of accurate thought and well considered action was a lesson which Americans especially needed to learn.

The Institute, as it stands to-day, represents an outlay of \$3,000,000. The grounds cover, in all, twenty-six and a half city lots, which were formerly a part of the old Schermerhorn farm on the banks of the East River. The present laboratory building, which is situated on an eminence, is five stories high and constructed of buff brick and sandstone. Its architecture is severe but dignified, and its equipment is the most complete possible, all the air admitted to the building is filtered and the interior is dust-proof throughout.

Every facility is afforded for research in the departments of pathology, bacteriology, physiology, physiological and pathological chemistry and comparative zoology.

The Institute not only carries on experiments in its own laboratories, but awards money grants to those who are engaged in medical research elsewhere. The results of investigators' work is published, if deemed worthy of publication, in the *Journal of Experimental Medicine*, which is issued by the Institute. The board of directors consists of Drs. William H. Welch of Baltimore, president; T. Mitchell Prudden of New York, vice-president; T. Freemon Hall of New York, secretary; Christian A. Herter of New York, treasurer; Simon Flexner of New York, director

of laboratories; Herman M. Biggs of New York and Theobald Smith of Boston.

It is said that at the dinner given in the evening by President Welch at the University Club, Mr. Carnegie grasping the hand of young Mr. Rockefeller, exclaimed, "The two Institutes, Rockefeller and Carnegie, against the World!"

It is sufficiently evident that this country will not suffer in the future for want of facilities for research, and we trust men will arise to accept the privileges which are now being so freely offered.

THE PREVALENCE OF SCABIES.

THE attention of readers of this JOURNAL has several times been called to the prevalence of scabies in this community, and to the frequency with which it goes undetected and apparently unsuspected by the practitioner of medicine. There seem to be no signs of abatement in this prevalence, and the number of cases presenting themselves at the various hospitals during the last two years has been greater than ever. As an instance of this prevalence may be cited the fact that at one of our large out-patient clinics the number of cases of scabies treated during each of the last two years exceeded that of any other skin disease, with the sole exception of eczema. These figures represent simply the individuals applying personally for relief; for in a large majority of instances a history of a number of additional cases in the same family could be obtained. In some instances families of from ten to twelve people were found to be affected at the same time.

It is well known that scabies came into prominence during the Civil War, when opportunity for its transmission was offered by the housing of troops in barracks and tents and their intimate association with one another. The disease then became much less frequent for the succeeding fifteen years until the increasing rush of immigration began to pour into America the diseases hitherto almost monopolized by the Old World. Still more recently the Spanish War has swelled the numbers, and the affection seems to have become pretty well established in our country, fed, as it is, by the enormous immigration.

Of late years, since the affection has increased so rapidly, the better classes have begun to be subject to it, and it is no great rarity to observe the disease in private practice, among the most cleanly and well-cared-for people. The possibility of scabies should never be excluded in any

pruritic affection, solely on the ground of the patient's social position or habits of cleanliness. It is here that a serious error is frequently committed, and people who could be easily cured in a few days by proper treatment are allowed to drag on a pruritic existence, because their symptoms are ascribed to error of diet or to some internal irregularity. It is true that in the more cleanly the most typical appearances are somewhat masked. The pictures in the atlases of fingers and hands covered with crusts and burrows, and the body, from the neck to the knees, the seat of excoriations and crusts are not duplicated in the more cleanly. But a little experience, such as the well drilled medical student of to-day is favored with, will enable the observer to come to a correct decision in a large majority of cases. In the beginning, and as an axiom, scabies should be at least thought of in every case where itching is a prominent symptom, and not obviously due to other causes, with utter disregard to the social position or habits of cleanliness of the patient. Next, the nocturnal nature of the itching should be considered as suspicious. Scabies, by reason of the habits of the female acarus, in preferring warmth for her activities, torments its object especially at night. This is not a pathognomonic sign but one of considerable importance. The localization of the cutaneous lesions, represented by excoriations due to scratching, papules, vesicles and pustules, such as are seen in a dermatitis from different causes, is a most important diagnostic sign, perhaps the most important sign; certainly so in cases that admit of any doubt. These localizations are the hands, especially the inner sides of the fingers, and wrists, the folds of the axillæ, the penis in men, and about the breasts in women. It should be emphasized that burrows are not to be found in a large proportion of cases, especially in those of cleanly habits, so that a failure to find burrows is of very little negative value. In the male the occurrence of one or more papular infiltrations upon the penis, especially if elongated and not round, is a sign of great importance, as such lesions in this position almost never occur in any affection which might be confounded with scabies. It will be seen, therefore, that scabies presents a sufficient number of diagnostic signs to warrant its recognition in the majority of instances, and that its prevalence and occurrence among the better classes render its consideration imperative in any pruritic affection of doubtful etiology.

ARE SURGEONS SCAMPS?

It hardly seems worth while to dignify the twaddle which Mr. Bernard Shaw lately indulged in before the British Union for the Abolition of Vivisection by a reference to it. In criticising the attitude of the medical profession toward vivisection he is reported as saying that when "it was a question of earning sixty guineas in an afternoon it was a very strong temptation to a man who could do that by performing an operation to believe that an operation was necessary, where it was not necessary. That he did not think it was good public policy for any person to have a strong pecuniary interest in mutilating his fellows. He did not desire to say that the surgeon actually knew that an operation was unnecessary, but if they gave a man sixty guineas to believe a thing he would have a strong disposition to believe it."

In other words, men sometimes yield to temptation. What truth there is in this is a platitude of the most ancient description. What has it to do with antivivisection? Shall we advocate a law that surgeons shall not operate or shall not be paid for operating? Even surgeons are neither impeccable nor infallible. But we have heard more and more bitter criticisms for failure to operate than for too keen operative zeal. Guineas or no guineas, the question is undoubtedly at times a hard one to decide. On the whole, we believe the layman is at least as safe in trusting his medical adviser as in trusting his lawyer, his banker, his clergyman or even his rationalistic philosopher. "Lead us not into temptation, but deliver us from evil," is part of a good old prayer which was in use before the brief day of "Mrs. Warren's Profession," and there has been no desire to abolish it since.

RETIREMENT OF DR. HENRY P. BOWDITCH.

By the retirement of Dr. Henry P. Bowditch from the faculty of the Harvard Medical School the university loses from its active teaching force one of its most conspicuous and distinguished members. Dr. Bowditch has served the Medical School as one of its teachers for thirty-five years during that period he has seen his special department, physiology, develop both here and elsewhere, in a way which could not have been foreseen when he began his work. It should be a lasting source of satisfaction to Dr. Bowditch to feel how large a part he has played in this development, a fact which has been generously recognized abroad as well as in this country. He retires from active work at a time when the

Harvard Medical School is about to enter a wider field of usefulness, owing in no small measure to his efforts in her behalf. It is not to be expected, however, that his retirement from active teaching will preclude the possibility of his counsel in the problems which are immediately facing the Medical School, and in this capacity we trust he may have many years of usefulness. Well earned as his rest may be, it will be received with regret by his colleagues with whom he has long been associated in the best development of medicine in all its branches.

THE GOVERNOR'S VETO OF THE TYPHOID BILL.

For vetoing the pernicious measure, not inaptly termed "the typhoid bill," which provided for practically unrestricted use of the waters of certain of the great ponds of the Metropolitan water supply for purposes of pleasure Governor Guild deserves the thanks of every citizen and the warmest commendation of every member of the medical profession. This bill, which would have made possible the most serious and the most dreaded forms of pollution, was rushed with unnecessary and indecent haste through both branches of the legislature, without opportunity for debate, and great pressure was brought to prevent a veto; but the Governor, recognizing the danger of trifling with the public health merely for the gratification of the few, was equal to the emergency and Massachusetts will continue to enjoy its well-earned prestige in the fields of water supply and protection of the public health.

MEDICAL NOTES.

DELAYED ISSUE OF INDEX MEDICUS. The Carnegie Institution of Washington, Washington, D. C., announces that the issue of the Index Medicus has been unavoidably delayed, owing to recent printers' strikes. For this reason, the Index Medicus for March, 1906, has not as yet been published, nor has it been possible to complete work on the index to the volume for 1903.

Urgent measures are being taken to relieve the situation, however, and it is hoped that an end to the trouble will soon be reached, and that the work of publication will be resumed on its regular basis.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.

For the week ending at noon, May 16, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases:

Diphtheria 41, scarlatina 35, typhoid fever 7, measles 85, tuberculosis 35, smallpox 0.

The death-rate of the reported deaths for the week ending May 16, 1906, was 19.45.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, May 12, 1906, was 226, against 230 the corresponding week of last year, showing a decrease of 4 deaths and making the death-rate for the week 19.80. Of this number 126 were males and 100 were females; 218 were white and 8 colored; 133 were born in the United States, 87 in foreign countries and 6 unknown; 46 were of American parentage, 148 of foreign parentage and 32 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 44 cases and 1 death; scarlatina, 28 cases, 1 death; typhoid fever, 12 cases and 2 deaths; measles, 101 cases and 2 deaths; tuberculosis, 49 cases and 12 deaths; smallpox, no cases and no deaths. The deaths from pneumonia were 29, whooping cough 5, heart disease 28, bronchitis 5, and marasmus 10. There were 15 deaths from violent causes. The number of children who died under one year was 48; the number under five years, 79. The number of persons who died over sixty years of age was 43. The deaths in public institutions were 73.

There were 3 cases and 3 deaths reported from cerebrospinal meningitis during the week.

BEQUESTS. — By the will of the late Dr. Charles M. Cumsten, of Monmouth, Me., the Carney Hospital in Boston receives \$15,000, somewhat restricted during the life of one person. By the will of the late Miss Clara E. Hillyer, of Hartford, Conn., the Hartford Hospital receives \$50,000.

MIDDLESEX EAST DISTRICT MEDICAL SOCIETY. — The annual meeting of the Middlesex East District Medical Society was held in Red Men's hall, Stoneham, Wednesday afternoon, May 9, and the following were elected officers: President, Harrison G. Blake, Woburn; Vice-President, Corydon W. Harlow, Melrose; Secretary, Harold Gale, Winchester; Treasurer, Charles Dutton, Wakefield; Councillors, G. N. P. Mead, Winchester; F. E. Park, Stoneham; S. H. Parks, Reading; Robert T. Edes, Reading; Arthur H. Cowdrey, Stoneham; Censors, F. E. Park, Stoneham; Mott A. Cummings, Winchester; George F. Dow, Reading; Ernest S. Jack, Melrose; William H. Keleher, Woburn; Auditor, Lilley Eaton, Winchester.

NEW YORK.

DR. ALBERT VAN DER VEER, MEMBER OF BOARD OF REGENTS. — Dr. Albert Van der Veer, of Albany, has been elected a member of the Board of Regents, University of the State of New York, to fill the vacancy left by the death of Dr. George R. Fowler, of Brooklyn.

STEVENS-WAINWRIGHT BILL. — The lower house of the state legislature adjourned without passing the Stevens-Wainwright bill, requiring medicinal preparations containing alcohol or other narcotic or potent drugs to have labels giving their constituents, which had been passed by the Senate. In the Assembly the bill was killed by amendments. It is gratifying to learn, however, that the Assembly failed to pass the osteopathy bill, which had also been passed by the Senate.

EXTERMINATION OF MOSQUITOES. — Governor Stokes has signed the "mosquito bill," which was passed by the New Jersey Legislature a few weeks ago. Under its provisions an appropriation of \$350,000, \$50,000 of which is to be expended annually for seven years, is available for the purpose of exterminating mosquitoes. State Entomologist Voorhees, it is announced, has already perfected elaborate plans for carrying on the warfare, and the work will be begun immediately.

APPOINTMENT OF DR. CHARLES W. PILGRIM. — Governor Higgins has appointed Dr. Charles W. Pilgrim, at present superintendent of the Hudson River State Hospital for the Insane at Poughkeepsie, president of the State Commission in Lunacy, to succeed Dr. William Mabon, and the appointment has been confirmed by the state senate. Dr. Mabon has received and accepted the position of superintendent of the Manhattan State Hospital, on Ward's Island, made vacant by the death of Dr. Emmet C. Dent.

REVOCATION OF MILK LICENSES. — The Appellate Division of the New York Supreme Court has just handed down a decision upholding the authority of the Health Department to revoke licenses for the sale of milk. The action calling forth this decision was a suit for \$30,000 damages brought by the Metropolitan Milk and Cream Company against the department, because the latter had revoked its license for the sale of milk in New York City. The department alleged that the company maintained a dairy in Orange County which was in an unsanitary condition, and also that it had shipped to New York milk

which had been watered and adulterated. Consequently, the department revoked its license, and the company claimed that this procedure was without legal authorization.

MEDICAL RELIEF COMMITTEE FOR SAN FRANCISCO PHYSICIANS.—The New York Academy of Medicine, the Medical Society of the County of New York, and the Richmond County Medical Society (of Staten Island), acting in concert, have appointed a medical relief committee to raise funds for the physicians of California who have suffered losses in the recent disaster. The societies of Kings and Queens, Nassau and many other county medical societies are also engaged in the work of relief.

AN UNFORTUNATE DECISION.—In a most extraordinary decision, handed down on April 23, United States Commissioner Ridgway has ordered the discharge of Dr. W. H. Hadley and those other defendants concerned in the "Force of Life" company, who were indicted some time ago, under charges made by the counsel of the County Medical Society, for fraudulently using the United States mails in maintaining a quack medical institution in New York. Notwithstanding all the evidence to the contrary which was presented, the commissioner expresses the opinion that there was nothing to show that the company employed fraudulent or deceptive means in the conduct of its business. He even goes out of his way to state that such methods of treatment exert "a benign influence in the community."

MORTALITY.—The weekly reports of the Health Department show that the mortality in the city during the month of April represented an annual death-rate of 19.79, as against 20.15 in March and 20.20 in April, 1905. Among the diseases in which there was a diminished fatality were the following: The weekly average of deaths from diphtheria and croup decreased from 53.5 in March to 43 in April; the weekly average from influenza, from 9.5 to 6; from pulmonary tuberculosis, from 191.25 to 182.75; from acute bronchitis, from 41 to 31.25; from pneumonia, from 170.5 to 161.5. Among the diseases in which there was an augmented mortality were the following. The weekly average of deaths from typhoid fever increased from 5.5 to 7.75; from scarlet fever, from 11.75 to 14.75; from epidemic cerebrospinal meningitis, from 21 to 29.25; from diarrheal diseases in children under five years of age, from 35.75 to 38.5; from cancer, from

53.25 to 58.25; from organic heart diseases, from 109 to 117.25, and from Bright's disease and nephritis, from 125 to 127.25. While the weekly average of deaths from measles was practically the same as in March, during the past month there has been a progressive decline in the mortality of this disease. In the first week of April the deaths from it numbered 72, and in the last week, 39. The mortality from bronchopneumonia continues high (considerably higher, in fact, than in the winter), and this is no doubt attributable to the severe epidemic of measles, which is now on the decline. In the fourth week of April there was one death from smallpox, the first that has been recorded during the present year. The corrected death-rate, excluding non-residents and infants under one week old, was 18.44, as against 19.07 in March.

A NEW HOSPITAL FOR TREATMENT OF DEFORMITIES.—A new hospital, to be conducted under Jewish auspices, which was licensed by the State Board of Charities in October last, is to be opened on June 1. It is to be devoted to the treatment of deformities and joint diseases in accordance with the Lorenz methods, and will occupy a dwelling-house of three stories and basement on upper Madison Avenue. The director will be Dr. Henry W. Frauenthal, who has had a large experience in orthopedics at Bellevue Hospital and as the assistant of the Sayres, father and son; and on the consulting staff will be a number of prominent surgeons. The dispensary staff will consist of twelve physicians, and in connection with this department nurses will be supplied, when necessary, to look after patients in their own homes.

DELAY IN CONSTRUCTION OF NEW BELLEVUE HOSPITAL.—The construction of the new Bellevue Hospital is at present delayed on account of a conflict of views between the State Board of Charities and Dr. John W. Brannan, president of the Board of Trustees of Bellevue and Allied Hospitals. According to Dr. Brannan's plan, which has been approved by the city officials, the new hospital would have 2,400 beds, and the State Board is opposed to the erection of hospitals with more than 1,000 beds, believing in smaller institutions and more of them. Some time ago Commissioner Stewart of the State Board demanded the plans of the new institution, on the ground that under the law, the Board's approval was necessary before the construction of the new buildings could be begun; but Dr. Brannan, contending that Bellevue did

not come under the jurisdiction of the State Board, because it had been separately established by the legislature, refused to submit them. The State Board then laid the matter before Attorney-General Cunnene, who was at the time in office, and he wrote an opinion deeking against Dr. Brannan's contention. Recently the present attorney-general prepared an opinion still more decided in favor of the State Board, and, as a result, Dr. Brannan has called on Corporation Counsel Delany for advice and support. The latter states that so many delicate legal points are involved that the entire matter will have to go to the courts before a settlement can be arrived at. This resort to the courts will shortly be made, as Attorney-General Mayer is now preparing mandamus proceedings against Dr. Brannan, the result of which will be to decide the issues at stake.

Correspondence.

CONTRIBUTIONS FOR PROFESSIONAL BROTHERS IN CALIFORNIA.

Boston, May 14, 1906.

Mr. Editor: I enclose a letter which may interest you and your readers, from Dr. Wallace I. Terry, president of the San Francisco Medical Society.

The \$300 from the Norfolk District Medical Society, which he refers to, was increased by \$100 from the Brookline Medical Club, and by \$7, individual contribution. These sums, aggregating \$407, were sent to Dr. Terry before receipt of his letter.

In addition to the above, the Suffolk District appropriated \$500, the Essex North District \$200 and the Bristol South District \$100.

If this is brought to the attention of the other districts in the state, they may be inclined to add their contributions.

Very truly yours,

GEO. W. KAN, M.D.

PRESIDIO SANITARY DIVISION, SAN FRANCISCO, CAL., May 5, 1906.

DRS. G. W. KAN, G. W. CLEMENT, S. CROWELL AND MEMBERS OF THE NORFOLK DISTRICT OF THE MASSACHUSETTS MEDICAL SOCIETY:

Gentlemen, — Your letter of April 25, 1906, to Dr. R. F. Rooney, president of the Medical Society of the State of California, stating that you had appropriated \$300 "for the California sufferers, and preferably for the medical fraternity" was forwarded to me as president of the San Francisco County Medical Society.

On behalf of all the physicians of San Francisco, numbering about one thousand four hundred, I wish to sincerely and gratefully thank you for your generosity. The immensity of this city's loss is difficult to realize even by those of us who are here, and fully one thousand physicians have lost their offices and equipment. Outside of that their greatest difficulty will be in making a living for the next year until the city is partially rebuilt and the refugees come back.

I have appointed a committee of nine representative men who will take charge of the relief of physicians without regard to school or other affiliations. I would respectfully request you to send your timely contribution to Dr. T. W. Huntington, chairman of the Finance Committee, Lane Hospital, San Francisco.

Later we shall request the medical libraries of this country to aid us in the formation of a new library as that

of the County Society as well as many private ones were swept out of existence by the fire.

We shall ever be under a deep debt of gratitude to our fellow members of the medical profession for their immediate thought of us in our distress.

Again with thanks, I remain,

Yours very truly,

WALLACE I. TERRY, M.D.,

President, San Francisco County Medical Society.

ERRATUM.

Boston, May 9, 1906.

Mr. Editor: Please correct an error in figures on page 511, in my address to the Boston Medical Association, published in your issue of May 10. The Register of the Massachusetts Medical Society for 1905 gives 858 members in greater Boston. I wrote 627, but I included only the Suffolk District. The new ratio would give one regular physician to about 700 inhabitants instead of one to 1000.

Truly yours,

DAVID W. CHEEVER, M.D.

LETTER FROM LISBON.

THE INTERNATIONAL MEDICAL CONGRESS AT LISBON.

(SPECIAL CORRESPONDENCE.)

Lisbon, April 22, 1906.

Mr. Editor: The most noticeable thing in going to the International Congress at Lisbon was the absolute carelessness of the railroads as to any adequate arrangements. Spanish railroads anyway are the slowest things on record. The distance from Seville to Lisbon is about three hundred and forty miles. It took us twenty-four hours to make the trip, and we had to change cars three times. It was known that there would be quite a number going to the congress from Seville, but no provision was made. There were no sleeping cars and no restaurant cars. There are no toilet arrangements on Spanish cars. When a stop of a few minutes is to be made at a station there is a general rush for the "lieu d'aisance." The first comers usually have the worst of it, for the next rows do not wait their turn but use the floor as a urinal. The closets are mere squatting places with sometimes a foot place that is not covered with filth.

The contrast at Lisbon was very agreeable. All arrangements had a room in the station where they told arriving congressists where the rooms were to which they had been assigned, and changed their money to the Portuguese coinage. Portuguese beds and furniture were not always to the taste of the outsider, who generally preferred a softer bed and more luxury, but the places were clean and conveniently situated. Those who were fortunate enough to get into the larger hotels had every luxury.

Lisbon is a charming city and a clean one. The streets are wide, and parks and squares are frequent. The presence of tropical trees gives a certain charm which would otherwise be lacking, in spite of a multitude of other handsome trees on the wide avenues and squares.

The place of meeting for the congress was the new school of medicine, a large and splendid building, eminently well fitted for the meetings of the many sections, and furnishing rooms for general meeting. The post and telegraph had a special room in the building for the benefit of the members. There was an abundance of uniformed attendants to see to the wants of everybody. No one without a member's ticket was allowed in the building. The opening exercises were conducted under the special auspices of the King and Queen in the great hall of the Royal Geographical Society, a hall reminding one of the Boston Symphony Hall. There was a most brilliant assembly from the court as well as members of the congress. The King read a short speech of welcome in a clear voice that could be distinctly heard throughout the hall. On one side sat his charming wife and on the other the queen mother. At the conclusion of his address he declared the Fifteenth International Congress of Medicine as opened.

There followed a tiresome lot of speeches by the representatives of the different governments. The speakers with only a few exceptions could not be heard twenty feet from the platform. The Frenchman and the Italian, however, made eloquent addresses which called forth applause. The royal band furnished the music.

The most noticeable phase of the congress was the

by the city at the handsome Hotel de Ville was enhanced by an exhibition, in the square, of the city fire department. To us Americans also of special interest and enjoyment was a dinner given by the United States minister, Mr. Charles Page Bryan. He is an ornament to his position. He not only gave us all a most hearty welcome, but together with his secretary, Mr. Chandler, of Brookline, went out of his way to assist us in any and every manner.

The real work of the congress was not neglected in the meantime. There was, however, nothing very new brought out. Synphysiotomy was entirely discredited, the newest operation of high, cutting the iliac bone, taking its place. A suprapubic, extraperitoneal Cesarean operation was recommended by Dr. Frank, especially in septic cases. The American operation for fibroids was indorsed.

In the department of national medicine there was much discussion about yellow fever, doubt being expressed as to mosquitoes being the only cause of the fever. Considerable interest was manifested in the discussion on tuberculosis. A campaign of general public education by posters and object lessons, such as have been given in Boston, was advocated.

There were about twenty-five Americans present, among whom were, Dr. Wise of the Navy, Dr. Richards of the Army, Dr. Seign, Dr. Gutierrez, Dr. Van der Veer, Dr. Furck and Dr. McDonald, of New York; from Boston, Dr. Washburn, and Dr. Chase with his moving pictures showing epileptics and chorionic movements. Among the foreigners, Dr. Doyen made the most stir, reading papers in several sections and showing moving pictures to illustrate surgical technique. Dr. A. Martin of Germany was also a prominent figure. The hospitals of Lisbon made a

Medical School Building at Lisbon, built around a hollow square

cordial reception given it and the series of fêtes and receptions given. These included a garden party by their majesties in the royal gardens. The King and his charming Queen received the guests and requested them to walk about the garden and partake of a most elaborate collation served under the shadow of magnificent trees and vines. Another garden party was given by the Marquess of

Furck and Dr. McDonald, of New York; from Boston, Dr. Washburn, and Dr. Chase with his moving pictures showing epileptics and chorionic movements. Among the foreigners, Dr. Doyen made the most stir, reading papers in several sections and showing moving pictures to illustrate surgical technique. Dr. A. Martin of Germany was also a prominent figure. The hospitals of Lisbon made a

Amalgamated group of the congress

Montserrat in his wonderful grounds at Estoril. Before the marquis, an Englishman, named Cook, and I, who received us on the train terrace. The Geographical Society gave a reception, at which we were treated to the old national music and dances and to some stereopticon views of the Portuguese colonies. An elaborate reception

was given by the Portuguese government from the cathedral, and up to date, Lisbon was being treated by the French light of the large hospital.

We were very sorry when the congress was closing. We were all taken back to the ships of the fleet, which had been waiting for us since the day of the opening of the congress.

Am. Med. Soc. Rep.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING MAY 2, 1906.

KALOCH, P. C., surgeon. Granted leave of absence for one day, April 30, 1906. April 27, 1906.

CARRINGTON, P. M., surgeon. Granted leave of absence for three days from April 30, 1906, under paragraph 189 of the Service regulations.

NYDEGGER, J. A., passed assistant surgeon. Leave of absence granted Passed Assistant Surgeon Nydegger for seven days from April 23, 1906, amended to read for five days only. May 2, 1906.

LUMSDEN, L. L., passed assistant surgeon. Granted leave of absence for two months from June 1, 1906. May 1, 1906.

STANSFIELD, H. A., passed assistant surgeon. Granted leave of absence for five days under paragraph 191 of the regulations.

STANSFIELD, H. A., passed assistant surgeon. Granted leave of absence for fourteen days from April 30, 1906. May 2, 1906.

BURKHALTER, J. T., passed assistant surgeon. Granted extension of leave of absence for four days from May 3, 1906. May 2, 1906.

FOSTER, A. D., assistant surgeon. Granted leave of absence for one month from April 1, 1906, on account of sickness. April 28, 1906.

ROBERTSON, H. MCG., assistant surgeon. Granted leave of absence for one month and twenty-one days from May 14, 1906. April 25, 1906.

MASON, W. C., acting assistant surgeon. Granted leave of absence for three days from April 30, 1906. April 26, 1906.

STEARNS, H. H., acting assistant surgeon. Granted leave of absence for five days under the provisions of paragraph 210 of the service regulations.

TUTTLE, JAY, acting assistant surgeon. Granted leave of absence for thirty days from May 1, 1906. May 1, 1906.

RYDER, L. W., pharmacist. Granted leave of absence for two days from April 30, 1906. May 1, 1906.

BELL, J. M., pharmacist. Granted leave of absence for thirty days from May 18, 1906. April 20, 1906.

SOCIETY NOTICES.

AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION.—The ninth annual meeting of the American Gastro-Enterological Association will be held at Boston, Mass., Monday and Tuesday, June 4 and 5, 1906. Monday meeting at Sprague Hall, Boston Medical Library, No. 8, The Fenway. Tuesday meeting at Harvard Medical School, Boylston and Exeter streets, Lecture Room E.

AMERICAN PROCTOLOGICAL SOCIETY.—This society will hold its eighth annual meeting, Boston, Mass., June 5 and 6, 1906. Headquarters and place of meeting, Hotel Vendome, Commonwealth Avenue. "Annual Address" by the President, Lewis H. Adler, M.D., Philadelphia. The profession is cordially invited to attend all meetings.

A. B. COOKE, M.D., Nashville, Tenn.,
Secretary.

AMERICAN ACADEMY OF MEDICINE.—The thirty-first annual meeting of the American Academy of Medicine will be held in the Banquet Hall of the Brunswick, Copley Square, Boston, on Saturday, June 2, and Monday, June 4, 1906.

AMERICAN GYNECOLOGICAL SOCIETY.—The thirty-first annual meeting of the American Gynecological Society will be held at "The Homestead," Hot Springs, Va., Tuesday, Wednesday and Thursday, May 22, 23, 24, 1906.

APPOINTMENTS.

DR. CARROLL E. EBPSON, formerly of Boston, has been appointed to the professorship of theory and practice in the University of Colorado.

JOHN LOVETT MORSE, M.D., has been appointed assistant professor of Pediatrics in the Medical School of Harvard University for five years from Sept. 1, 1906.

GEORGE GRAY SEARS, M.D., has been appointed assistant professor of Clinical Medicine, in the Medical School of Harvard University, for five years from Sept. 1, 1906.

ELMER ERNEST SOUTHAUD, M.D., has been appointed assistant professor of Neuropathology, in the Medical School of Harvard University, for five years, from Sept. 1, 1906.

RECENT DEATHS.

DR. PHILANDER COLLARD, of Ossining-on-the-Hudson, died from diabetes on May 7. He was born in Westchester County, New York, in 1845, and had practised in Ossining since 1885.

DR. LEROY D. MCWAYNE, a well-known specialist in diseases of the throat and nose, died at his home in Hoosick Falls, Rensselaer County, N. Y., on May 10, from cardiac disease. He was a veteran of the Civil War, and began the practice of medicine in 1879.

WILLIAM MICHAEL EDWARD MELEN, M.D., M.M.S.S., died in Chicopee May 14, 1906, aged fifty-eight years.

BOOKS AND PAMPHLETS RECEIVED.

Ellis's Demonstrations of Anatomy. Being a Guide to the Knowledge of the Human Body by Dissection. Twelfth edition, revised and edited by Christopher Addison, M.D., B.S., Lond., F.R.C.S. Illustrated. New York: William Wood & Co., 1906.

Transactions of the Eleventh Annual Meeting of the American Laryngological, Rhinological and Otological Society held in Boston, Mass., June 5, 6 and 7, 1905. St. Louis, 1906.

Annual Report of the Trustees and Officers of the Ohio Hospital for Epileptics at Gallipolis to the Governor of the State of Ohio for the Fiscal Year ending November 15, 1905. Columbus: F. J. Heer. 1906.

University of California Publications. Physiology. The Toxicity of Atmospheric Oxygen for the Eggs of the Sea-Urchin (*Strongylocentrotus Purpuratus*) after the Process of Membrane Formation. By Jacques Loeb.

A Manual and Atlas of Dissection. By Simon Menno Yutzey, M.D., Illustrated. With an Introduction by J. Playfair McMurrich, A.M., Ph.D. Philadelphia: P. Blakiston's Son & Co., 1906.

Medico-Chirurgical Transactions. Published by the Royal Medical and Chirurgical Society of London. Vol. 88. London: Longmans, Green, & Co., 1905.

The Localization of the Higher Psychic Functions, with Special Reference to the Prefrontal Lobe. By Charles K. Mills, M.D., and T. H. Weisenburg, M.D. Reprint.

The International Medical Annual: A Year Book of Treatment and Practitioner's Index. By various contributors. Twenty-fourth Year. New York: E. B. Treat & Co., 1906.

Transactions of the American Climatological Association. For the year 1905. Vol. xxi.

Manhattan.—The greatest number of cases (100) was reported during the week ending Sept. 2, the smallest (7), during the week ending April 22.

The number of cases, deaths, death rate, and case fatality were all lowered during 1905, the death rate (1.28) being lower than for years. The map of Manhattan, on which the cases were plotted, showed no definite localization of the disease, except that there were relatively more cases in the upper west side of the borough.

Brooklyn.—Although quite an extensive outbreak of the disease occurred in Brooklyn during the summer of 1905, the total number of cases for the year being 1,913 as compared with 1,050 in 1904, yet the disease was of a very mild type, there being fewer deaths than in 1904, a lower death rate, and a decrease in the case fatality of almost 50%.

In July, 1905, a marked increase took place in the number of cases reported, the weekly number being greater by from twenty to twenty-five. From that date the number of cases steadily increased until by Sept. 1, 1,287 cases and 195 deaths had been reported, as compared with 483 cases and 152 deaths for the same period of 1904. The number of cases reported weekly reached the normal average number (25 to 40) about Oct. 1. The epidemic was not very fatal, the case fatality being about 15%. Of 1,081 cases classified according to causation, in 360 no cause could be assigned (probably due to infected water); 102 were milk drinkers; in 196 the disease was contracted out of the city; in 95 the disease was contracted probably from another case in the family; in 27 there was a history of oysters having been eaten.

The Thirtieth Ward.—The outbreak of typhoid fever in Brooklyn was especially marked in the Thirtieth ward (Bath Beach and Bensonhurst) there being 109 cases reported during the first three weeks of August. A house-to-house visitation was instituted, and circulars of instructions strongly advising the boiling of all drinking water and milk were left at each house. On Aug. 19 a special sanitary staff was organized, 7,692 inspections were made, and 1,670 orders issued

against existing unsanitary conditions. Of these 1,097 were against unnecessary cesspools and privy vaults, and 106 against wells and cisterns used for drinking water. Two hundred and fifty-eight sewer connections were ordered. Work was done in filling in offensive dumps and stagnant ponds, and in disinfecting offensive sewers and privy vaults. The water and milk supply, including the Ridgewood watershed, was investigated. Of 60 wells used for drinking purposes, 47 were condemned as unfit for use after chemical analysis of the water.

Consideration of the facts makes it probable that the majority of the cases were due to infection of the water supply, such infection taking place: (a) Outside the city (sources of supply); (b) locally, from leaky cesspools; and (c) in Gravesend Bay, which is largely used for bathing purposes, and where many sewers empty. Direct contact probably played a considerable part, also.

The Bronx.—In this borough also there was a slight, fairly well localized outbreak of typhoid fever, late in the year. Between Nov. 15, and Dec. 31, 126 cases were reported. Of these 92, or 73%, were in the area bounded by Westchester Ave., East 170th St., Tinton Ave., and Washington Ave.

The death rate for the year was slightly increased, but the case fatality was diminished, it being lower than in any other borough. The same steps were taken as in Brooklyn: a house-to-house inspection made in all tenement neighborhoods, circulars of instructions widely distributed, and personal, oral instruction given to the family of each patient. By the first of January, 1906, the outbreak was at an end.

No evidence of any milk-borne infection was obtained, but it is interesting to note, that the section of the borough above mentioned received its water from the Williamsbridge reservoir, which is supplied by the Kensico and Byram watersheds. The southerly portion of the borough, supplied by the Westchester Water Company, and the westerly portion supplied by the Croton watershed, had but few cases.

Queens.—The number of cases and deaths were about the same as in 1904. The case fatality from the disease, for some unexplained reason, was extremely high in this borough.

Richmond.—There were fewer cases and deaths than in 1904, both the death rate and the case fatality being reduced.

Greater City.—Although there were almost 100 more cases in 1905 than in 1904 (due to the Brooklyn and Bronx outbreaks), yet there were fewer deaths, the death rate being reduced to 1.61 and the case fatality to 15%.

Tabulation of Cases.—As previously stated, detailed information was obtained regarding every case of typhoid fever occurring in the city of New York, especial attention being paid to the sources of infection. The results have been tabulated by boroughs and are given in the following table:

TABLE III.

| | TYPHOID FEVER, 1905. | | | | | |

REMARKS.

Ser.—Fifty-five per cent of the cases occurred in males, except in Richmond, where they constituted 71%.

Age.—About one half were between the ages of twenty and fifty years. Only 8 (0.2%) patients were under one year of age, while 186, or 5.1%, were between the ages of one and five years; 3% were over fifty. About the same percentages hold good for the various boroughs.

Occupation.—The large percentage of clerks, school children and housewives is readily explained by the fact that so many of the population fall into those classes. Actresses and salesmen travel, and acquire their disease elsewhere. But why were no actors among the number? It is difficult to explain the high percentages of cooks, bakers and waiters; also of persons following one of the various occupations connected with sewing.

Dwelling and Condition.—The social status of the patients can be gathered from the character of their dwellings. In Manhattan 66% were tenement-house dwellers—*i.e.*, of the lower classes. In Brooklyn only 36% were tenement-house dwellers. The proportion of dwellers in private houses was much higher in Brooklyn than in Manhattan. In 8%, the sanitary condition of the dwelling was found to be bad, the proportion being highest in Brooklyn.

Result of Blood and Urine Examination.—A blood test for the Widal examination was made in 54% of the cases, and the diagnosis confirmed in 86%. Fifty-three per cent of the examinations were in Manhattan cases, as compared with 31% in Brooklyn. Yet the number of cases in the two boroughs was about the same.

Other Clinical Signs.—Rose spots were present in 55%, and enlargement of the spleen in 60%.

Occurrence of Other Cases.—Other cases occurred in the same family in 6%, and in other families in the same house in only 3%.

Source of Infection.—In 2,273 cases an expression of opinion as to the probable source of infection was obtained from the attending physician or inspector as follows: Due to infected water 38%; milk, 23%; oysters, 5%; exposure to other cases 9%; infection acquired outside of New York City 3%.

These figures are of little value, however. About 10% of the cases were water drinkers, and 84% used city water.

General Conclusions.—Typhoid fever is transmitted from the sick to the well in one of two main ways: 1. By infection of water with typhoid excreta. The great majority of all cases arise from this cause. From such infected water typhoid bacilli enter the human system through (a) Drinking water; (b) milk (contaminated by water); (c) oysters; (d) food stuffs (salads, fruits, etc.); (e) water used for bathing purposes. 2. By direct contact of the well with the sick. 3. Infection of food stuffs, etc., by flies.

INFECTION OF WATER.

Proof of Infection.—The one absolute proof of infection of water, milk, etc., is the detection therein of typhoid bacilli. Unfortunately, this is almost never possible of attainment. The occurrence of a case of typhoid fever is evidence only of infection two weeks previously. Typhoid bacilli may be present in water or milk for a day or two only, work a great deal of mischief in that time, and then disappear. The source from which infection comes may be transient—the accidental emptying of sewage into a water supply, or the temporary encampment of a party of workmen or tramps by a stream or lake.

At present bacteriologists practically discourage any hope of finding typhoid bacilli in samples of water, as the bacillus is differentiated with great difficulty from the other organisms almost invariably present; and as it is relatively short lived, examination for that end alone is usually a waste of time. Far more assistance is given by examination for the bacteria of sewage (the colon bacillus, etc.) and by chemical analysis. Given the presence of the colon bacillus and of ammonia and nitrites in water, it is practically certain that sewage contamination has occurred; that the water contains typhoid bacilli can be only a matter of inference. In small communities having limited and localized sources of water supply, tracing out the cause or causes of an epidemic of typhoid fever is relatively simple. In New York City, with its many sources of water supply, some of them covering many square miles; its daily milk supply of thousands of gallons, coming from hundreds of different dairy farms; its supply of oysters from all along the Atlantic coast; and its green salads and fruits from everywhere, typhoid bacilli are probably brought in steadily and constantly by all of these.

Earlier in this report, in the tabulation of data, cases are classified according to supposed source of infection—water, milk, oysters, exposure to other cases, contraction of the disease outside the city, etc. The figures given are of relatively little value, however, the fact that a person drinks milk or water, eats oysters, has been out of town for a day or so during the preceding month, or has been exposed to another case of typhoid, does not alone warrant our ascribing the disease to that particular cause. Even the most confirmed drinker of bottled water drinks water from the city supply now and then and the biter of milk occasionally takes it in some form.

Taking up now the various sources of infection in turn:

1. (a) *Drinking Water.* As has been said it is at present practically impossible to detect typhoid bacilli in drinking water. Yet a visit to any of the various watershed will convince the most skeptical of the extreme facility with which such contamination may take place. It is improbable that much, if any, local contamination occurs. In outlying sections of the city (e.g., the Thirtieth ward of Brooklyn), where drinking

water is obtained from wells, leaky cesspools may cause infection. But where the water is piped and under constant pressure it is practically impossible for typhoid bacilli to gain ingress.

As soon as the occurrence of an increased number of cases of typhoid fever was recognized in Brooklyn and the Bronx the Department of Health, by means of circulars and oral instructions, urged most strongly that all water should be boiled before being used for drinking purposes in those boroughs. This advice was widely adopted; in each borough the outbreak came to an end within a few weeks, i.e., the period required to demonstrate the effectiveness of such a procedure.

OBJECTIONS TO THE DRINKING WATER THEORY.

The objection is at once raised by many that if the drinking water is responsible for much of the typhoid fever in New York City, we should have, instead of a hundred cases weekly, a thousand or ten thousand. Possible answers to such objections are as follows: (a) To contract typhoid fever the bodily powers of resistance to the entrance of the typhoid bacillus must probably be below par. Unless typhoid bacilli are taken in in large numbers or are exceedingly virulent, the protective functions of the organism are sufficient to cope with them. Such functions are the secretion of acid, bactericidal gastric juice, the bactericidal powers of the cells lining the intestinal canal, and the similar powers of the blood (serum and cells). But when temporary indigestion or diarrhea are present the defenses of the citadel are weakened and the enemy storms the gates. The case is analogous to cholera; during severe cholera epidemics it has been noted that diarrheas are prevalent, the drinking water containing organisms which set up such diarrheas which in turn inflame and irritate the gastro-intestinal mucous membrane, and pave the way for the entrance of cholera bacilli.

Typhoid fever is more prevalent during the summer and autumn, might not this be partly due to the increased prevalence of other diarrheal diseases at that time? (b) It is extremely probable that a considerable proportion of the population is relatively immune to typhoid fever from having previously suffered from the disease in an unrecognized form. The view that the disease invariably runs a course of from two to four weeks is no longer held by most authorities. Abortive forms occur lasting only a few days. As a rule such attacks are termed "bilious attacks," "ephemeral fever," etc. In the Diagnostic Laboratory of the Department of Health it has frequently been noted that a typical Widal reaction may be present in the blood, and yet the entire duration of the febrile attack be only a few days.

1. (c) *Milk.* The rôle played by milk in the causation of typhoid fever is not to be lightly disregarded. Undoubtedly a certain percentage of the cases of typhoid fever in New York City are milk-borne. The milk supply of the city

comes primarily from hundreds of dairy farms, on any of which infection of the milk through washing the cans, etc., with infected water may readily take place. Yet two facts must be borne in mind: (a) That the greater part of the milk supply of the city is controlled by a few large companies. All these companies maintain a staff of inspectors who visit each farm periodically to see that all conditions are satisfactory. (b) That the Division of Inspections of the Department of Health of New York City keeps careful watch over the milk supply of the city; not only are the individual distributing points under supervision, but, following back through the wholesalers, the entrance of the milk into the city is most carefully watched—it must come up to a certain standard, must not contain more than a certain number of bacteria to the cubic centimetre, and must be properly cooled and shipped. Further, inspectors of the Department visit any farms forwarding unsatisfactory milk to determine if unsanitary conditions exist.

Recent Outbreaks.—To show how carefully the evidence must be weighed, the experience of the Department of Health in connection with the recent outbreak of typhoid fever in Brooklyn may be cited:

Investigation of the source of the milk supply showed that of 941 cases, 244, or 38.7%, received their milk supply from one large wholesale and retail milk company. Examination of the milk records in other boroughs showed that the proportion of cases supplied by this same company was only 7%. It was at once thought that the cause of the epidemic was not far to seek, but further investigation showed that the milk of this company probably had nothing to do with the epidemic, for the following reasons:

The company supplied fully 75% of the milk consumed in the Borough of Brooklyn. Of 113 milk permits issued in one ward this company had 89. Investigation of the company revealed the following facts: The officials expressed themselves as being most desirous of assisting the Department and working with it in any investigation thought necessary or advisable. The company constantly employed a physician and a veterinarian who made inspection of the farms and cattle. Such an inspection had been recently made. Moreover, when the daily papers intimated that one or two milk companies might have been at fault in this local epidemic, a special inspection was made of all farms whence milk sent to Brooklyn was obtained. In all cases of illness found on such farms, the company shut off the milk but continued to pay for it according to contract, thus removing temptation to conceal illness. There was no illness known of among either dairymen or cattle. The company at once ordered another inspection made of the farms supplying Brooklyn, special attention being paid to possible water contamination. This inspection showed that there had been no cases of typhoid fever on said farms for over two years. This incident has been described in detail as showing how readily a biased observer might

have ascribed the cause of the epidemic to infected milk.

Bearing in mind that a great majority of persons use milk and cream, it is not to be wondered at that a history of such use is obtained in a large number of cases.

1. (c) *Oysters.*—It is well recognized that raw oysters may contain living virulent typhoid bacilli, and may transmit the disease. The pernicious practice in this vicinity of fattening oysters in tide-water inlets, the water of which contains large quantities of sewage, is responsible. Yet only a small proportion of the total number of cases is due to this cause,—it is a curiosity more than anything else.

1. (d) *Infected Food Stuffs.*—Theoretically, it is quite possible that green salads and fruits, which have been sprinkled with infected water may be the means of transmission of typhoid fever. So far no authenticated case of such a mode of infection has come to our notice.

1. (e) *Injection of Water Used for Bathing Purposes.*—At many places used for bathing purposes along the North and East rivers and the Long Island shore sewers empty in the immediate vicinity, and contaminate the water. The water may enter the mouths and noses of the bathers and be swallowed; if typhoid bacilli are present in sufficient quantity the disease is set up. In the thirtieth ward of Brooklyn (Bath Beach and Bensonhurst) this mode of infection undoubtedly played a considerable part in the outbreak. It was also found that in several instances (notably in the Harlem River) the public swimming baths were moored in the immediate neighborhood of discharging sewers; it is entirely possible that some of the users of said baths may have contracted typhoid fever. But as a cause of the disease bathing in infected water plays a part only in a few localities.

2 and 3. *Transmission of the Disease by Direct Contact.*—We have no means of determining what percentage of cases is due to the above cause. Judging by the number of instances in which two or more cases occurred in the same family, it is not considerable. Yet such cases undoubtedly constantly occur. Further consideration of this important side of the question is beyond the province of this article, as is the question as to the relation between flies and typhoid fever.

Conclusion.—In conclusion, therefore, it is the writer's opinion that the majority of cases of typhoid fever in New York are due to infected water. The grounds for such belief may be summed up as follows: 1. By exclusion. Investigation of the city's supply of milk, oysters, etc., has so far failed to reveal enough to account for the number of cases occurring in the city.

2. Distribution of cases into areas corresponding to different sources of water supply (*vide*, the Bronx).

3. Ample opportunity afforded for infection in the various watersheds.

4. Suppression of outbreaks by the boiling of all drinking water and milk.

The remedies for this state of affairs can be put

in a few words: 1. Isolation and protection of all sources of water supply. 2. Introduction of filtration systems. This has been strongly and ably urged by Dr. Thomas Darlington, President of the Department of Health, in a report to Mayor McClellan. 3. Education of the medical profession and public, outside of as well as in the city, as to the necessity of the immediate sterilization of all typhoid excreta.

Could an efficient system of filtration of the water supply of New York City be introduced, there is every reason to feel confident that the death rate of typhoid fever of Greater New York would sink from 16 per 100,000 to 5 per 100,000 at the most. Such has been the result of the introduction of filtration in the large continental cities—Berlin, London, etc.—and it is due to such filtration and to nothing else.

Typhoid fever is a preventable disease. The mode of prevention seems clear; it is little short of criminal if the community fails to act.

REMARKS ON THE INFECTIONS OF JOINTS.*

BY ROBERT W. LOVETT, M.D., BOSTON

IN no department of joint disease has so great a disturbance occurred in the last few years as in the views regarding infections in their relation to joint affections.

For many years it has been recognized¹ that joint inflammation of a more or less severe type occurred in connection with certain forms of general sepsis, as in pyemia; in certain forms of specific infection, such as gonorrhea, scarlet fever, typhoid fever and pneumonia, and after trifling local infections. But that acute articular rheumatism was an infectious disease and possibly only "an attenuated pyemia," and that the joint manifestations accompanying rheumatism were possibly very closely allied to those septic joints mentioned above, is a point of view that has dawned on the medical community only of late years, and is at present the most interesting question before one interested in the diseases of joints. A quotation from a paper by Poynton, however, points out better than I could do the difficulties of the situation:² "It is no easy task to grapple with the subject of arthritis . . . for around gout, rheumatism and rheumatoid arthritis, theory has cast her bright and attractive mantle, beneath which gray and sober fact is liable to be stifled."

In general, acute joint infections fall into four groups:

(a) Acute osteomyelitis of the articular end of one of the long bones involving the joint secondarily.

(b) Acute suppurative synovitis or joint abscess.

(c) Acute plastic synovitis leading to joint obliteration.

(d) Acute serous synovitis.

Tuberculous and chronic joint disease are not considered in this classification.

I shall pass briefly over the first three divisions, which are treated at length in all modern textbooks, and call your attention particularly to the relation of infection to serous synovitis.

(a) *Acute osteomyelitis*,³ involving the joints needs only to be mentioned. It is an acute suppurative inflammation of bone, due to infection of the bone marrow by pyogenic organisms. The staphylococcus is the most frequent, the other organisms found being the streptococcus, the pneumococcus and the typhoid bacillus. The bacillus fetidus, the colon bacillus, the pyocyanus and anthrax have been reported. The condition can be produced in animals by the introduction of pyogenic organisms into the nutrient arteries of the bones and by trauma to animals infected through the general circulation. The bone infection occurs in infectious diseases, such as measles, typhoid fever and the like. It appears following some slight local suppuration such as paronychia or furuncle. It is to be found as the result of direct infection, as in septic compound fractures, and in many cases no source of infection can be found. It must be remembered, however, that what is to be said of the throat as a port of entry for pyogenic organisms in connection with rheumatism, applies here as well. A typical instance is as follows:

A healthy boy of six blistered his heel from his boot, and this blister was opened by his mother with a pin. That night a chill occurred, followed by great pain in the left tibia. This tibia was operated upon and opened a few days later and found to be stripped of periosteum over much of its surface. The left hip then became extremely swelled and painful, and was flexed and abducted. Sleep was impossible and general sepsis was present, the temperature was 103 and the child's condition most serious. The hip was incised and a collection of pus found in the joint. The neck of the femur was drained, the hip a few days later dislocated spontaneously, but was replaced and held by a plaster bandage, and the boy made a good recovery.

The treatment of such cases consists in the earliest possible free drainage of the joint, with a careful search for the infected area of bone, which should be opened.

(b) *Acute suppurative synovitis*, or joint abscess, occurs as the result of various infective organisms and appears in infectious diseases of a wide range, and also as the result of direct infections of the joints, as in wounds.

The infectious diseases in which joint infections have been reported are as follows:

Cerebro-spinal meningitis, diphtheria, dysentery, erysipelas, epidemic parotitis, glanders, gonorrhea, epidemic influenza, measles, pneumonia, pertussis, puerperal fever, pyemia, septicemia, scarlet fever, smallpox, tonsillitis, typhoid fever, typhoid fever, after the use of sounds and catheters, and possibly in malaria.⁴

The treatment consists in free drainage of the

joint as soon as the evidence of suppuration can be established by aspiration or other means.

(c) Plastic or ankylosing synovitis, in which an acute and severe joint inflammation is followed by partial or complete obliteration of the joint without suppuration, is most familiar as an accompaniment of gonorrhea. It occurs in connection with other infections and is seen following attacks of general febrile disturbance, often designated as "grippe," in which very acute joint inflammation is present. Beyond the fact that it is at times clearly of infectious origin, and presumably always of this sort, but little can be said of its etiology. No satisfactory treatment has been formulated.

(d) *Acute Serous Synovitis*. That acute serous synovitis occurs in connection with general infectious diseases has long been recognized. It is familiar under the names of "scarlatinal rheumatism," "rheumatic typhoid arthritis," "gonorrheal rheumatism," etc., and the occasional occurrence of simple joint effusions in most of the general infections is a matter of common information. Aside from these demonstrably infectious cases are the cases of single, or more often multiple, acute serous synovitis without obvious infectious cause, which are universally classed under the name of "articular rheumatism." Of course to the laity and to some of the profession, every joint pain is rheumatism until it is demonstrated to be something else, but taking the cases of legitimate acute articular rheumatism, it may be properly asked, What is the evidence for and against their infectious character?

(1) In the first place they do not differ essentially in type from cases of synovitis obviously due to infection, except that "articular rheumatism" is assumed not to suppurate; if it suppurates it must be considered infectious. An acute polyarticular or monoarticular serous synovitis occurring in the course of scarlet fever, for example, is recognized as infectious; if a similar synovitis occurs without obvious source of infection, it is generally classed as "articular rheumatism."

(2) The bacteriology of acute rheumatism has been carefully studied. Cocci in general resembling the streptococcus have been found in the joint effusion, in the endocardium and in other structures in acute articular rheumatism by many observers.⁶ This organism injected into animals has produced synovitis and endocarditis,⁷ and even choreiform movements were observed in some rabbits thus inoculated.⁸

The identity of this coccus has been disputed and its relation to the streptococcus is not clear. Three names have been given to it,—micrococcus rheumaticus (Walker),⁹ diplococcus rheumaticus (Poynton),¹⁰ streptococcus ans chora (Wasserman). Menzer, who has been one of the pioneers in this subject, sees no reason to assume that this

is a specific organism any more than is the coccus of erysipelas, and would regard it merely as a modified streptococcus.¹¹ Cole¹² has produced, by the injection of streptococci from various sources into animals, synovitis and endocarditis. In spite of the weight of English opinion,¹³ it cannot therefore be regarded that the existence of a specific micrococcus has been established.¹⁴ As against the infectious theory of rheumatism, Cole and Jochmann failed to find any microbe in the joints or blood in cases of typical articular rheumatism, and McCrae,¹⁵ in two hundred and seventy cases of acute articular rheumatism, reported the bacterial results as "practically negative." It must be remembered, however, that the bacillus of tuberculosis is found with difficulty in tuberculous joint abscess, and that the organisms of typhoid fever and gonorrhea are frequently absent from the joint effusions of those affections. Moreover, positive evidence is always more valuable than negative, and the identification of the bacteria found has been made by perfectly competent observers.

It is, of course, possible that the joint inflammation may be due to toxins produced by the bacteria rather than by the bacteria themselves. Charrin¹⁶ produced suppurative arthritis in joints by the injection of a sterilized culture of the bacillus pyocyaneus.

(3) *Source of Infection*: The existence of a primary focus of infection is wanting in many if not most cases of acute articular rheumatism; that is to say, no obvious source of pyogenic infection is found. The difficulty that such cases may offer is shown in the following cases:

A healthy young woman, the relative of a physician and under his observation, was confined and delivered of a healthy child. Her convalescence was absolutely normal and free from all suspicion of sepsis. On the tenth day, before sitting up, she developed an effusion in the left knee, accompanied by little or no pain. Traumatism in the ordinary sense was not in the question and her health and temperature were normal. No source of infection could be found, and a diagnosis of infectious synovitis of unknown source was made. The affection pursued a sluggish course and completely recovered. Some weeks later she had a doubtful attack of appendicitis which brought out the fact of former pains in the region of the appendix. Some six months after the synovitis the appendix was removed and was found to be full of pus and showing chronic inflammation of long standing. Here was a source of infection at least competent to have produced the joint symptoms.

A long step toward explaining a possible source of pyogenic infection in articular rheumatism was made some years ago in the recognition of the existence in the tonsils of organisms capable of producing the symptoms of rheumatism when injected into animals.¹⁷ The tonsils act as a filter and are more effective as such when they

are normal than when inflamed. When their cells are injured or diseased it is obviously easier for the pyogenic organisms of the locality to enter the circulation, and the frequent association of sore throat with the early stages of rheumatism suggests a lesion of the tonsils, impaired efficiency of filtration and consequent easier entrance into the circulation for the pyogenic organisms. This, to a certain extent, explains the more frequent occurrence of rheumatism during the cold and damp weather most likely to attack the throat. Chronic tonsillitis is, therefore, to be regarded as a most likely source of rheumatic infection, either in the acute cases or in the chronic joint affections to be mentioned.

A healthy boy of twelve was attacked by a sore throat followed by inflammation of the middle ear, accompanied by the usual high temperature, and the ear drum was punctured. A few days later a throat infection was made evident by a rise of temperature and sore throat. A second increase of throat symptoms followed again in three or four days. About two weeks after the onset of the original trouble, the left ankle swelled, and in a few hours became exquisitely sensitive and extremely painful to any movement and suggested the beginning of a serious purulent joint infection, but the temperature was normal and leucocytosis was absent. It was fixed in a millboard and sheet wadding dressing and two days later was free from pain. On the third day after the involvement of the ankle an effusion of less acute character appeared in the left knee. This was treated in the same way, and in a week from the onset in the ankle both joints were practically well.

The case then stands as follows: The synovitis of acute rheumatism does not differ clinically or pathologically from the synovitis of infectious diseases, except that it is more benignant. It can be produced by the injection of cultures of pyogenic organisms, and pyogenic organisms have been found in the joint effusions. The specific character of these has not been accepted. No satisfactory explanation of rheumatism has ever been offered, and the history of late years shows a steadily larger number of "rheumatic" cases constantly being classed among the infections. It cannot as yet be regarded as a specific infectious disease, but the evidence rather tends to identify it as an "attenuated pneumonia," as it has been called. The evidence is not yet conclusive and the fact that the symptoms are so readily controlled by salicylic acid in many instances is not in accord with what we know of infections.

With regard to the relations to each other of chronic rheumatism, arthritis deformans, chronic infectious arthritis and the like, and with regard to their infectious origin, there is little convincing evidence. Their frequent outcome from what appears to have been an acute rheumatic attack, the almost universal failure to recognize arthritis deformans as such when it begins acutely, and the close clinical resemblance of all the affections to each other suggests the possibility of a common cause.

The bacterial evidence for the infectious

nature of these conditions is suggestive, but nothing more.¹⁸ Organisms have been found in a comparatively few cases. These organisms have in some cases given negative results on inoculation, and in others have caused lesions similar to those of arthritis deformans, but in most cases organisms have not been found. The clinical evidence in many cases suggests an infectious origin for those processes, some of them especially in children originating during some general infection and pursuing a chronic course.¹⁹

Summary.—Acute infections of the joints of undoubted bacterial origin occur in all grades of severity in connection with many infections. As a rule, any one of two or three types of joint inflammation may occur in connection with any one infection, no one type of joint disease constantly accompanying any one infection. In many cases the source of infection cannot be established, and in such cases the importance of remembering the function of the tonsils and the presence of pyogenic bacteria in the mouth as a ready source of infection is of importance. That acute articular rheumatism is an infection seems probable from bacterial and especially from clinical evidence, but this cannot yet be regarded as definitely proved.

THE TEACHING OF HEMATOLOGY.

BY EUGENE LAURIE, M.D., BOSTON.

Instructor in Hematology and Medicine, Tufts College Medical School, Physician to the Patients of Boston City Hospital, Physician for the Children in a Department, Italian Dispensary.

This paper is based upon the writer's experience in teaching hematology at Tufts College Medical School. As our methods differ somewhat from those commonly employed, it has seemed worth while to present this brief account of them.

Our course is in charge of an instructor, who, with two assistants, is responsible to the Department of Clinical Medicine. It is given in the first part of the third year. The student has then finished his courses in anatomy, histology, pathology and other fundamental subjects, including the elementary study of the blood and its pathology. He is familiar with the use of the microscope and has just begun the clinical work in which his technical knowledge of laboratory methods will be needed and applied.

Laboratory work occupies the student two hours a week for ten weeks. The class is divided into sections of about twenty. This is a convenient number for two assistants to handle and saves needless duplication of costly apparatus.

An important item when it is considered that each student must have at his disposal a counter and a microscope with an immersion lens and a No. 5 lens objective. The first four laboratory exercises are devoted to teaching technique.

and simple: (1) Puncturing, preparation and study of fresh (wet) spreads, preparation of dry smears, hemoglobin estimation. (2) Counting the red corpuscles, care of pipette, color index. (3) Counting the leucocytes. (4) Staining and examination of films, differential counting. The six remaining exercises are devoted to the study of pathological conditions. Those taken up last year were chlorosis, secondary, pernicious and splenic anemia, leucocytosis, eosinophilia, leukemia, malaria and the blood of normal infancy. Proficiency in technique is only to be obtained by much practice — more than can be afforded in the time allowed — and the importance of this subject does not seem such as to demand more. Yet each student was required to examine and report upon at least ten smears and to make at least five counts of corpuscles. Judging from the subsequent work of a number of these students at hospital clinics, this amount of practice is enough to insure tolerable efficiency.

One of our most difficult problems has been to find laboratory material for our classes of seventy to eighty students. There is no difficulty for the first four exercises, those covering technique. Each student uses blood from his neighbor. There is a distinct advantage in seeing even the trivial operation of puncturing the ear from the patient's standpoint. One's fellow-student does not hesitate to criticise one's cleanliness or clumsiness — which is also healthful to the soul. In studying diseases, the blood of rabbits is used, though only for counting. This is, perhaps, no better practice than counting the normal blood of a fellow-student, but it is so much more interesting that it justifies the extra work involved. All count the same blood and see that it is abnormal. Having carefully counted it himself, the instructor is able to check the accuracy of each student's work, and he can set an increasingly high standard.

Rabbits may easily be made anemic by hemorrhage. Blood is best withdrawn by cardiac puncture. The animal is etherized, the region of the heart shaved and disinfected and a sterile needle attached to a syringe is introduced directly into the ventricle. The withdrawal of 10 or 15 cc. of blood, repeated in twenty-four hours, accompanied each time by the injection subcutaneously of an equal amount of normal salt solution, will produce a very considerable reduction of red cells. The animal does not appear to suffer. We have not tried the possibly simpler method of injecting solutions of toluenediamine or other hemolytic agent. Leucocytosis may be studied in rabbits with "snuffles," or, if the laboratory is fortunate enough not to have a case of this disease among its animals, leucocytosis may be produced by inoculation with a culture of one of the pyogenic bacteria. We have tried intraperitoneal injections of turpentine suspensions, but the results have proven uncertain and ephemeral.

To withdraw blood for purposes of study, the rabbit's ear must be carefully shaved over the marginal vein and thoroughly dried. The ear

should be warmed or rubbed to dilate the veins. Puncture with a surgeon's needle, or better, a large hypodermic. Direct the needle upwards against the blood current. The needle must be new and sharp. If the blood ceases to flow, start it again by introducing the needle an eighth to a quarter of an inch into the vein, wiping away the first drop to get rid of clots. After ten or fifteen minutes it will be necessary to puncture in a new place. With care to avoid needless trauma, we have been able to use the same ear for four successive sections on alternate days. The rabbit rarely evinces any pain, and will generally be contented to munch a carrot during the process, which, it should be added, is performed by an instructor and not by the students themselves. In this way twenty-five students may easily fill their pipettes.

For studying the morphology of the corpuscles, human blood must, of course, be used. Rabbit's blood is employed only for practice in counting corpuscles. It is always easy to get films illustrating such conditions as chlorosis, secondary anemia and leucocytosis. These are given to the students, who stain and keep them. To save the trouble of cleaning large numbers of cover-glasses, we have hit upon the happy idea of asking each student at the beginning of the course to clean up six covers and contribute them to the general supply. Clinical material for such diseases as leukemia, malaria and pernicious anemia not always being available, a considerable collection of stained and mounted films is essential. We have found that Wright's stain is sufficiently permanent for this purpose. Our collection at Tufts numbers about 2,800 slides. There are ten sets of 200 slides each, eleven sets large enough to supply one section at a time, and a constantly increasing number reserved for purposes of demonstration. There is a card catalogue containing clinical records of all cases represented. Specimens are loaned to be kept throughout the course, and the students are encouraged to borrow specimens from the collection other than the required ones.

In carrying out this somewhat elaborate plan we have felt the need of brief, printed directions for the students' guidance — something on the plan of that excellent little book, "Outlines of Medical Diagnosis," prepared for the use of students in the Harvard Medical School. We have accordingly prepared a "Laboratory Note Book," which will be used next year. The first part consists of brief directions for carrying out the ordinary steps in the examination of the blood. It is interleaved with blank pages for notes and drawings. The last part consists of clinical histories of the cases in the collection, the blood from which is studied. Each case occupies a page, and the pages are interleaved with blanks for recording results. The method thus becomes an adaptation of "case teaching." The student reads the history, the results of physical examination and the estimation of corpuscles and hemoglobin. Then he examines the films and finally discusses the case with an instructor.

Such a notebook need not be printed and bound in the ordinary way. With the typewriter and neostyle its pages can be reproduced very cheaply, punched and fastened into a stout brown paper cover. This permits of frequent editions—at least one every second year—and allows new sheets to be inserted as new cases are added to the collection.

Chart and Diaphragm for teaching use of Counting Chamber.

Wall-charts illustrating such things as the structure of the counting apparatus, and colored ones illustrating normal corpuscles and their morbid alterations are easily prepared. They should be made on cloth-backed paper and kept in a large portfolio. The diagram shown in the accompanying figure has proven of considerable help in teaching the use of the counter. Nothing is more difficult than to teach a beginner to use the ruled chamber; the difficulty arising from the fact that the instructor cannot look through the microscope at the same time as the student actually point out the cells as they are counted. To remedy this difficulty the diagram is made to represent the counting chamber with the corpuscles upon it. A diaphragm mounted upon a handle and having an aperture corresponding to the field of the microscope may be moved over the chart and each corpuscle pointed out as it is counted. It is easy then to show that the slide is moved about in this way that this corpuscle touching a boundary line is counted or ignored. Or a student may go to the chart, take a pointer and count the cells represented—a

proceeding that makes his errors at once evident to the instructor. When he has learned the method from the chart, he can turn to the microscope, apply his knowledge and clinch it by practice.

The demonstration of microscopical specimens is often of little value. Hours may have been spent in preparing a display, but the student too often passes along the row of instruments, looks through each in a perfunctory manner and carries away no impression at all. One is reminded of a motto by Van Steen which hangs in the laboratory of histology at the Harvard Medical School, and which has been translated by Professor Minot:

"What good can light or lenses be
When owls look and will not see!"

The student is much more apt to see what he looks at if the demonstration is arranged with the idea of helping him in the individual problem that he is at the moment trying to solve. To illustrate: In the specimen of pernicious anemia studied last year, each student was required to demonstrate megaloblasts. Yet many hunted for more than an hour before they were successful. Meanwhile a series of demonstrations were prepared, showing amongst other things nucleated reds in their various varieties, as well as other structures frequently mistaken for them. By referring to these specimens the student found he could answer questions that his own work had demonstrated. Demonstrations so used are of much greater value than when shown by themselves.

The labor of preparing demonstrations is very considerable, but it may be materially decreased if some system of records is devised whereby desired slides and desired objects on such slides may be found at once without searching. At Tufts, as has been said, we have a collection of slides for this purpose, and a memorandum book kept to aid in its use. There are several methods of finding a particular field desired. The simplest is to swing out or remove the condenser, tip up the microscope and mark a ring on the bottom of the slide about the center of the objective. In finding the same field later one only has to focus with the low power on the bottom of the slide and the ring, raise the objective, center the specimen and replace the dry lens with the immersion. Much labor is saved by this little expedient.

Lectures are of much less value than laboratory instruction, yet they cannot be wholly dispensed with. In our course they are given every Monday before the meeting of the first laboratory section. The subject matter of the lecture corresponds with the laboratory work of the week. Thus the first four cover technique and are rather demonstrations than lectures. It is easy to demonstrate the method of preparing the cut to a class of seventy in a small, well-lit lecture hall, or to a section of twenty crowded about a desk in the laboratory. In the lecture room also techniques not of enough importance to be taught in the laboratory may be discussed, and, in general, the work for the week may be laid out. In the

last part of the course, too, when diseases of the blood are being considered in the laboratory, the lectures run parallel to the laboratory work. They are in part explanatory of the laboratory work to come, and in part are devoted to criticisms of the work of the week just finished. Diseases of the blood are considered as a whole, not merely in their laboratory aspects. The lecture room is inferior to the clinic for the purpose of bringing before the student clinical pictures of disease types, and is even more inferior to the laboratory for teaching hematological findings, but it will always be the most practicable place to discuss theoretical considerations, such as the metabolism of iron, the "leukemia question," pathogenesis and historical and literary matters. Here, too, it is helpful to use freely the lantern and apparatus for opaque projection.

Textbooks are of little importance in this subject. We encourage our students to use the literature and place standard works at their disposal, but no systematic reading is required.

Marks and examinations are a necessary evil, but they are none the less so if they are improperly managed. In grading the students at Tufts we take into consideration the daily work in the laboratory (40%), a practical examination (20%) and a written examination (40%). In the practical examination the students are asked to perform one of the common hematological procedures, such as counting the white corpuscles, and to report on a specimen smear or identify a series of normal and abnormal blood cells placed under microscopes and indicated by pointers. This examination is conducted in sections. In marking the students on their daily work in the laboratory, we consider not merely the accuracy of the work, but also the care of the apparatus. The *vis a fronte* of ambition is often insufficient to make a student wipe his lenses or dry his pipette without the *vis a tergo* of a possible "docked" mark. A possible betterment of his mark, too, will often stimulate a student to do extra work outside the classroom.

The relations between a laboratory course in hematology and the general clinical courses in medicine ought to be very close indeed. The technique of counting, staining and the examination of smears is best taught in the laboratory under the guidance of one head, but many teachers in clinical lectures or in small sections at hospital or dispensary must share in the demonstration of cases. Students working in small sections, or acting as assistants in clinics, or preparing cases for conferences or reports, or doing research work, should receive from the instructor in hematology every possible assistance by the loan of apparatus and otherwise in studying blood conditions in actual cases of disease. In short, everything possible should be done to encourage the student to use his technical knowledge, lest, as so often happens, he relegate it to the limbo of the forgotten.

In arranging instruction in hematology, it must always be borne in mind that the subject is a practical one. A study of the catalogues of a number of medical schools will lead one to

suppose that laboratory instruction in this branch is quite frequently given only in connection with laboratory departments like pathology or chemistry. In some schools it forms part of special departments of clinical microscopy or clinical pathology. It seems far better that the subject should be taught as a clinical one by the department of clinical medicine. If the student is not taught to make blood examinations by those he looks up to as his teachers in practical matters, he will never use his laboratory technique in his own practice. This is a matter of the greatest importance. If the student could see in the hospital clinic every case whose blood he examines in the laboratory it would be greatly to his advantage. For obvious reasons this is impossible. Still at Tufts we try to bring it about as often as we can. Cases of hematological interest are demonstrated in the hospital amphitheater by the instructor in hematology. Enough smears are made from each case so that each student may have one for study in the laboratory. A few are permitted to do the counts and hemoglobin. Pure "paper cases," whose blood alone is seen, possess no such interest as these. When, as occasionally happens, such a case comes to autopsy and the organs can be demonstrated, we feel that we have made a long step towards establishing in the student's mind the close relationship that should exist between laboratory and clinic.

PRURITUS ANI: ITS ETIOLOGY AND TREATMENT.

BY T. CHITTENDON HILL, M.D., BOSTON,
Surgeon to Rectal Department of the Boston Dispensary.

THE writings and teachings of some of our most eminent authorities on the subjects of dermatology and proctology enshroud the condition known as pruritus ani with a good deal of mystery. "At a recent meeting of the British Medical Association at Oxford, an interesting discussion took place, in the Section on Dermatology, on the causation and treatment of pruritus ani; any one reading that debate cannot fail to be struck with the enormous number of distinct diseased conditions to which this annoying symptom was attributed by the various speakers, and large as the number of supposed causes assigned were, the various plans of treatment advocated were still greater. All the resources, not only of the Pharmacopeia but of the extra Pharmacopeia being in turn favored."¹

Hence we find among the profession conflicting views in regard to the nature of the disease and a wide diversity of opinion as regards the best methods of treatment.

Some maintain that the itching is due to such gross lesions as internal hemorrhoids, anal fissures, fistule, prolapsus recti, etc., and are greatly surprised that operative treatment has not resulted in a cure. When these conditions are not found the patient is considered neurotic

¹ Bull: Brit. Med. J., 1905, i, 113.

and but scant sympathy is wasted on the unfortunate individual.

Others are in the habit of attributing the cause to some constitutional disease, as diabetes, rheumatism, gout, tuberculosis, or syphilis, and their treatment is principally constitutional and dietetic. However, neither of these views seems reasonable to the writer and practical experience in the treatment of this annoying affection has proved the cause, in the vast majority of cases, to be far different.

In this consideration it is proposed to discuss only the more chronic and aggravated forms of pruritus ani, such as are commonly associated with characteristic changes in the peri-anal skin. Slight transitory itching is not to be included.

Symptoms.—The picture of a typical pruritus case, with which nearly every practitioner is familiar, is much as follows: The patient, generally a man of otherwise robust health, tells you he is a martyr to an itching so intense that pain in comparison would afford him much relief. In fact his greatest aim in life is to find a panacea for this affliction which is rendering life almost intolerable. He has dictated himself in every possible manner, he has used all kinds of local applications, he has taken internal remedies of every description, he may even have been operated upon, and has gone in vain from one physician to another seeking a cure.

He feels that in certain instances his medical attendant has made light of his ailment, in others they did not understand his case, and that he is getting worse instead of better. Now can we offer any hope of permanent cure to these patients? I believe that in nearly every instance we can and that it is frequently the most inveterate cases that yield most readily to treatment.

Pruritus ani should be regarded as a symptom caused by an unnatural moisture or discharge which is produced by either lesions about the anus, or by congestion or some pathologic condition in the rectum or sigmoid. This constant discharge, even though slight and scarcely discernible, eventually brings about pathognomonic changes in the structure of the epidermis in this region.

It is of a mildly inflammatory nature and is in reality a dermatitis which passes into the chronic form when the skin loses its natural color and presents a sordid, blanched appearance.

Treatment. The most important thing is to find out and eliminate the exciting cause. Next in importance, or rather equally important, is that appropriate treatment be instituted which will tend to restore the skin of this region to its normal state. At this juncture it might be advisable to state that only those who are willing to observe details should undertake the care of these patients. Very little can be left to the patient even after the cause has been removed.

The exciting causes and their treatment will be considered in the order of their frequency as follows:

(1) Ulcerations or abrasions of the anal canal.

This lesion is very constant and should always be sought for. Mr. F. C. Wallis² of London, first called attention to the frequency with which it occurred in pruritus. He maintains that 90% of all cases may be attributed to this cause.

His method of treatment, briefly described, is as follows: The ulcer is cocoonized by the injection of a few drops of the solution immediately beneath it. This elevates the lesion so that it can the more readily be cauterized with the galvanic cautery knife. After this it is smeared with vaseline and an opium suppository inserted in the rectum. In very bad cases when there is considerable ulceration, Mr. Wallis is in the habit of using a general anesthetic in order that the sphincters may be stretched and the actual cautery used.

Three years ago I had an opportunity of seeing Mr. Wallis treat a large number of cases* by this method, and was greatly surprised that the cure of such a small lesion as was sometimes discovered would so quickly relieve the patient of the intense itching. Since then in my own practice I have often demonstrated the fact that the whole cause of the pruritus may be attributed to a very small ulcer or abrasion of the mucous membrane of the anal canal.

(2) Catarrhal diseases. The rectum in such instances is never entirely free from feces, a condition which is productive of chronic forms of proctitis, sigmoiditis, superficial ulcerations, etc. The passage of flatus at such times allows a small quantity of mucus to escape, thus irritating and rendering moist the anal region.

These patients are best treated by securing soft evacuations of the bowels at least once in every twenty-four hours, by means of a suitable aperient taken at bed-time. After the bowels have moved in the morning they should be washed out with a half pint of a 4% boric acid solution. Furthermore it will be found beneficial to make stimulating applications of silver nitrate or balsam of Peru to any abrasions or ulcerations which may remain. This is best effected with the proctoscope, with the patient in the knee chest position.

(3) External hemorrhoids are more frequently the cause of pruritus than internal ones. These ragged tarsi of redundant skin render it almost impossible for the patient to properly cleanse the anal region after defecation. This persistent fecal soiling sooner or later produces a dermatitis in persons predisposed to its occurrence. This variety of hemorrhoid may be easily removed after injecting with a 1% solution of eucaine. The wound may be allowed to heal by granulation, yet if the base of the hemorrhoid was broad it is better to close it with catgut sutures. When the folds are numerous only two or three should be removed at one time lest anal contraction take place.

(4) Situated from 3 to 9 mm. above Hilton's white line are several small pockets, the functions of which are still under discussion, yet it is

¹Wallis, Brit. Med. J., 1905, i, 1029.

*These patients were treated at St. Mark's Hospital for Diseases of the Rectum, London.

generally conceded that they have something to do either with the storing or secreting of rectal mucus.

These little pockets will admit a probe, which has been bent upon itself, from $\frac{1}{4}$ to $\frac{1}{2}$ an inch, and by means of the anoscope³ which I have devised they may be readily seen and explored. The thought had frequently occurred to the writer that these little crypts when inflamed or infected might not functionate properly. This being the case they produce an over-abundance of rectal mucus which would escape at the anal orifice.

Thus they would account for the moisture present whichever theory we may hold as to their normal physiological function. For instance, if we believe them to be reservoirs then when diseased they may fail to take up the normal rectal mucus, while on the other hand, if we consider that their function is productive, if diseased they would produce an excess of mucus (blenorragia).

However it may be I have, in a few instances in which there was no other ascertainable cause for the pruritus, succeeded in curing my patient by swabbing out these little pockets with stimulating lotions of 5% silver nitrate, or balsam of Peru, 5%.

Growing from the margins or surfaces of these valves one frequently finds little white projections or teats which can be made out by the exploring finger. Stroud⁴ explains their presence here as "accessory sense organs of a higher degree of development than the major part of the pecten, and not pathological outgrowths." Whatever their nature may be it is certain that when hypertrophied they are prolific of many distressing sensations about the anus.

Among them may be mentioned, uneasiness in the rectum, such as a "creeping," "crawling" sensation, and a feeling of incomplete relief after defecation. Quite frequently pruritus is the most prominent symptom.

The treatment of these cases is very satisfactory. It consists in snipping the growths off with a pair of nasal scissors as they protrude through the window of the anoscope.³ It is best to apply a strong solution of cocaine before removing them.

(5) Small polyps of the anal canal, protruding internal piles, prolapse of the rectum and anal fissures, as well as other conditions, do doubtless occasionally cause itching about the anus, but very seldom in the writer's experience are they the cause of an old chronic or inveterate pruritus ani.

When encountered, however, associated with pruritus, they should be dealt with according to their special surgical indications.

Now, notwithstanding the fact that the exciting cause has been discovered and eliminated, it is necessary to direct appropriate treatment to the unnatural skin before much amelioration of the itching can be expected. It seems probable that

it is the product of a chronic inflammation of the skin, with more or less thickening and infiltration, which in some way throws out of gear the "simple nerve endings which exist so abundantly in the epidermis." It is this departure from the normal which produces the sensation of itching; therefore it is our task to make such applications as will restore the skin to normal.

At the beginning of treatment it is of prime importance that the necessity of absolute cleanliness should be remembered by both surgeon and patient.

The patient should be instructed to thoroughly cleanse the anal region after defecation, preferably with absorbent cotton which has been wrung dry of some antiseptic solution.

The parts should be protected from friction and the irritation of the discharge by wearing day and night an anal pad held in place by a T-bandage. The pad is best made with absorbent cotton wrapped with but one thickness of sterilized gauze. Too many thicknesses of gauze when ointments are used absorb the greasy portion of the ointment, and shortly the anal region becomes dry and coated with only its irritating mineral ingredients.

The methods of applying and removing ointments are such important matters that in the first few weeks of treatment the patient should be seen daily by the surgeon. To simply give instructions to use some of the ointment morning and night will inevitably result in failure.

Those cases in which the dermatitis is acute (eczema ani), accompanied by many excoriations from scratching and rubbing, require applications and ointments of a soothing and protective nature.

However, in the class of patients which are here especially referred to, the skin is nearly always tough and leathery and covered with dead and sodden epithelium.

The local appearance is very typical and once seen can never be mistaken.

The problem in these cases is to bring about a gradual destruction of this new formed epidermis, without too much inconvenience to the patient, and I know of no agents that serve the purpose better than nitrate of silver and citrine ointment (ung. hydrarg. nit.) rightly applied. Dr. Lewis J. Adler, Jr., of Philadelphia, first called attention to their use in the treatment of pruritus ani.

At the first visit the peri-anal skin is painted with a saturated solution of nitrate of silver. Provided any abrasions present are previously anesthetized with a 10% solution of cocaine this should occasion no discomfort. The application of the silver should be repeated at intervals of four or five days until all the dead epithelium has been removed. After the silver has dried the anal region is smeared with citrine ointment. I have observed that individual skins differ in their reaction to this ointment and one should always be cautious when making a first application.

It is best to reduce the strength of the ointment by the addition of an equal quantity of lard for

³ Hill: Jour. Am. Med. Assoc., 1906, xlvii, 585.

⁴ Stroud: Ann. of Surg., 1896, xxiv, 1.

the first visit, and then gradually, if the skin of the patient will permit, increase it to full strength. The ointment should be perfectly prepared, as any gritty particles render it unfit for use. The patient is seen daily for the first two weeks, and then every other day for a like period. After this, once or twice a week until the skin has regained its original color, suppleness and elasticity.

Ordinary cases may be cured in four weeks, yet one should be guarded as to prognosis, as stubborn cases will often require as many months.

During the past two years I have treated at my office and at the Boston Dispensary fifty-two cases of pruritus ani, and where the treatment has been conscientiously followed up I have had almost universal success.

To illustrate the methods of treatment five are selected at random and their histories and treatment briefly appended.

CASE I. Mr. S., age thirty-four, occupation, business man, was referred to me in April of last year. He had pruritus for twenty years. During the past three months he could sleep but little at night because of the intolerable itching. He had been under treatment by a New York proctologist eight years ago, but had received no permanent relief.

Rectal Examination.—Numerous excoriations from scratching about the anus. Perianal skin sodden and blanched looking. Two large and one small external piles. Mucous membrane of anal canal congested and inflamed.

Treatment.—April 4, under eucain $\frac{1}{4}$ of 1%, the three external piles were removed, and a dry dressing was continued for six days. Then the following daily treatment was begun: The rectum was irrigated daily with boric acid solution. Every four or five days the skin about the anus for two inches was painted with a saturated solution of nitrate of silver. This last had to be repeated four or five times. A pad of cotton covered with sterilized gauze and smeared with citrine ointment was worn continually day and night for the next two months. The treatment was continued daily for two weeks, then every other day for the next two, and once a week for the next month.

Was under treatment two months in all, but the itching disappeared after the first two weeks' treatment. There has been no recurrence to date.

CASE II. March, 1905. Mr. S., age forty; lawyer. Symptoms began gradually a year and a half ago. Described in his own language they are: Feels as though there was something live under the mucous membrane. At times, especially after the bowels move, there is a "creeping" sensation just inside the anus. Cannot sleep nights. Has been the rounds of general practitioners and one rectal specialist. In fact, he has become neurotic on the subject.

Rectal Examination.—Greatly hypertrophied sphincters and four hypertrophied anal papillae.

These little growths were removed by the method previously described, and Mr. S. has been free from rectal symptoms since.

CASE III. Another case similar to the one just reported was that of a Boston physician, forty-five years old, who had had pruritus for sixteen years. In this case there was an eczema involving the perineum and scrotum.

These papillae were discovered, removed, and the most distressing symptoms subsided at once, yet he even now occasionally has slight itching. His symp-

toms, however, were so greatly relieved that being a very busy practitioner, he neglected then necessary after treatment which should have been undertaken to cure the eczematous condition of the perineum and scrotum.

CASE IV. Aug. 1, 1905. Dr. M., a dentist, thirty-eight years old. Had been a great sufferer from pruritus for twelve years. His itching was caused by very small superficial ulcerations (three or four) of the rectum and sigmoid. These were treated locally, and the external treatment was the same as in Case I. He was under treatment six weeks and has since remained well without treatment.

CASE V. Aug. 1, 1905. Mr. A., age forty, was referred to me for a very bad pruritus. He was a high liver and indulged rather freely in alcohol. Duration of disease three years. Did not get more than three or four hours' sleep at night. Of late has been sleeping in steamer chair aboard his yacht, as that is about the only way he gets any rest.

Rectal Examination.—Small posterior ulcer located between the sphincters.

Treatment.—His mode of living was not in any way interfered with. The small posterior ulcer was cured with lactic acid applications and the same external dressings as in Case I were used. There was no itching after the first week's treatment, and no recurrence to date. He was under treatment eight weeks.

The cardinal principles to remember in treating pruritus are:

Cure all affections of the anal canal and rectum, no matter how trivial they may seem, as they do cause an irritating moisture of the parts.

Maintain absolute cleanliness by protection of the parts from friction by the wearing of a T-bandage with a pad.

Make local applications for the restoration of the altered skin to normal, using strong caustics when required.

Clinical Department.

A CASE OF PSORIASIS CURED BY LAPAROTOMY AND CURETTAGE.

BY CHARLES F. STEVENS, M.D., DORCHESTER, MASS.

MRS. E. H., twenty-seven years old, blond, always strong and healthy, except for constant leucorrhoea following birth of child six years previous; bowels regular; fond of candy; menstruations normal, but rather free.

In March, 1903, she had severe attack of tonsillitis, which so closely resembled diphtheria that 5,000 units of antitoxin were given while awaiting culture reports, all of which were negative. Five weeks later punctiform macules appeared on face and body, scaly and itching, with tenderness of muscles and painful joints. The patches slowly increased in size and number until pretty nearly the whole body, including scalp and face, and excepting palms and soles, was covered with the blisters, scaly patches, some of which, around the umbilicus and scrotum, coalesced to form areas as large as the palm, while most of them did not enlarge to the size of a dime.

Different internal and external remedies were used without much effect, including mercury and potassium iodide, as the sore throat, followed by the eruption, suggested syphilis. The subsequent history, however, eliminated this disease. Vaginal examination revealed

a large, retroverted uterus, with a polypus projecting from the external os, and a small fibroid on the posterior wall of the fundus. The cervix was slightly torn on the left side. There was an offensive viscid discharge. An operation was advised for the removal of the tumors, for restoring normal position of uterus, for relieving leucorrhœa, and as the best chance of curing the psoriasis. The patient refused surgical treatment.

The disease assumed more and more of a chronic nature until finally, six months after its appearance, it began to gradually fade, and by the following January, 1904, had entirely disappeared. The next September it appeared again and progressed steadily until in December the patches were more thickened and hyperemic than at any time during the previous attack, and her face looked so badly to the patient that she would not venture out of doors. Operation was again strongly advised and agreed to.

She was taken to the Moultrie Street Hospital, Dorchester, and on Jan. 4, 1905, after curetting and removing polypus, I performed a laparotomy, removed a small fibroid and attached, the uterus to the anterior abdominal wall. Four days later the eruption seemed much improved, and in two weeks was not visible on the face. She made an uneventful recovery from the operation, and on the fifteenth day left the hospital.

On March 1, less than two months after the operation, there were no visible signs of the eruption, except a slightly erythematous appearance, around the umbilicus and sacrum, where the most indurated patches occurred. Up to the present time there has been no recurrence of either the psoriasis or the leucorrhœa, and she is at present a superb specimen of health. The neuralgia in the joints did recur for a time, and was so intense occasionally that safe doses of morphia would not control it. The shoulders and elbows were the principal seats of the pain.

Unfortunately, the cause of psoriasis is unknown. While it has some characteristics which would seem to suggest a parasitic origin similar to the ringworm fungi, this belief does not generally prevail. Vasomotor neurosis, neuralgia, an inherited sequel of syphilis, tuberculosis, rheumatism or gout are ascribed as causes. It has been called a deformity rather than a disease of the skin. It has appeared after vaccination and scarlet fever, in other words, when there has been an irritant circulating in the blood.

Psoriasis is, in my opinion, a manifestation of a toxicosis, the neuralgia which sometimes occurs with it and which is attributed as a cause, being simply another manifestation. The case above reported would agree with this theory. Either the streptococcal infection of the throat, the administration of antitoxin, or the infected endometrium, one or all, on the one hand, or the reflex irritation of the retroverted uterus and the tumors, on the other, furnished the cause. Relieving the leucorrhœa, which was kept up by the polypus and the displaced uterus, in all probability effected the cure. A laparotomy diet for one or more weeks may not be without beneficial effects, if psoriasis is due to an auto-intoxication.

JAPAN'S HALT AND BLIND.—According to the Nagasaki press Her Majesty the Empress had presented 984 artificial eyes and 1,797 limbs to soldiers injured during the recent war.—*Medical Record*.

Medical Progress.

REPORT ON PROGRESS IN DERMATOLOGY.

BY JOHN T. BOWEN, M.D.,
AND
HARVEY P. TOWLE, M.D., BOSTON.

THE SPIROCHETE PALLIDA IN SYPHILITIC LESIONS.¹

Bodin gives in this article the results of his examination of 37 cases. He found the spirochete pallida in 10 out of 16 chancres examined. Three of these 6 negative cases had used a calomel ointment on the lesion and 3 were over two months old and were cicatrizing. From 17 cases of secondary syphilis he obtained a positive result in 10. The 7 negative cases comprised one untreated case with a roseola, one with aeneiform syphilide, who had been treated for several days, one with an erosion of the vulva to which permanganate of potash had been applied and one case of a moist lesion on the palpebral commissure from which the material for examination had been removed under unfavorable conditions. Two cases of tertiary syphilis also gave a negative result. Of two cases of hereditary syphilis, one, a child fifteen days old with a pemphigoid eruption on the extremities and an interstitial hepatitis, gave a positive result. The other, a macerated fetus, was negative. Several non-syphilitic lesions examined were invariably negative. Bodin concludes from these results that the presence of the spirochete pallida is constant in the untreated and still evolving syphilitic chancre and also in the secondary papular, papulo-squamous, ano-genital and erosive syphilides. He is certain that the germ is so sensitive that it can easily be made to disappear by applications of mercury or of the ordinary antiseptics. Mercury given internally works in the same way so that its use for five or six days is enough to render the microscopic examination negative. His researches brought out two points which impressed him especially. All the authors give the number of spirals as varying from four to fourteen. Bodin has seen the organism with more than fourteen but close examination has convinced him that in such instances he had to do with two stuck together end to end. He also found in the same preparations bifurcated spirochete in the form of a letter Y. These he regards as evidences of the active multiplication of the germ at the moment of longitudinal division like the trypanosomes, and in that stage where the two individuals born by division are still adherent by their extremities. He was also struck by the fact that in all of his preparations the microbes were most abundant in the parts which were richest in red blood corpuscles. This points, he thinks, to the desirability of obtaining for the examination material which contains blood.

SPIROCHETE OF SCHAUDINN FOUND IN THE LIVER AND SPLEEN OF A MACERATED FETUS.²

At the December, 1905, meeting of the Société Française de Dermatologie the authors reported

¹ Bodin: *Ann. de Derm. et Syph.*, December, 1905, p. 984.

² Queyrat, Levaditi and Feuille, *Ibid.*, p. 982.

that they found the spirochete pallida in the liver and spleen of a syphilitic eight-months fetus. The mother had had syphilis five years before, for which she had taken pills of the protoiodide of mercury for seven months. The fetus was found to be macerated externally and internally, the liver being especially affected. The spirochete pallida were found in sections of the liver and spleen and were especially abundant about the vessels. The authors believe that this case proves the etiologic relationship of the spirochete of Schaudinn to syphilis beyond a doubt. They argue that here was a fetus born of a syphilitic mother, dead before birth and, therefore, unable to take in any organism either by the digestive or respiratory apparatus, in whose liver and spleen they found at autopsy an abundance of the spirochete of Schaudinn and no other microbe, with the greatest number in the liver as is the rule in infections by way of the placenta. They believe that the case shows further that the microbe can exist for a long time in a living and transmissible state in an imperfectly treated syphilitic.

THE SPIROCHETE OF SYPHILIS. MORPHOLOGY AND CLASSIFICATION.²

¶ Burnet considers the etiological rôle of the spirochete pallida in syphilis as practically settled in view of the fact that the only link missing in the chain of evidence is the experimental inoculation. The morphology and classification, however, are still in doubt, which has led Burnet to review Schaudinn's work in order to show how the latter's opinions changed as his investigations progressed and also to present the present status.

Schaudinn and Hoffman found two forms of microbes in the serum obtained from a primary lesion of syphilis. One was easily stained by the usual methods, had large spirals, was stumpy and was strongly refractile. The other was difficult to stain, had fine spirals, was thinner and was only slightly refractile. The first they called spirochete refringens, the second spirochete pallida. The second they considered to be the active agent in syphilis. In their early articles they ascribed the following characteristics to the spirochete pallida: a length of from four to ten μ , a width always less than one-half μ , from three to twelve fine, almost angular spirals. The organism has a characteristic motion which consists of a rotation on its longitudinal axis with displacements in front and behind together with flexion of the whole body. There are no flagellæ. The ends are pointed and in some there is seen an indication of a wavy membrane which suggests the morphology of the trypanosomes.

In a later article, published in October, 1905, Schaudinn modifies some of these views as the result of more extended investigation. He still speaks of the tenuity, the feeble refraction and the difficulty of staining, but he now places the number of spirals at from ten to twenty-six. He doubts the existence of the wavy membrane

mentioned in his earlier article. On the other hand, he says that he has demonstrated by means of the Loeffler bacterial stain a single long cilium at each pole.

In regard to the differential diagnosis, Schaudinn emphasizes the necessity of prolonged and energetic staining in order to obtain satisfactory preparations. As distinguished from the other forms of spirochete the pallida is more pointed, has more spirals, is more difficult to stain, is paler than the other forms with the same stain and finally it is thinner and longer. Schaudinn at first classed his microbe among the spirochete but as a result of this later work he now believes that it is not a true spirochete because it possesses numerous and pointed spirals which are an integral part of the body of the organism as is shown by the fact that they do not disappear after death as do the spirals of the true spirochete, because they have no wavy membrane and because they have flagellæ. He concludes that it is, therefore, a microbe of a new type. Burnet goes on to say that these new characteristics noted by Schaudinn bring the pallida nearer the spirillum group. These, however, have a bouquet of flagellæ about the poles instead of only one as in the pallida. Because of this doubt as to the classification of Schaudinn's microbe, Villenim of Nancy has suggested, with Schaudinn's consent, that the name be changed to *spiroplasma pallidum*.

THE INOCULATION OF SYPHILIS UPON APES.

Neisser publishes his third communication upon this subject since he began his experiments in Java.³ He met with many unexpected difficulties, such as the collection of proper syphilitic material, since the native Malay population seldom present themselves during the incubation periods. The maintenance of the animals was also found difficult, as many of them died from intestinal affections. He used an enormous number of animals, about 9000, of which a small proportion, naturally, were of the anthropoid species.

Many interesting facts were brought out, although it cannot be said that any very important results were attained. As in the human subject, the time of incubation was several weeks, in the majority of cases three to five, seldom less. The inoculations were made by deep scarification and rubbing the material thoroughly in. No particular difference could be made out between the different species of monkeys with respect to the appearance of the primary manifestations. The primary glands were found to offer an especially valuable material for inoculation, especially the peripheral parts of the glands. Only once was he able to record a successful inoculation from a tertiary product. He is inclined to think that the passage of virus from animal to animal causes it to become more active. Naturally, the higher apes were more susceptible than the lower, and the lower apes could only be inoculated on the eyebrows and

² Burnet: *Ibid.*, November, 1905.

³ Deutsch. Med. Wch., 1906, No. 13.

genitals, whereas in the higher apes any part of the body was susceptible.

In common with the results of other observers Neisser was unable to inoculate the animals by subcutaneous injection, nor to produce immunity in that way. While it was found that lower apes could be inoculated comparatively easily with primary lesions of other lower apes, and that orang-outangs could be inoculated easily with spleen and bone marrow of lower apes, it was seldom that lower apes could be inoculated cutaneously with spleen and bone marrow of other lower apes.

With regard to the spirochete pallida, it was found that it was almost constantly present in syphilitic efflorescences, and in far greater profusion than other spirilli. This is important as indicating the specific character of the spirochete, inasmuch as spirilli and allied organisms are especially abundant in Java, in purulent secretions from the skin and mucous membranes. They were found in greater numbers in the serum obtained after deep curetting than from the superficial secretion. They were also found in efflorescences that were not broken open and in lymph glands. They were not found in tertiary lesions. Neisser is rather skeptical as to the possibility of always distinguishing the spirochete pallida from other forms of spirochete by its form, if the origin of the material to be examined is unknown. He is also skeptical as to the value of this discovery for practical diagnostic purposes, when no spirochete are found in the tissue under examination. In 12 fresh, typical cases of human syphilis and 8 syphilitic apes, the spirochete could not be found. He admits, however, that these figures would probably have been smaller had a longer time been given to the search for the organisms. Neisser considers that these micro-organisms in all probability have a causal relationship to syphilis. This is shown by the almost constant finding of them by experienced observers in the secretion blood and tissues of both hereditary and acquired syphilis, in men as well as in apes, by their presence in the primary lesion of an ape that was inoculated with the blood of a syphilitic man, by their absence in affections other than syphilis, and by their characteristic form.

CONTRIBUTION TO THE QUESTION OF THE LOCALITIES CONSIDERED TO BE RARELY AFFECTED IN TUBERCULAR LEPROSY.⁵

Bjarnhedinsson, the physician in charge of the leper hospital in Reykjavik, publishes some interesting cases relating to this question. It is well known that leprous nodules appear only rarely on the flexor side of the extremities, the chest, abdomen, serotum and penis. Hansen and Looft had never found nodules upon the glans penis, palms of the hands, soles of the feet, or upon the scalp. Some rare cases of palmar and plantar leprosy have been published by Crocker and others.

The writer's experience in the leper hospital

of Reykjavik is an interesting exception to what has just been cited. He has examined 53 patients with tubercular leprosy since 1901, with the result that he found 26 affected with leprous nodules upon the soles of the feet. These nodules were sometimes multiple, sometimes isolated. They were found partially or totally ulcerated. He remarks that the only disease which one is likely to confound with plantar leprosy is syphilis, but that Iceland has, so far, pretty generally escaped a visitation from this disease, it being confined to a few isolated cases in the towns.

With regard to palmar leprosy, 10 of 52 patients with tubercular leprosy examined were found to be affected in this place.

In 12 patients from the 52 examined, there were found to be lesions in the scalp, either nodules, or circumscribed or diffused infiltrations. In most of these cases there was an alopecia corresponding to the localization of the lesions.

Of 32 cases, 12 showed pathological changes in the male genital organs.

In the same number of Lepra, Charles Nicolle, director of the Pasteur Laboratory in Tunis, describes an experimental inoculation of leprosy on a monkey. Two patches of skin were excised from a case of tubercular leprosy, one of which served for a microscopic examination to control the diagnosis. On the 24th of November, 1904, a few minutes after its excision, the other piece was macerated in sterile water and inoculated upon a female "bonnet chinois" in several places; first, upon the frontal region upon both sides after superficial scarification; second, upon the conjunctiva of the right eye by rubbing, without previous excoaration; third, upon the two nasal mucous membranes, which had been previously excoarated; fourth, under the skin in front of the left ear; fifth, in the pavilion of the ear.

Another monkey belonging to a kindred species was inoculated at the same time in the same manner except that he was not inoculated in the tissue of the pavilion of the ear, while several drops of virus were injected into the peritoneal cavity. The reason why he determined upon so many points of inoculation was the failures of his predecessors. The nasal region was considered especially hopeful as it had probably never before been inoculated, and as leprosy appears to begin frequently in the nose in the human subject.

Four days after the inoculation, every trace of it had disappeared in the two monkeys. After two months no symptoms were observed. It is remarked that the two monkeys at the time of the inoculation were in perfect health. On the 29th of January, the 62d day, the left pre-auricular region of the "bonnet chinois" became slightly elevated, and a small subcutaneous nodule, hard, irregular and painless, was detected. The same lesion was observed on the other monkey, but the nodule was smaller. During the next two days the lesion increased in size in the case of the first monkey and the skin became

⁵ Lepra, vol. v, Fasc. 3.

adherent and of a dark red color. On the 4th of February, a new lesion appeared in the same animal, consisting of two small red nodules seated in the pavilion of the ear and a cordlike induration uniting the two lesions could be felt.

From this time until the 11th of February the appearance of the lesions has remained the same, while their size has somewhat increased. The preauricular nodule of the "bonnet chinois" was then excised. Microscopically the corium showed several small nodules made up of accumulations of lymphocytes and of mononuclear leucocytes. There were no giant cells, nor was there any trace of caseation, and the vessels did not appear to participate in the inflammatory process. The leprosy bacilli were in comparatively small number, situated solely, or almost solely, in the cells. They contained one or two or several leprosy bacilli, while one that was seen contained a dozen. Large lepra cells filled with an enormous number of bacilli, such as are found in man, were not seen. This is the only difference, and the writer thinks it may have been due to the difference in age. In these cells the leprosy bacillus had its ordinary characteristics; it was usually rather short — shorter than the tubercle bacillus. Most of the bacilli were deeply stained by the Ehrlich method, and some presented the well-known granular aspect. The writer concludes that there is no doubt that the disease produced was leprosy, and offers hope that the experimental study of this infection will become possible in the future. Experiments were being made to determine if this lepra of the monkey was re-inoculable upon the infected monkey and could be re-inoculated from this animal upon a new monkey.

THE INFLUENCE OF LIGHT IN THE PRODUCTION OF CANCER OF THE SKIN.⁵

Hyde discusses the various theories of the etiology of cancer, observing that a decided reaction seems at last to have set in against the tide that bore in the direction of its parasitic origin. Many of the bodies which it was once thought were parasites have been proved to be irregular cell inclusions. Hyde's purpose in the present paper is to draw attention to a certain group of facts which give promise to the lines of future advance. The idea was suggested by a recent study of three cases of xeroderma pigmentosum.

It would seem that xeroderma pigmentosum offers an object lesson for the study of cutaneous cancer. The disease is uncommon, only about 100 cases being on record. (While the disease is rare, many typical cases have not been reported, so that it is not so exceptional as these figures would indicate. Rep.) It begins usually in the second year of life as a cutaneous hyperemia followed by a pigmentation of the exposed parts of the body, which takes the appearance of brown or black freckles. There is hyperemia of the lids, conjunctivitis and photophobia.

After the freckles, angiomas begin to form, which, interspersed with the freckles give an extraordinary variegated appearance to the skin. Finally, verrucous growths appear on the affected parts and, later, epitheliomatous growths, usually multiple and often of a most malignant nature. The malignant growths may occur at an early age or the disease may run quite a long course, before a fatal termination.

Unna and others who have studied this question claim that this chain of events is due to the weakened resistance of the skin of the young child to the more refrangible rays of the solar spectrum, the hyperemia and pigmentation being simply different endeavors to paralyze the injurious influence of light, the surface hyperemia acting like the red light of the photographer in excluding the ultraviolet and blue rays. In this case then we have a true formation of cancer in childhood directly due to the more refrangible rays of the solar spectrum and limited to the exposed parts of the body at first.

Carcinoma of the sailor's skin has also been described, in which the ears, cheeks, temples, backs of the hands become at first pigmented, later verrucous and epitheliomatous. Here the histological appearances are quite similar to those of xeroderma pigmentosum.

As in these instances cancer occurs obviously as a result of exposure to light, the question naturally arises whether all cutaneous cancers are not influenced by the actinic rays. The physiological and pathological effects of ultra-violet rays, x-rays, the Becquerel and radium rays are similar. They produce in the skin, first, hyperemia, second pigmentation, third atrophy, fourth "cancerosis." Telangiectasis often occurs as a secondary consequence. The first two changes are obviously protective in character.

The senile skin is instanced in which the well-known pigment deposits may be regarded as an effort to protect the integument from the chemical rays to which the subject has become extraordinarily susceptible.

An examination of the census reports of the United States for the year 1900 shows that a large proportion of the deaths from cancer of all organs in males occurred among people who have an out-of-door occupation, and of these men who are engaged in agriculture afford the greatest number. It is not believed that this is due to greater exposure to the weather, as has been maintained, as the farmer is practically not as much exposed as are other classes among which cancer is not prevalent. Those who work in atmospheres of extreme cold are not subject to cancer of the skin. Cancer is almost unknown in Iceland, Greenland or the Faroe Islands. In Alpine regions the "cold burn of the face" is due to exposure to the ultraviolet rays and not to frost. That heat rays are not responsible for the preponderance of cancer among those with out-of-door occupations is suggested by the immunity reported in the inhabitants of Arabia, Egypt and North and South Africa. If this is true, the most natural explanation is the

⁵ J. Nevins Hyde: *Am. Journal of the Med. Sciences*, January, 1906.

protection afforded by the colored skin of the large part of these inhabitants.

It is further shown by figures that in the United States the inhabitants of cities suffer less from cancer than does the rural population, also that it is more prevalent in the northern than in the southern states. A map is inserted showing graphically that cancer is most prevalent in the eastern, central and northwestern states.

The writer's conclusions are:

1. The skin of the human body in a certain proportion of individuals, and in these only, is hypersensitive to the action of the actinic rays of the spectrum.

2. This hypersensitiveness may be exhibited in the production of either hyperemia, pigmentation, telangiectasis, atrophy, hyperkeratosis or cancerosis of the skin, or by all, at times, in a determined order of succession.

3. In the form of childhood cancerosis known as xeroderma pigmentosum, the pigmentation, telangiectasis, atrophy, hyperkeratosis and cancerosis of the skin resulting from exposure to rays of light are exhibited early in life, instances of this disorder being exceedingly rare.

4. Pigmentation, telangiectasis, atrophy, hyperkeratosis and cancerosis of the skin occur in adults much more frequently than in childhood, reaction to the play of actinic rays of light upon the surface being chiefly determined after the middle period of life has been reached.

5. Physiological pigmentation of the skin in the colored races seems to furnish relative immunity against cancerosis of that organ.

Reports of Societies.

THE MEDICAL JURISPRUDENCE SOCIETY OF PHILADELPHIA.

STATED MEETING, MONDAY EVENING, MARCH 19, 1906, AT 8.15.

The President, DR. HENRY W. CATTELL, in the Chair.

QUACKERY: WHAT ARE WE GOING TO DO ABOUT IT?

The above title was the subject of an address by Hon. CHAMPE S. ANDREWS, official counsel of the Medical Society of the County of New York. Mr. Andrews described the laws of the state of New York and their successful application against illegal practitioners in the metropolis, and gave suggestions for similar action in this city.

A great cause of surprise is the fact of the different classes of society interested by the quack: The lawyer from one view; the doctor from an entirely different standpoint; the student of religions from a still different view. There is much to attract the sociologist and the criminologist. Among the different branches of the healing art which the quack in his various parts took up were mentioned those of the occultist; the water-curst; the electropath; the fraud pure and simple, who claims to be a physician; the osteopath; the vitapath; the fraud who practices on the consumptive poor; the so-called specialist in diseases of men; the patent medicine quack. Mr. Andrews recounted specific instances of quackery and of arrests. One instance was that of a Mrs. Browning Weaverson,

who belonged to a cult which claimed to cure disease by the application of human waste. The patient was a woman of sixty years of age with cancer of the leg. For five days a plaster composed of human waste of the patient had been applied. Gangrene had set in and the patient was at the point of death. Another was that of a Jew named Benjamin, who practiced among the women of the East Side, claiming to have a drug which cured sterility. About twenty-five women had appeared in court who had taken the drug, the effect of which was to cause a swelling of the abdomen.

The midwives were said to be the most difficult class of quacks to convict. They are most effectively reached through the post-office authorities. The water-cure fad seems to dominate the German section. A curious fact brought out in these trials is that almost every quack when brought into court has somebody who has been deceived into believing that he has been greatly benefited. Among the electropaths was one Roher, who had established a diploma mill, operating chiefly among Swedish immigrants. Fifty of these graduates had been convicted. Roher was himself the head of what might be called the massage trust of New York. He is an example of the men who use electricity and claim that they are free from the medical law. In this class are the quacks who have the so-called electric chair, electric shoes, electric trusses, etc. There was mentioned in this class the illustrious case of "Professor Hildreth," who supplied the magic boot. This man, formerly a cobbler, had a list of twenty diseases which he claims to cure. The chief victims are those suffering from congenital hip disease. One room, which he called the chamber of horrors, was filled with braces taken off of patients originally applied in scientific hospitals in New York. When arrested, he had in his safe sixty contracts, each calling for one pair of boots at \$500. Few quacks have done so much harm as this one. An account was given of the Koch quack who had represented himself as being associated with the celebrated Dr. Koch. Action has been brought against him which will make impossible the existence of the Koch Lung Institutes.

A case of special interest was that of a carpenter, rejected for life insurance on account of a slight condition of the kidneys, who had fallen into the hands of one Kane, who was professing to cure by the use of radium. He greatly exaggerated the man's condition, but said that if he could afford to buy of him a certain quantity of radium, which would cost \$10,000, he could cure him. The man actually did get together \$9,872, which he paid the quack, being treated for about a year. An arrest followed for grand larceny, and the man is now serving a term in the penitentiary. A vial filled with a greenish-colored fluid, claimed to be the so-called radium, and which had been taken from the safe of the quack was shown. The vial was about an inch and a quarter in diameter, and the part which was said to have cost \$10,000 was about an inch in depth.

The professional abortionist will not give drugs because this makes his conviction easy. It was said that Mr. Jerome has been petitioned to have the law amended, making it a crime to offer or contract to perform an abortion. Under the present law the offender must be caught red-handed to be convicted. Mr. Andrews said that when every state shall have a comprehensive medical law, the profession will have a medical instrument which will enable them to check the practice of almost every class of medical quackery, except the man who is a charlatan inside of his own profession. In referring to the attitude of the newspapers toward quackery, it was the opinion of Mr.

Andrews that in their acceptance of the advertisements of the so-called specialists in diseases of men, abortionists and patent medicine dealers, active assistance was given to the evil. He believed the time would come when the newspapers would be obliged to give up these advertisements, as some were now voluntarily doing. The president of the Board of Health of New York has sent to the County Society over one hundred complaints against illegal practitioners. A police officer is detailed to the work of the Society and does nothing else. The court sets aside a day in the week for the trial of these cases. There is the problem of much work to be done with but a small amount of money, but Mr. Andrews believes that the profession of New York will awake to the necessity of asking the general public to contribute toward the carrying on of the work which in reality affects the general public more than the profession. While much has been accomplished, Mr. Andrews believes that if the work were neglected for twelve months, the city would be again overrun with quacks. He believes there should be some organized body behind the movement, some concentric effort made to enforce the laws. He urges the formation of an organized body with a charter under the general corporation laws of one of the states. Should the American Medical Association, organized as it now is in every state of the Union, undertake the splendid work of suppressing the quack, he believed the work would be attended with much success.

Dr. SAMUEL G. DIXON, health commissioner of the state of Pennsylvania, thought the time had come when the members of the profession should present to the legislature a bill empowering the state Medical Examining Board to revoke the license of a physician practicing as a charlatan or a quack. He felt that physicians should take as much pride in having a high standard of honesty and honor in the profession as did the members of the Bar. In his opinion the law makers are ready to pass laws forbidding the sale of medicine unless the label be printed in full, detailing the formula.

Dr. JOHN B. ROBERTS said he did not believe that the patent medicine or the quack evil is entirely a disease of the community, but a disease, to a certain extent, of the medical profession. The ease with which the public is duped by those whom intelligent men in general call quacks, he said, is partly the result of quackish men in the professional ranks. The essence of quackery, he stated, is a boastful assertion of skill and infallibility, and a desire to obtain large sums of money for treating disease. The sick often seek the advertising doctor and believe the false assertions of the patent medicine label, because they have found the medical men known to them to be incapable, inefficient, or so exorbitant in fees that help seems impossible at their hands. The family which can obtain efficient medical aid for a moderate fee never at home does not often drift into the hands of the recognized quacks.

Dr. Roberts declared that the college which graduates an ignoramus, the state examining board which gives a license to an unfit applicant, and the physician who places an unjust value on his services, or who deceives his confiding patient, are potent agents in encouraging quackery. Some years ago, he said, the alumni of various medical schools were obliged to compel their alma maters to stop the output of half-educated graduates, and the profession has had need to be on the alert that medical examining boards did not permit improper men to obtain licenses to practice. These sources of supply of quasi-physicians, Dr. Roberts said, had now been pretty satisfactorily checked. There remain, however, the secret remedy

prescribers, the commission-giving consultant, and the big-fee doctors to be disciplined by the medical profession itself.

Dr. HENRY BEATES said that the inability to carry out successfully the prosecution of quacks is due to the feebleness of the Act of Assembly governing such matters. Efforts had been made to so amend the present law that to the usual fine there should be added a term in the penitentiary; also conferring the power to revoke the license of a practitioner who carried out quackish methods. These attempts to elevate the standard, he said, had met with opposition from every commercial medical college in the state of Pennsylvania. In connection with Dr. Roberts's reference to illiterate graduates, Dr. Beates read the remarkable answer given by an applicant for state license to a question propounded by the Medical Examining Board. It showed absolute lack of knowledge of the subject. Dr. Beates strongly urged the organization of a movement to correct the evil of quackery.

THOMAS W. BARTOW, Esq., of the Philadelphia Bar, said that if an organized effort were made to prosecute offenders in Philadelphia as was being done in New York, there must of necessity be a change in the police rule; for, while in New York a day each week is given by the courts to the work of the Society, in Philadelphia, were an arrest made, it would take from thirty to sixty days to secure an indictment and probably six months to obtain conviction.

Dr. S. SOLIS CORNEI said that it was especially difficult to control the evil when men who are looked up to as leading lights, founders of colleges, etc., use their political influence against the effort. He felt that the medical profession as a whole, and the medical press in particular were not free from contamination with the patent medicine evil. He expressed the hope that those interested, not of the medical profession, would point out to the newspapers the wrong they were doing in printing many of the objectionable advertisements. Until the medical press was clean, he felt that the profession could not work in this direction. He doubted whether the American Medical Association were the body to lead in an organized movement against quackery; but felt that it might properly co-operate with a national body such as the lecturer had suggested, and that it would be quite proper for the Philadelphia County Medical and other bodies of physicians interested in the work to co-operate individually and collectively with such an organization.

Regarding the suggestion of so amending the medical laws that a license may be revoked, he thought it would be unjudicious to place such power in the hands of any other body than a court, and that a license should be revoked only by order of court after a full judicial hearing.

Dr. BENJAMIN FRIZZER said that there were as many quacks in geology and chemistry, possibly, as in the practice of the healing art. They were not, however, perhaps so well known. He felt that Dr. Dixon could speak authoritatively of the different kinds of professions entirely permeated with quackery. He felt that the practical application of the ideas suggested by Mr. Andrews to other professions than those of medicine would be of much value.

Dr. DIXON, referring to Mr. Bartow's mention of police laws of Philadelphia, said that the state now has a law sufficiently broad to cover the questions under discussion.

Dr. ANDREWS, in closing, said that while it was well to discuss such problems, they could only be solved by hard, conscientious and efficient work. His plea was for practical beginnings, which were bound to come to full fruition.

Recent Literature.

The Physical Examination of Infants and Young Children. By THERON WENDELL KILMER. M.D., Adjunct Attending Pediatricist to the Sydenham Hospital; Instructor in Pediatrics in the New York Polyclinic Medical School and Hospital, New York; Attending Physician to the Summer Home of St. Giles, Garden City, New York. Illustrated with 59 half-tone engravings. 12mo. Pp. 86. Philadelphia: F. A. Davis Company, Publishers.

The author states in his preface that he "makes no pretense as to outlining physical diagnosis nor pathological conditions of any kind whatsoever; his only aim is to instruct the student and physician how to examine a baby." He has not, however, adhered as strictly to his text as he might have done. We think it would have been better if he had written a larger and more comprehensive treatise, as this one is, from its small size, necessarily incomplete and unsatisfactory. The photographs and methods of examination are, on the whole, good. We are glad to see that the author approves of a stethoscope with a small bell, rather than of the phonendoscope or the naked ear, and that he includes a tape measure in his outfit. We do not approve of the percussion hammer in preference to the fingers in the examination of infants and do not believe that the infant's back can be satisfactorily auscultated while it is lying on its face. The examiner in Fig. 29 appears to be listening to the liver. We doubt the correctness of the areas of the absolute cardiac dullness as portrayed in the photographs and are surprised that the more important relative dullness is not given. While many other criticisms might be made, this little book is fairly good as far as it goes and should prove useful to beginners.

Materia Medica, Pharmacy and Therapeutics, including the Physiological Action of Drugs, the Special Therapeutics of Disease, Official and Practical Pharmacy, Minute Directions for Prescription Writing and Avoiding Incompatibility, also the Antidotal and Antagonistic Treatment of Poisoning. By SAM'L O. L. POTTER, A.M., M.D., M.R.C.P., London. Formerly Professor of the Principles and Practice of Medicine in the Cooper Medical College of San Francisco; author of the "Quiz-Compend of Anatomy and Materia Medica," "An Index of Comparative Therapeutics," etc. Tenth edition. Revised, and in greater part rewritten. Philadelphia: P. Blakiston's Son & Co. 1906.

This well-known book does not need an extensive review. The present edition has been largely rewritten and is brought into accord with the new (1905) United States Pharmacopeia. It is well arranged and contains a mass of information. In its scope it covers more ground than most books on the same subject.

A Textbook of Human Physiology. By ALBERT P. BRUBAKER, Professor of Physiology and Hygiene in Jefferson Medical College. Pp. 715. Philadelphia: P. Blakiston's Son & Co. Second edition. 1905.

Since the first edition of this textbook, reviewed in these columns last year, Professor Brubaker has taken the opportunity to prepare additional statements relating to the chemistry of the proteids and of digestion, the movements of the intestines, the production of lymph, the nerve mechanism of the heart, and the physiology of vision. These additions have been made to the second edition.

Lippincott's New Medical Series. Edited by FRANCIS R. PACKARD, M.D., The Medical Diseases of Infancy and Childhood, with points on the Anatomy, Physiology, and Hygiene peculiar to the Developing Period. By ALFRED CLEVELAND COTTON, A.M., M.D., Professor of Pediatrics, Rush Medical College, University of Chicago; Attending Physician for Diseases of Children, Presbyterian Hospital; Consultant to the Central Free Dispensary, etc. Pp. 670. Philadelphia and London: J. B. Lippincott Company. 1906.

It is impossible to review a book of this size in detail. The arrangement is unsatisfactory and the terminology bad, diseases and symptoms being hopelessly confused. While it is easy to pick out minor defects, the text on the whole is very satisfactory. The book is full of good sense and sound advice. It is fully up to date in every way. The author is a little too much inclined to give all the theories on debatable points and not quite willing enough to commit himself as to his own opinions. The directions for treatment are practical and rational.

A Reference Handbook of the Diseases of Children. For Students and Practitioners. By PROF. FERDINAND FRÜHWALD, of Vienna. Edited, with additions, by THOMPSON S. WESTCOTT, M.D., Associate Professor of Diseases of Children in the University of Pennsylvania. Octavo volume of 553 pages, with 176 illustrations. Philadelphia and London: W. B. Saunders Company. 1906.

As we have already remarked about several other books recently translated from other languages, it hardly seems worth while to translate second-rate books into English when there are first-rate books in English and in other languages. This book is distinctly second-rate. Much stress is laid on the alphabetical arrangement with numerous cross references. This seems to us sufficient of itself to condemn the book. Much space is given to treatment which is much more elaborate and more heroic than that commonly used in this country. We fear that it would not agree with American babies. The illustrations are excellent and to the point. The additions by the editor, Dr. Westcott, are very good. We regret that Dr. Westcott did not write a book himself instead of translating some one else's.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, MAY 24, 1906.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
 120 BOYLSTON STREET, BOSTON, MASS.

CHANGE OF PUBLISHERS. ANNOUNCEMENT.

BEGINNING with this issue the JOURNAL will be published by D. C. Heath & Co., of Boston. This firm has long been favorably known as a publisher of books relating to education, and has recently begun the publication of medical books. It has, therefore, seemed fitting to the managers of the JOURNAL that its publication should be undertaken by a concern which has the best interests of medicine at heart. In making this change there will be no radical alteration in the long-established policy of the JOURNAL as an independent medical organ owned and controlled by a board of medical managers, except in the way of such gradual expansion as we trust its continued success will both justify and necessitate. We bespeak, therefore, the loyal and increased patronage of the medical profession.

REPORTS OF PUBLIC INSTITUTIONS. PAUPER INSTITUTIONS DEPARTMENT AND BOSTON INSANE HOSPITAL.

UNDER the increasingly unfortunate and misleading title of the Pauper Institutions Department, the ninth annual report of the institution at Long Island has recently appeared. We have continually protested against the use of the term "pauper" in connection with an institution which has become essentially a hospital for chronic disease. Nothing could more definitely indicate this hospital tendency than a perusal of this report, which is taken up essentially with a consideration of the medical needs and medical statistics of the institution.

The trustees draw attention to the increasing

feebleness of the population and to the fact that the character of the entire institution is steadily progressing toward that of a great chronic hospital requiring enlargement and improvement along hospital lines. Although a virtual distinction is made between the hospital department and other buildings, it is pointed out that some of the wards in the dormitories are to all intents and purposes hospital wards. It is also worthy of note that nearly nine hundred cases, or practically 75% of all admissions, were sent directly to the hospital, which must be regarded as a most significant fact. The tuberculosis problem at Long Island is not a new one, nor is it one easily to be met under existing conditions. Complete segregation at present is absolutely impossible owing to lack of room, so that both men and women are of necessity cared for in general wards. It should be borne in mind that the erection of a consumptive hospital elsewhere will not relieve Long Island to an appreciable extent. It is not to be supposed that patients will not be forthcoming in spite of whatever provision it is proposed to make for them elsewhere. If they are admitted, they should be segregated far more than is at present possible. The trustees have done all in their power toward this end, but without more room palliation of the present condition must remain imperfect.

The situation regarding the training school for nurses also demands attention. The nurses' home is too small; more nurses are needed, not only because of the exceptional difficulty of the work they are called upon to do, but also because the nursing staff has not kept pace with the increase in hospital population.

The report of the visiting medical staff is largely a reiteration of what has often been said before, but which must be repeated until the public is awakened to the full necessities of the situation. The staff again urges the establishment of a hospital for chronic disease, which shall absolutely exempt its patients from the stigma of pauperism. There is no more important question than this before the trustees of the institution and through them before the people of Boston. The time must be near at hand when disease of whatsoever character shall be looked upon as worthy of the most enlightened care under the best obtainable social status. It is worthy of comment that the resident house officer staff has been increased from four to six, and that the visiting medical staff has also been increased, which has conduced to greater regularity of visits and to improved care of the patient.

During the past year Dr. Abner Post has resigned his position on the staff. Dr. Post was the first to be appointed when the medical reorganization of the Long Island institution was undertaken, more than ten years ago. The institution owes much to his wisdom and foresight in the early days of the attempt to establish hospital methods. In general, it may be said that apart from the misleading name the Long Island institution to-day stands as a hospital of high rank. Its complete recognition as such should be quickly forthcoming.

The ninth report of the trustees of the Boston Insane Hospital likewise indicates progress in that part of the city's work. We find a small increase in the number of patients treated over that of the preceding year, with the usual and justified complaint of lack of room. Facilities for the treatment of the increasing number of patients is demanded both in the men's and women's department. The trustees urge further that the land now under lease should be owned by the hospital. It is also suggested that small buildings on the colony system be erected for certain of the men patients. Dr. William Noyes has succeeded Dr. Edward B. Lane as superintendent. It will be remembered that Dr. Lane resigned his position some time since under stress. Dr. Noyes in his report calls attention to a recent law which extends from sixty days to six months the time during which patients may be away on trial visits without necessitating new commitment papers. This is a step in advance and should tend toward a juster estimate of the final mental conditions of the patients.

NEW YORK BAY POLLUTION BILL.

MAYOR McCLELLAN, of New York, has signed a bill, passed by the recent legislature, known as the New York Bay Pollution Commission Bill, which provides for a commission to consider means for protecting New York Bay from pollution. This bill is the result of the labors of a previous commission, of which Dr. Daniel Lewis, recently the head of the State Department of Health, was chairman, and Dr. George A. Soper, the well-known sanitary expert, one of the members. This original commission was appointed in 1903 to investigate certain matters connected with sources of pollution and a special threatened defilement of the waters of New York Harbor. It spent two years in investigating the questions at issue, presenting its report to the Governor in April, 1905. The bill

then proposed was not, however, introduced into the legislature, as the session was too near its close, but, under authority of Chapter 701 of the Laws of 1905 the life of the commission was extended to April 30, 1906.

The bill which now goes into effect provides for the appointment by the Governor of a new commission of five members, three of whom are to be engineers, who shall serve until May, 1909. In connection with a similar commission which the state of New Jersey is to be asked to appoint, they are to prepare and submit by the expiration of their term of service an outline plan for the initiating and governing of a permanent metropolitan sewerage commission covering portions of both states, New York and New Jersey, that final body to have powers of investigation and planning for the future disposal of sewage or other polluting matters which now do and which must for some years to come continue to reach the waters of New York Harbor. The new commission is to be known as the New York Metropolitan Sewerage Commission, and, in addition to the five appointed members, the state engineer and surveyor, the state attorney-general and the Mayor of the city of New York are by the terms of the bill constituted members of the commission. To provide for the expenses of the commission the city controller is authorized to sell corporate stock to the amount of \$16,000.

The members of the commission will receive no salary, but are to be paid their necessary expenses incurred in the prosecution of their duties, and the five citizen members are each to be paid a reasonable *per diem* compensation, to be determined by the Governor, for the time actually and necessarily employed on the work of the commission. It is sincerely to be hoped that this commission will succeed in devising at as early a date as practicable a comprehensive plan for future development, to safeguard the health and comfort of a vast population. While similar boards for drainage and water questions have been established in Massachusetts, the peculiar and important interstate conditions involved in the present instance have not had to be taken into consideration by them.

MEDICAL NOTES.

AMERICAN CLIMATOLOGICAL ASSOCIATION. — At the twenty-third annual meeting of the American Climatological Association, held in Atlantic City, May 12-14, the following officers

were elected for the ensuing year: President, Dr. Thomas Darlington, of New York City; vice-president, Dr. Frank Fremont Smith, of Washington, D. C.; secretary and treasurer, Dr. Guy Hinsdale, of Hot Springs, Va.; councillor, Dr. E. L. Shurly, of Detroit. Dr. E. L. Trudeau, of Saranac Lake, and Dr. Leonard Weber, of New York, were elected honorary members. The next meeting will be held in Washington, D. C., May, 1907.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, May 23, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 41, scarlatina 29, typhoid fever 8, measles 83, tuberculosis 50, smallpox 0.

The death-rate of the reported deaths for the week ending May 23, 1906, was 19.80.

BOSTON MORTALITY STATISTICS.—The total number of deaths reported to the Board of Health for the week ending Saturday, May 19, 1906, was 214, against 198 the corresponding week of last year, showing an increase of 16 deaths and making the death-rate for the week 18.75. Of this number 116 were males and 98 were females; 210 were white and 4 colored; 137 were born in the United States, 66 in foreign countries and 11 unknown; 49 were of American parentage, 139 of foreign parentage and 26 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 34 cases and 5 deaths; scarlatina, 26 cases and no deaths; typhoid fever, 6 cases and 2 deaths; measles, 85 cases and 1 death; tuberculosis, 43 cases and 21 deaths; smallpox, no cases and no deaths. The deaths from pneumonia were 33; whooping cough 3, heart disease 25, bronchitis 4 and marasmus 5. There were 11 deaths from violent causes. The number of children who died under one year was 35, the number under five years 60. The number of persons who died over sixty years of age was 50. The deaths in public institutions were 74.

There were 2 cases and 2 deaths reported from cerebrospinal meningitis during the week.

A GIFT TO THE BOSTON CITY HOSPITAL.—The children of the late Mrs. A. Shuman have recently given to the Boston City Hospital a large collection of books to be placed in the wards. This gift is to be known as the Hetty Lang Shuman Memorial Library and starts with twelve

hundred volumes. A fund has also been deposited with the city treasurer, the interest of which is to be used for the purchase of new books and for other purposes pertaining to the library.

MASSACHUSETTS MEDICAL SOCIETY, MIDDLESEX EAST DISTRICT.—Officers, 1906-07: H. G. Blake, M.D., president; C. W. Harlow, M.D., vice-president; Harold A. Gale, M.D., secretary; Charles Dutton, M.D., treasurer. Councillors: G. N. P. Mead, M.D., F. E. Park, M.D.; S. H. Parks, M.D.; R. T. Edes, M.D.; A. H. Cowdrey, M.D. Censors: F. E. Park, M.D., Supervisor; M. A. Cummings, M.D.; E. S. Jack, M.D.; G. F. Dow, M.D.; W. H. Keleher, M.D. Auditor: Lilley Eaton, M.D.

DARTMOUTH MEDICAL COLLEGE ALUMNI ASSOCIATION.—At the annual meeting of this Association, held at Concord, May 17, the following officers were elected: President, Dr. W. A. McGrath, of London; first vice-president, Dr. R. V. Baketel, of Methuen, Mass.; second vice-president, Dr. D. R. Goodhue, of Springfield, Mass.; secretary and treasurer, Dr. H. N. Kingsford, of Hanover.

ONE HUNDRED AND FIFTEENTH ANNUAL MEETING OF THE NEW HAMPSHIRE STATE MEDICAL SOCIETY.—The one hundred and fifteenth annual meeting of the New Hampshire State Medical Society was held in Concord, May 17 and 18. There was an unusually large attendance. Dr. F. A. Stillman, of Concord, presided and delivered the annual address. The House of Delegates organized for business with a majority of the delegates present. Its meetings were largely occupied with a consideration of the question concerning the acceptance of contract work by members of the society. After considerable debate, the delegates reported to the society in favor of the enforcement of the policy of expelling from membership in the society all those who persisted in performing contract work. This includes professional work of that character in connection with fraternal societies. The annual banquet was held at the Eagle Hotel, about two hundred members being present. Dr. G. P. Conn, who has served the society as secretary for thirty-seven years, retired from that office. The following officers were elected: President, Dr. Ira J. Prouty, Keene; vice-president, Dr. John H. Neal, Rochester; secretary, Dr. D. I. Sullivan, Concord; treasurer, Dr. D. M. Currier, Newport; neurologist, Dr. L. I. Graves, Pennacook.

NEW YORK.

ANNIVERSARY OF MT. SINAI HOSPITAL TRAINING SCHOOL FOR NURSES. — On May 15 the training school for nurses of Mount Sinai Hospital celebrated its twenty-fifth anniversary and on this occasion sixteen young women were graduated. Three of the graduates were recipients of the Murray-Guggenheim scholarships, amounting to \$1,000 each.

FORTIETH ANNIVERSARY OF ST. BARNABAS'S HOSPITAL, NEWARK, N. J. — The fortieth anniversary of the founding of St. Barnabas's Hospital, Newark, N. J., was celebrated during the second week in May. It is stated that by painstaking efforts the endowment fund of the institution has been nearly doubled within the past two years, and now amounts to about \$80,000. In connection with the anniversary exercises, on May 9, the new nurses' home, erected at a cost of \$23,000, was formally opened.

REPORT OF SANITARIUM FOR HEBREW CHILDREN. — The twenty-eighth annual report of the Sanitarium for Hebrew Children has just been issued. The objects of the Society controlling the sanitarium, and of which Dr. Samuel Kohn is president, are to give free trips on land and water to destitute and sick children of the Jewish faith and to supply them with medical attendance. During the year 1905, 2,028 patients were treated in the sanitarium, as against 1,513 in the preceding year, and about 20,000 children were taken on seashore trips. At the annual meeting on Jan. 9 the need of an additional building was presented, and Mr. Jacob H. Schiff headed the subscriptions for this purpose with a gift of \$10,000. Since then a sufficient fund has been raised, and the new building is now rapidly approaching completion. It will be large enough for 175 beds, making the total capacity of the institution 335 beds. The sanitarium is located at Rockaway Park on the Long Island shore.

EXTENSION OF WATER SUPPLY OF NEW YORK. — The State Water Supply Commission of which Ernst J. Lederle, ex-President of the City Health Department, is one of the members, has unanimously approved, with some slight modifications, the plan of the city's commission for an extension of the water supply of New York into Ulster County, at an estimated expenditure of \$160,000,000. The city, before it takes possession of lands in the area required, must pay to the owners a sum equal to half of the assessed value of the property, make compensation for buildings or improvements on lands entered, and also pay

damages for decreasing the value of property, as well as for the deprivation of employment to persons engaged in manufacturing establishments the business of which may be injured or destroyed. This approval by the State Commission permits of the beginning of the work at once.

CONDEMNATION OF POLICE STATIONS. — The Health Department has officially condemned thirty-three police stations in the Borough of Manhattan, and unless the Board of Estimate and Apportionment is willing to provide \$2,000,000, which Police Commissioner Bingham has requested for new stations, the Department may close the stations as public nuisances and compel the city to provide temporary quarters for prisoners and for the sleeping accommodations of policemen. This would be an enormously expensive as well as unsatisfactory makeshift. The action of the Health Department in the matter may be regarded as a triumph for the Society of Medical Jurisprudence. The bad condition of the police stations, in which the plumbing and other arrangements are in violation of the provisions of the Sanitary Code and most of which are very old buildings, was first brought to the attention of the Society in a paper by former City Magistrate Ommen, who became familiar with the unsanitary conditions during his official service. The Society at once took action, and the President, Dr. Carl Beck, appointed Judge Ommen chairman of a committee to make a full investigation. Dr. R. W. Wilcox acted as medical expert on this committee and in due time an elaborate report was presented, setting forth that the thirty-three police stations now condemned were unfit for human use and calling upon the Health Department to take official action in the matter.

Obituary.

DR. ESTHER H. HAWKES.

At a special meeting of the New England Hospital Medical Society, held May 21, 1906, it was

Resolved, That in the death of Dr. Esther H. Hawkes, of Lynn, Mass., the Society has lost one of its oldest and most honored members, whose life has been an inspiration and example to successive generations of medical women.

Resolved, That while deploring this loss to the profession, we also extend to her family our sincere sympathy in their bereavement.

Dr. Hawkes was born May 6, 1834, and died at the age of seventy-two, May 7, 1906.

Dr. Hawkes served as surgeon in the Civil War, assisting her husband, Dr. J. M. Hawkes.

BLANCHÉ A. DENIG, *Secretary*,
New England Hospital Medical Society.

Miscellaneous.

OPENING EXERCISES OF LABORATORIES OF THE ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.

THE opening exercises of the laboratories of the Rockefeller Institute for Medical Research were held at four o'clock on Friday, the 11th of May, in the new building, a five-story structure of stone and brick, plainly but practically constructed and equipped with every form of apparatus needed for the carrying on of its work. The location is at Sixty-sixth Street and Avenue A, on a high bluff which overlooks the East River, Blackwell's Island and Long Island, and covers twenty-six and a half city lots.

The assembly rooms were somewhat small, but filled, together with the main hall leading from them, with an audience, many of whom were men active in progressive medicine and in general scientific pursuits. Among these outside New York were Mr. Henry Phipps, Dr. W. W. Keen and Dr. Flick, of Philadelphia, Dr. John S. Billings, Dr. D. C. Gilman, of Washington, and Dr. H. P. Walcott, of Boston.

The exercises were opened by a few remarks by Dr. Wm. H. Welch, of Johns Hopkins, the president of the Board of Directors of the Institute, who then introduced the first speaker, Dr. L. Emmett Holt, secretary of the board. In his address Dr. Holt gave a sketch of the development of the Institute and told of the early work done in its establishment, outlining in brief the policy. In part he said:

"In considering what use should be made of the funds at first placed at its disposal to make them immediately productive of some scientific results, and at the same time, to get a general view of the field, the board decided not to centralize work in a single place, but to create a number of scholarships or fellowships to be distributed in existing laboratories throughout the country. In this way it was hoped several ends might be attained; first, to enlist the co-operation of various investigators in different places; secondly, to aid some promising lines of research which could not be continued for lack of funds; and, finally, to discover who and where were the persons who desired to undertake research work and what were their qualifications.

"From a large number of applications received, twenty-three grants were made to eighteen different laboratories in this country, and three men were sent abroad to pursue special investigations, two in Ehrlich's laboratory in Frankfurt and one in Koch's Institute in Berlin."

The laboratory building was begun in July, 1901, after eighteen months of study and thought over the plans, during which time five of the directors visited Europe in order to profit by the experience of other institutions of a similar character, and was completed a few weeks ago, representing an outlay of about \$320,000.

In 1903 Dr. Simon Flexner was elected director of the laboratories, and at that time having a staff of four men under him. The present staff is composed of the following persons:

Department of Pathology and Bacteriology: Drs. Simon Flexner, E. L. Ohne, H. Noguchii, J. L. Sweet, H. S. Houghton, Department of Physiology: Drs. S. J. Meltzer, John Auer, Department of Chemistry:

Drs. P. A. Levene, W. Beatty; Resident Fellows and Scholars: B. F. Terry, zoology; R. D. McLaurin, chemistry; Chas. A. Roniller, chemistry; E. H. Shore, bacteriology; Bertha J. Barker, bacteriology.

Many applications for positions in the Institute have been received from England, France and Germany; but the feeling of the Directors has been that it was the American type of mind with its genius for practical results that was wanted, and this has made the board doubtful as to the wisdom of choosing European heads for any of its departments. Many young men and women were found in this country with evident capacity, yet few possessed necessary training which should fit them to work independently. With each year's experience, the conviction has steadily grown that the Institute must in large measure train its own staff, selecting from the promising young applicants such as give evidence of a special fitness and giving them subsequently such training both here and abroad as would fit them for their special work.

To get in close touch with such a class, a number of resident scholarships and fellowships have been created. For these, thirty-one applications were received during the present year and five have been awarded. This plan, if successful, will be continued, and from this corps, from time to time, will be recruited the future workers of the Institute.

The present organization provides for the following departments: Pathology, Bacteriology, Physiology and Pathological Chemistry, Physiology, Comparative Zoology. To these it is expected that a department of Experimental Therapeutics will soon be added.

The fully organized staff will consist of a chief director and a head for each of the different departments. Each head will have his associates and corps of assistants. The heads of departments, associates and first assistants it is expected will constitute the permanent staff of the Institute. The other workers will be less closely attached. Besides, there are contemplated scholarships and fellowships for workers who may come for a limited period; and, finally, it is expected to provide for a limited number of voluntary workers who will be given the facilities of the Institute for working out, under supervision, their own problems.

While the purpose of the Institute will be research, not instruction, it cannot fail to exert a considerable influence in medical education, since many of those who will receive their training within its walls will, doubtless, go elsewhere to assume positions of responsibility in teaching institutions.

The present scientific staff consists of fourteen persons; the laboratory building when fully equipped, will furnish facilities for about fifty workers.

Much work must always be done in the fundamental subjects of chemistry, biology, physiology and pathology, for upon these basic sciences, future discoveries in medical science must largely rest. While fully realizing the importance of these and liberally providing for them in its laboratory, the Institute aims at the same time to keep close to the practical side, and will endeavor to apply the latest discoveries in science to problems connected with the prevention and cure of disease. In order that the greatest good may be accomplished along these lines, the board realizes that a hospital closely affiliated with the Institute is indispensable. Only in this way is it possible for those who work in the laboratory to appreciate the relation of their work to the problems of practical medicine.

From the very beginning the Institute has sought not to monopolize the field, but to cooperate with possible workers with existing agencies for medical research in this country.

While it has been impossible to tell from that a signi-

proportion even of the suitable ones asking for assistance, still an average of twenty grants has been made each year, and much excellent work done which otherwise could not have been undertaken.

With the opening of a central laboratory for research in New York, these foreign grants will necessarily become a less important part of the work. It is not, however, the intention of the Institute to discontinue them altogether. The board hopes always to be ready with a grant of money or by sending a trained man, to assist in the solution of any important emergency problem which may arise in connection with the public health in any part of the country.

After Dr. Holt's address, Dr. Welch delivered his masterly presentation of the "Triumphs of Preventive Medicine," making an eloquent appeal for scientific work in this country. He spoke of the necessity of the laboratory as a means of advancing medical science and the stimulus to research work resulting from the establishment of such institutions as the Rockefeller Institute, The Memorial Institute of Infectious Diseases in Chicago, the Phipps Institute for Tuberculosis and the Carnegie Institution, and said that these represented the beginning of a new science of medicine in America.

President Eliot, of Harvard University, made an address upon the "Needs, Methods and Rewards of Research Work in Medicine." He said in part:

"Biological research is more arduous than physical, chemical, or other inorganic research, because vital processes are difficult to observe accurately, and all the conditions of experimentation are harder to control. The medical investigator must often fish in troubled waters; and sometimes he cannot find again the promising fishing ground he has once visited, because unexpected fog prevents him from seeing the intersecting bearings of his desired ground.

"Medical research habitually strives to arrive at something beyond abstract truth. It seeks to promote public and private safety and happiness, and the material welfare of society. Its devotees have in mind the discovery of means of remedying misery or warding off calamity; and they also know that whatever contributes to health and longevity in any community or nation contributes to its industrial prosperity; so that they are justified in hoping for results from their work which will promote human welfare. In short, medical research is research in science which is both pure and applied. Some genuine scientists affect to despise applied science; and certainly it is not discreditable to men of science that they are apt to value discoveries which have no popular quality or commercial utility more highly than those which immediately attract the favor of the multitude by their industrial effects, or by their striking novelty combined with intelligibility; but all scientists recognize the fact that medical research is directly related to the largest material interests of the community, such as manufacturing, transportation, sanitation, and the methods of providing light, heat and shelter, and of defending the community against frauds in foods, drinks and drugs. Many of its problems are economic as well as medical, and require in those who study them sound judgment in money matters as well as knowledge of natural law, and skill in scientific methods of inquiry. Medical research, therefore, requires in its devotees a combination of theoretical power with practical power—a capacity for both abstract science and applied science.

* * * * *

"In spite of the fact that medical research involves the suffering and death of many of the lower animals used for purposes of study, the work of medical research is in reality the most human work now done

in the world; for its secondary objects are to prevent disease in men and animals, to defeat the foes of life, to prevent the industrial losses due to sickness and untimely death among men and domestic animals, and to lessen the anxieties, terrors and actual calamities which impair or crush out human happiness. The primary object in medical research, as indeed in all research, is the ascertaining of truth; but these secondary objects are ever before the mind of the investigator, and through them come his greatest satisfactions. These satisfactions ought to be shared by men, who, like the founder of this Institute, promote medical research by the exercise of their sound judgment and good will and by their money. The achievements of medical research since Jenner have been marvellous.

* * * * *

"May not we democrats find encouragement in the humble origin of Franklin, Faraday and Pasteur, and in the contributions democratic America has already made to anesthesia, surgery, the improvement of public water supplies, and the control of Texan fever, malaria, puerperal fever and yellow fever? May we not reasonably expect our country to produce many men like Louis Pasteur's father, a private soldier of the first Empire and a hard-working tanner? In the dedication of his best book the great son said to his father: 'The efforts I have devoted to these investigations and their predecessors are the fruit of thy example and thy counsel.'"

President Butler, of Columbia University, delivered a brief but forcible address upon the importance of the application of scientific methods to the practical problems of daily life.

The ceremonies closed with an informal dinner at the University Club given by Dr. Welch. There were present about forty members of the medical profession and guests. Speeches were made by Dr. W. W. Keen, Mr. Andrew Carnegie, Dr. Billings and Mr. John D. Rockefeller, Jr. One of the interesting features of the evening was the reading of congratulatory telegrams from the Pasteur Institute and from Ehrlich's Institute in Frankfort.

THE LABELLING OF DRUGS AND FOODS.

An act has been passed by the Massachusetts Legislature and signed, relative to the labelling of certain patent and proprietary drugs and foods, which should meet with the general approval of the medical profession. We append the bill in detail.

Be it enacted by the Senate and House of Representatives in General Court assembled, and by the authority of the same, as follows:

SECTION 1. Upon every package, bottle or other receptacle holding any proprietary or patent medicine, or any proprietary or patent food preparation, which contains alcohol to an amount in excess of the amount shown to be necessary by the United States Pharmacopoeia or the National Formulary as a solvent or preservative of the active constituents of the drugs contained therein, shall be marked or inscribed a statement of the percentage of alcohol by volume contained therein; and the provisions of section nineteen of chapter seventy-five of the Revised Laws shall apply to the manner and form in which such statements shall be marked or inscribed.

SECTION 2. Every package, bottle or other receptacle holding any proprietary or patent

medicine or any proprietary or patent food preparation shall bear a label containing a statement of the quantity of any opium, morphine, heroin or chloral-hydrate contained therein, provided that the package contains more than 2 gr. of opium, or more than $\frac{1}{4}$ gr. of morphine, or more than $\frac{1}{8}$ gr. of heroin, or more than 8 gr. of chloral-hydrate in one fluid ounce, or, if a solid preparation, in one avoirdupois ounce; and the provisions of section nineteen of chapter seventy-five of the Revised Laws shall apply to the manner and form in which such statements shall be marked or inscribed.

SECT. 3. It shall be unlawful for any person to sell, or to expose or offer for sale, or to give or exchange, any patent or proprietary medicine or article containing cocaine or any of its salts, or alpha or beta eucaine or any synthetic substitute of the aforesaid.

SECT. 4. It shall be unlawful for any person to sell, or to expose or offer for sale, or to give or exchange any cocaine or alpha or beta eucaine or any synthetic substitute of the aforesaid, or any preparation containing the same, or any salts or compounds thereof, except upon the written prescription of a physician, dentist or veterinary surgeon registered under the laws of the Commonwealth; the original of which prescription shall be retained by the druggist filling the same and shall not again be filled.

SECT. 5. The provisions of sections three and four shall not apply to sales at wholesale made to retail druggists or dental depots nor to sales made to physicians, dentists or regularly incorporated hospitals.

SECT. 6. Whoever manufactures, sells or offers for sale any medicine or food preparation in violation of the provisions of this act shall be punished by a fine of not less than five nor more than one hundred dollars. It shall be the duty of the state board of health to cause the prosecution of all persons violating the provisions of this act; but no prosecution shall be brought for the sale at retail, or for the gift or exchange of any patent or proprietary medicine or food preparation containing any drug or preparation the sale of which is prohibited or restricted as aforesaid, unless the said board has, prior to such sale, gift or exchange, given public notice in such trade journals or newspapers as it may select that the gift, exchange or sale at retail of the said medicine or food preparation would be contrary to law.

SECT. 7. This act shall take effect on the first day of September in the year nineteen hundred and six.

A GUIDE BOOK FOR PHYSICIANS VISITING BOSTON.

So many events of national significance have taken place in and about Boston and so many famous institutions have here existed and still do exist, that a guide book for the visiting physicians seemed necessary to the committee of arrangements of the American Medical Association

Such a guide book has been prepared by a sub-committee, and will be one of the features in the entertainment of the guests.

There already exist several good guide books of Boston, notably that prepared for the National Educational Association, which was edited by Mr. Bacon and is now published by Ginn & Co. Quite naturally, however, very little space is devoted in these publications to medical matters.

To surpass these books as efficient guides to historic Boston has not been attempted, but rather to associate with an adequate guide book facts of medical history and historical accounts of medical institutions, in other words, to prepare a guide book of Boston for physicians.

It is hoped that through this book the visitors may become familiar with our crooked streets and may have their attention directed to matters of medical and historic interest. Maps of the city proper and the surrounding country have been inserted, and such interesting localities as Plymouth, Concord and Lexington, and the beautiful North Shore have been featured.

A description of the elevated and surface car lines will be found helpful in understanding a system somewhat confusing to the visitor. Lists of churches, hotels, restaurants and places of amusement, together with a full index, complete a book of about two hundred pages.

A cover design of the Old State House has been drawn by Dr. W. P. Graves, and a tail-piece by Dr. H. H. Gallison, to whom thanks are due for many helpful suggestions.

The advertisements have been carefully selected and only those medical firms which are believed to conduct their business along ethical lines have been allowed space.

An edition of ten thousand copies has been printed and will be distributed gratis to the members of the American Medical Association and their guests.

Correspondence.

FRANKLIN'S CONTRIBUTIONS TO MEDICINE.

CINCINNATI, May 19, 1906.

Mr. Editor. The article in the *Boston Medical and Surgical Journal* of May 10, entitled "Benjamin Franklin's Contribution to Medicine," was very interesting and to the point. What with the proprietary medicine controversy and medical fallacies of the present day it is refreshing to read of Benjamin Franklin, Rush and Physick.

I dare say if those men came back on earth they would be able to prove that the chemical origin of disease has more truth in it than the fashionable malarial origin or so-called germ theory. Certainly, we have a clearer idea of diseases they had our ancestors but the important historical fact must not be lost sight of, that the people of the century in which they lived and worked did, from medical ignorance, suppose some very good theories. Therefore, we would gain by studying Benjamin Franklin with an insight to the germ theory since the two contrary doctrines have been alternately masters from antiquity.

Yours truly, J. M. YOUNG, M.D.

CHANGES IN THE MEDICAL CORPS U. S. NAVY
FOR THE WEEK ENDING MAY 19, 1906.

F. J. B. CORDEIRO, surgeon. Having been examined by a retiring board and found incapacitated for active service on account of disability incident thereto, is retired from active service, May 9, 1906, under the provisions of section 1433, Revised Statutes.

H. C. CURRIE, surgeon. Commissioned surgeon with rank of lieutenant commander from Dec. 16, 1905.

W. S. PITCH, JR., assistant surgeon. Ordered to the "Lancaster."

JAMES MILLER, JR., assistant surgeon. Died at Midway Islands, May 13, 1906.

J. P. HAYNES, assistant surgeon. Ordered to the Naval Hospital, Washington, D. C.

H. L. BROWN, assistant surgeon. Detached from the "Texas" and ordered home to wait orders.

J. D. MANCHESTER, assistant surgeon. Ordered to duty at the Naval Recruiting Station, Cincinnati, O.

R. A. CAMBELLE, acting assistant surgeon. Detached from the Naval Recruiting Station, Cincinnati, O., and ordered to the Midway Islands.

I. S. K. REEVES, assistant surgeon. Ordered to the Naval Hospital, Boston, Mass.

A. H. ALLEN, assistant surgeon. Appointed assistant surgeon, with rank of lieutenant (junior grade), from May 2, 1906.

SOCIETY NOTICES.

THE NATIONAL CONFEDERATION OF STATE MEDICAL EXAMINING BOARDS.—The National Confederation of State Medical Examining Boards will hold its annual convention in Room 240, State House, Boston, on Monday, June 4, 1906. The opening session will begin at 2 o'clock P.M. Dr. Walter P. Bowers, of Clinton, in behalf of the Massachusetts Board of Registration in Medicine, will deliver an address of welcome. Members and ex-members of State Medical Examining Boards, and physicians and educators, who are interested in the cause of higher education, are cordially invited to attend.

AMERICAN SOCIETY FOR THE STUDY OF ALCOHOL, INEBRIETY AND OTHER NARCOTICS.—The thirty-sixth annual meeting of this society will be held in the parlors of the Hotel Vendome, Commonwealth Ave., Boston, Mass., June 5, 6 and 7, 1906. The sessions will be held from 9 A.M. to 10.30 A.M. each day.

T. D. CROTHERS, M.D., Secretary.

ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY.—The twelfth annual meeting of the American Laryngological, Rhinological and Otolological Society will take place at Kansas City, Mo., June 11, 12, 13, 1906. The sessions will be held in the Midland Hotel, corner 7th and Walnut streets. The profession is cordially invited to attend.

WENDELL C. PHILLIPS, M.D., Secretary.

AMERICAN LARYNGOLOGICAL ASSOCIATION.—The twenty-eighth annual congress of the American Laryngological Association will be held at Niagara Falls, N. Y., May 31, June 1 and 2, 1906. The sessions will be held at the New Prospect House. The profession is cordially invited to attend.

JAMES E. NEWCOMB, M.D., Secretary.

RHODE ISLAND MEDICAL SOCIETY.—The Rhode Island Medical Society will hold its ninety-fifth annual meeting at eleven o'clock A.M., Thursday, May 31, 1906, in the Trocadero, 134 Mathewson Street, Providence, R. I.

STEPHEN A. WELCH, M.D., Secretary.

RECENT DEATHS.

JACOB LAFAYETTE WILLIAMS, M.D., M.M.S.S., died in Boston, May 15, 1906, aged eighty-two years.

CHARLES G. WILSON, who for eight years was president of the New York City Board of Health, died at his summer home near Goshen, N. Y., on May 18, at the age of sixty-two years. He was appointed head of the Health Department by Mayor Grant in May, 1889, and it was during his incumbency of the position that the famous "cholera scare" occurred.

Address.

MEDICAL STATISTICS AND THE SANITARY DEPARTMENT OF THE RUSSIAN FORCES IN THE FAR EAST.*

BY JOHN VAN R. HOFF, A.M., M.D.,

Colonel, Assistant Surgeon General, U. S. A. Military Observer with the Russian forces in the Far East, 1905.

The subject of my lecture is "Medical Statistics and the Sanitary Department of the Russian Forces in the Far East, 1905."

The morbidity and mortality bills which the Russian army was called upon to meet from Jan. ²⁸/_{Feb. 10}, 1904, to Sept. ¹/₁₄, 1905, exclusive of Port Arthur, totaled as follows:

The movement of sickness and wastage (from death and disability) among all grades of the (Russian) Manchurian field armies and services in rear of the same, due to wounds and diseases from Jan. ²⁸/_{Feb. 10}, 1904, to Sept. ¹/₁₄, 1905, was as follows:

TABLE I

| Wounded | Sick | | |
|---------|----------------|--|--|
| 3,393 | 7,445 Officers | | |
| 110,362 | 230,027 Men | Sent to hospital | |
| 51 | 14 Officers | From wounds and sickness | |
| 179 | 185 Men | | |
| | 22 Officers | From sudden death | |
| | 631 Men | | |
| 447 | 125 Officers | Died in hospital | |
| 2,861 | 6,065 Men | | |
| 8,237 | 16,018 Men | Discharged for disability | |
| 1,755 | 3,711 Officers | | |
| 57,937 | 111,142 Men | Returned to duty | |
| 1,161 | 2,585 Officers | | |
| 11,635 | 74,713 Men | Evacuated (transferred) | |
| 30 | 1,024 Officers | | |
| 378 | 22,661 Men | Remaining in hospital | |
| 214 | 825 Men | Remaining in convalescent institutions | |
| 3,447 | 7,481 Officers | | |
| 110,841 | 230,643 Men | Total accounted for | |

The foregoing table, which is official, presumably includes every case that appeared on the hospital registers of the armies for which the Medical Department became responsible, together with 1,185 cases of sudden death making a grand total of 352,412 cases. Of these:

8,983 died,
24,255 were discharged for disability,
120,391 were transferred to hospitals west of Lake Baikal,
173,645 recovered, and
25,135 remained under treatment.

352,412

I have no official writing as yet showing the mortality among the cases "transferred." This, with additional statistics, was promised to be sent me here, but I have a note of a personal conversation had with the statistical officer, Sept. 22, 1905, during which he told me that the total mortality from diseases was 18,830 to Sept. 1, 1905. Deducting the 5,142 deaths accounted for in the foregoing table from the number given by the statistical officer and there remain 13,388 deaths which must have occurred among those "transferred," a rate of 173 per thousand. As only serious cases were as a rule sent away from the army, this rate, though high, may be regarded as not excessive. This deduction is, of course, open to correction.

TABLE II

BATTLE LOSSES (RUSSIAN ARMY) DURING THE WAR BY MONTHS *

| Month 1904 | Killed | | Wounded and confused | | Died of wounds | | Missing | |
|---------------|--------|--------|----------------------|---------|----------------|-------|---------|--------|
| | Off | Men | Off | Men | Off | Men | Off | Men |
| February | | 1 | | 2 | | | | |
| March | 1 | 8 | 4 | 16 | | | | |
| April | 26 | 623 | 59 | 1,140 | 2 | 12 | 4 | 171 |
| May | 1 | 56 | 16 | 285 | 2 | 11 | 6 | 71 |
| June | 19 | 628 | 133 | 2,926 | 2 | 73 | 23 | 1,166 |
| July | 27 | 974 | 180 | 5,320 | 12 | 114 | 10 | 428 |
| August | 91 | 2,244 | 177 | 15,179 | 26 | 326 | 18 | 1,957 |
| September | 107 | 2,433 | 174 | 16,817 | 24 | 212 | 23 | 2,408 |
| October | 84 | 1,812 | 106 | 13,511 | 22 | 540 | 18 | 2,526 |
| November | 2 | 98 | 21 | 708 | 6 | 91 | 1 | 28 |
| December | 11 | 140 | 59 | 704 | 12 | 49 | | 63 |
| 1905 | | | | | | | | |
| January | 49 | 1,670 | 178 | 10,746 | 23 | 212 | 25 | 1,277 |
| February | 204 | 7,638 | 145 | 47,272 | 35 | 640 | 282 | 28,156 |
| March | 7 | 181 | 40 | 1,165 | 20 | 659 | | 225 |
| April | | 103 | 13 | 484 | 1 | 206 | 1 | 58 |
| May | 4 | 68 | 10 | 331 | | 88 | | 28 |
| June | 3 | 51 | 24 | 405 | 5 | 41 | | 40 |
| July | | | 11 | 287 | 3 | 10 | | |
| August | | | 19 | 150 | | 6 | | |
| Total | 667 | 18,830 | 1,770 | 117,707 | 201 | 1,340 | 421 | 39,308 |

* Exclusive of Port Arthur.

† Of these officers, 486 remained on duty.

‡ Of these men, 7,143 remained on duty.

The foregoing table accounts for 181,223 cases of which 19,167 were known to be killed and 3,511 died of wounds, making a grand total of

Killed 23,008
Wounded 121,186
Missing 39,729

The extraordinarily large proportion of missing is accounted for by the fact that the Russians, having been driven from every battle field, were forced to leave their dead to be buried by the Japanese, and as there were no means of identifying the Russian dead the Japanese could not bury them as "unknown" and the Russians carry them as "missing."

It is not to be presumed that any considerable number of the Russians deserted to the enemy, they could hardly expect a hospitable reception from the Chinese, and they could not get home, so it is safe to assume that practically all "missing"

* Lecture I, before the United States Army War College session of 1906.

Russians were buried on the battle field. As this fact is not susceptible of absolute proof, in making my estimate of "killed" I shall have to depend upon the statistics of other wars to reach a reasonable basis of calculation.

But before proceeding to a discussion of this question I will submit the following table of Russian losses by battles.

war" is 23,008, or, killed and missing, 62,737, of which we may assume from German experience that 37,642 were killed, making a total of

37,642 killed,
121,486 wounded, and
25,095 missing.
184,223

TABLE III.

| | | Killed. | | Wounded and contused. | | Missing. | | * Strength. |

| Lesser battles and skirmishes | | 42 | 843 | 439 | 11,529 | 46 | 593 | |
| Total | | 667 | 18,800 | 3,779 | 117,707 | 421 | 39,308 | |

* The strength is given on the authority of General Kuropatkin.

Assuming that the proportionate losses at the battles of Liao Yang, Sha-ho and Mukden, are a fair index to the proportionate losses in other battles it is not difficult to deduce the real strength of the Russian army in every battle nor to arrive at a reasonable conclusion as to total proportionate losses. The total casualties (exclusive of prisoners) in the specified battles were 21.45% of the strength given by Kuropatkin.

Of this total:

10.5% were killed,
61.5% were wounded, and
25 % missing,

or 1 killed to 2.5 missing, to 6.5 wounded.

The statistics of the German army in the war of 1870 show a loss of but 4.12% of the total force engaged, of which 0.75 were killed, 2.83 wounded, and 0.54 missing, or, roughly, 1 missing to 1.5 killed to 5.66 wounded. If then we assume the German figures as proportionately applicable to the Russian army we must take from the "missing" and add to the "killed" enough to make the proportion of 1 to 1.5.

By reference to table No. I it will be seen that 3,541 cases of wounds died in hospital and quarters, and it is more than likely that a proportionate number of the 13,388 estimated mortality among "transferred" cases died from wounds—but of these I have no record—and will leave them out of consideration in this report. Add the 3,541 wounded cases to the 19,467 killed, and the total dead from the "legitimate results of

I find it difficult to believe, assuming all the Russian prisoners in the hands of the Japanese to have been identified and reported, which I understand is the case, that 25,095 "missing" Russians are still in the land of the living. Yet this seems to be the only acceptable basis on which to work and I will therefore adopt it.

By reference to table No. I and comments thereon it will be seen that up to Sept. 1-14, 1905, 18,830 soldiers had died from disease, which is almost exactly one to two dead from battle injuries. It may be safely assumed that this proportion will not vary by more than a small fraction when the final statistics are compiled, and it stands as the best sanitary record up to this war.¹

The Russian losses by arms of the service are found in Table IV.

The military population which furnished the following statistics has been variously estimated and generally overrated until after Mukden, since which battle it has probably been underestimated by all except the two most interested nations. I have no statistics as to the Russian strength before the date of my arrival in the far East, but I have the unofficial statement of General Kuropatkin which may be accepted as authoritative. He says (the reasons are not here necessary to enumerate) that "in spite of our [Russian]

¹ It may be of interest to compare these statistics with those of the Japanese army given in the *Review of Reviews*, November, 1905, p. 584: February, 1904, to May, 1905, 43,892 killed; 145,524 wounded; total, 189,416. Died in hospital from wounds, 9,057; from disease, 11,992; total deaths from wounds, 52,946; from disease, 11,992.

apparent superiority in number of battalions we were always numerically inferior to the enemy. Thus at Liao Yang we had altogether 135,000 bayonets, at Sha-ho 115,000 bayonets, and at Mukden between 275,000 and 290,000, the exact figure has not yet been determined; in spite of this we took the offensive from Mukden well

TABLE IV

| Arm | Killed | | Wounded and contused | | Missing | | Proportional strength of fighting effective Per cent * |
|----------------|--------|--------|----------------------|---------|---------|--------|---|
| | Off | Men | Off | Men | Off | Men | |
| Infantry | 602 | 17,874 | 3,246 | 111,899 | 379 | 37,789 | 84.4 |
| Cavalry | 20 | 366 | 159 | 2,060 | 20 | 395 | 53.0 |
| Artillery | 20 | 427 | 310 | 3,671 | 15 | 747 | 7.0 |
| Engineers | 1 | 34 | 42 | 282 | 2 | 126 | 3.0 |
| Frontier guard | 10 | 98 | 15 | 312 | 3 | 196 | 0.6 |
| Other services | 2 | 2 | 7 | 14 | 2 | 54 | — |
| Total | 667 | 18,801 | 3,779 | 117,707 | 421 | 49,308 | — |

* I am indebted to Major Macomb for the estimate of proportional strength. Other services embrace the non-combatant branches, the strength of which is 10% of the fighting effective.

knowing that the enemy was superior in number.† Add to the foregoing 16% to cover the other combatant forces present in these battles and we find that the Russians had at

| | |
|------------|---------|
| Liao Yang, | 156,600 |
| Sha-ho, | 168,200 |
| Mukden, | 346,100 |

Aug. 20, 1905, the chief medical inspector told me in conversation that the combatant strength east of Baikal was \$70,000.

Oct. 2, 1905, the statistical officer informed me that the total strength of the Russian forces east of the Lake on that date was

| | |
|---|-----------|
| In the field, | 729,000 |
| Elaps and rear, | 112,000 |
| Pre-Amur district, | 116,000 |
| En route from Russia, | 80,000 |
| | 1,037,000 |
| Add 10% for non-combatant services in the theater of war, | 95,700 |
| Grand total, | 1,132,700 |

From these statistics it would appear that during the year 1905, Russia sent to the Far East nearly 800,000 soldiers or an average of 100,000 per month, and at the time of the declaration of peace had assembled an army numbering more than eleven hundred thousand men, almost every one of whom had been transported over a single-track railway for more than five thousand miles.

Wounds were inflicted by different missiles in the following proportion (per cent):

| | Rifle | Shrapnel | Shell |
|-----------|-------|----------|-------|
| Officers, | 74 | 11 | 18 |
| Men, | 79 | 13 | 8 |

Wounds from cold steel are almost negligible in spite of all that has been said of night attacks and bayonet charges. It is estimated that in 1,000 cases of Russian wounded, 17% suffered from saber or bayonet wounds. Of this number

17% were inflicted by the saber and 82% by the bayonet. In other words in the total number wounded (113,755) about 2,000 were the victims of cold steel,—340 receiving saber and 1,660 bayonet wounds. I presume if the "dead" and "missing" had been examined this proportion would have been maintained. The extraordinarily large proportion of wounded by artillery fire is certainly impressive. No other war has shown 29% of all wounded officers and 21% of men placed *hors de combat* by this arm. Wolseley says (Soldier's Pocket Book, p. 121): "According to the German medical returns the number of all ranks in the German army killed and wounded by rifle bullets during the war of 1870 was 6,969 killed and 49,093 wounded, whilst by artillery fire the numbers were 695 killed and 4,389 wounded; that is, out of every 100 men (wounded) 91 were hit by infantry and 9 by artillery fire." The chief surgeon writing from Gungalin, Sept. 2, 1904, in concluding a report on the action of the Japanese jacketed bullet says: "But all this bears no comparison with the progress made in the artillery arm. On the 17th and 18th of August [Liao Yang] our [Russian] artillery fired more than 100,000 shells and the Japanese artillery by far exceeded this. The havoc wrought by the latter can only be recalled with a shiver. The wounds caused by artillery fire were terrible and usually fatal."

It is interesting to note that the Russians report but 3,008 dead, of the wounded treated in hospital, and 533 of those in quarters. This is exclusive of the dead from wounds of those transferred to Russia, which, if in the same proportion numbered approximately 1,120, or a total of 4,661, in 113,755 wounded. The reported "killed" numbered 19,467 and the "missing" 39,729, which may be counted as killed; we have then:

TABLE V

| | Killed | Per cent of killed | Wounded | Per cent of wounded | Dead in hospital and quarters of wounds | Per cent of total wounded |
|-----------|--------|--------------------|---------|---------------------|---|---------------------------|
| Russians, | 59,967 | 57.4 | 113,755 | 43.8 | 4,661 | 4 |
| Japanese, | 44,892 | 42.6 | 145,527 | 56.2 | 9,054 | 6 |

* This includes the missing but not the Prisoner of War statistics.

These figures are significant or would be if we knew all the facts and suggest the following questions:—Proportionately

Why were 12% more Japanese wounded than Russians?

Why were 14% more Russians killed than Japanese?

Why did one-third more wounded Japanese lie in hospitals than did wounded Russians?

Being glad that at the results of the military work of the Russian armies in the Far East, let us now consider the means by which these results were reached.

It might be well to state that during the period of my service in Manchuria the entire region

east of Lake Baikal was under the jurisdiction of General Linevich, commander-in-chief; that the troops there were distributed among four armies, indeed five, the first, second and third armies at the front, the rear army and the Pre-Amur District including the Fortress of Vladivostok. West of the lake the line of communication was given over to institutions of the rear and controlled from St. Petersburg, the sanitary department of this region being under command of Major-General Chlinowsky, general staff, stationed at Irkutsk.

Furthermore, it will be remembered that under the Chief of Staff of the army, and indeed of each army, were three departments. Those of the quartermaster general (the duties of which seem to have little correspondence with our quartermaster's department), the adjutant general, and the general of roads and communications, while directly under the commander of the army were the intendants (supplying food, clothing and forage), inspector of artillery, inspector of engineers, chief paymaster and controller (auditor).

Among the subsidiary departments were the sanitary, the judge advocate's, the chaplain's, etc., which according to regulations were under the adjutant general. Practical experience in the field, however, forced an independent organization for the sanitary department with a chief reporting directly to the commander-in-chief.

The Sanitary Department of the Russian Military Establishment has a *cadre* of military officers into which fit the various elements making up such an organization, the principal one of which is the Medical Department, others being the Red Cross, Evacuation, Veterinary Department, etc. The chief of this service in the Far East was General Ivanov, a lieutenant-general of artillery; he was a staff officer of the commander-in-chief and himself had a staff the officers of which represented the various above mentioned departments, the medical department being represented by Medical Inspector Dr. Gorbacevich, civil counsellor. Each of the armies had its own chief of the sanitary department (a staff officer of the army commander) who was a lieutenant-general or major-general, usually but not necessarily of the general staff, with assistants representing the various subdivisions of his department all of whom were more or less independent of each other. The subdivisions were administered in considerable part by combatant officers detailed from the several branches of the service, and the entire organization was conducted on strictly military lines by military officers. The physician's part in this organization was almost wholly within the limits of his own profession, and such administration as fell to him was correspondingly narrowed. To be sure a recent regulation gave the command of field hospitals to the senior physician, on duty therewith, and relegated the combatant officer, detached for duty with the hospital, to the subordinate control of the enlisted personnel, property, train, etc., but as a practical fact I saw not a few hospitals in which the officer commanded, for the surgeon

untrained in and without taste for administration was quite willing to relinquish authority to avoid responsibility, and devote himself strictly to professional and more congenial work.

The strength of the Sanitary Department in the theater of operations at the close of the war was approximately 75,000, of whom at a rough estimate 500 were combatant officers, in rank from lieutenant to lieutenant-general. The physicians numbered something over 3,000.

The units constituting this department of the Russian army in war cease to exist in time of peace as cohesive bodies and are resolved into their elements. The *cadre*, of course, is maintained. The combatant officers are assigned to command the hospitals in which some of the physicians who elect to remain in the service do the purely professional work. There is, to be sure, a medical inspector general, a physician, whose chancery is in St. Petersburg, and who is the custodian of the medical archives. He is the senior colleague, so to speak, of all physicians serving with the army, but outside of those in his office he has little control over them, he is also medical purveyor. Recently he was made a member of the staff of the Minister of War, and in the absence of the latter is authorized to decide questions relating to medical business. Such regiments as are with the colors have surgeons, and the various medical institutions are liberally provided with them, but those who serve in fixed hospitals are usually the medical attendants to the community in which they live.

Practically every physician in Russia belongs to the Reserve until he reaches the age of forty-five years, but, unlike his German *confrère* who must serve in the ranks for a year, no military service is required of him except in case of actual war. Should he desire duty with the forces in peace time he makes application to the Minister of War, whereupon, if his services are needed and his references satisfactory, he is forthwith appointed on probation, without examination, and if satisfactory he is given a permanent appointment and remains as long as it may please him to do so, and his government to keep him, of course within the limitations of age requirements.

This unusual condition of affairs, for Russia is now almost the only nation of any importance that has not a distinct military sanitary corps officered by medical officers with a fixed military status, must not lead to the inference that the physicians employed are not highly educated in their profession, or that Russia in any way falls short of other nations in the care of her soldiers, for this would be a mistake. One cannot reach the doctorate there without giving evidence of high professional attainment.

Russia is too experienced in military affairs to permit herself to be wholly dependent upon the voluntary service of her physicians for medical attendance to her soldiers in peace times, and for more than a hundred years has maintained a military medical academy from the graduates of which have come a considerable percentage of her

army and navy physicians. Any one desiring to study medicine, who has graduated at an approved intermediary school, may enter this institution by paying the regular fees and enter the army or navy after graduating, as can the graduate of any of the seven Russian universities. Most of the students of the Military Medical Academy are beneficiaries of the school, and after the second year receive a stipend from the government in return for which they are obliged to serve at the rate of eighteen months for each year in the Academy, as a beneficiary, a maximum of four and a half years, the whole course covers a period of five years.

One is astonished, upon visiting this institution, at the extent and perfection of its plant: A stately academic building with capacity for 750 students. A completely appointed hospital of 850 beds. A library containing over a hundred thousand volumes and receiving seven hundred current medical publications from the entire world. Anatomical, physiological and bacteriological laboratories occupying a great two-story building. A physico-chemical institution. A botanical garden. A laboratory of hygiene (established in 1865). In addition there is a school for *feldshers* (male nurses), quarters for commandant, who in this institution is a physician, parks, etc.,—all covering an area of one hundred acres in the heart of a great city, and representing an investment of probably much more than twenty million dollars. Surely, this is evidence enough that the Russian army physician must be thoroughly abreast of the latest advances in his profession, and he is.

What is the relation of the medical man to the military body? The physicians attached to the Russian army, many of whom pass their lives in the service, have no military rank; as one of them said to me, "There is a huge book defining our duties, but not a word as to our rights." He seems to occupy a position somewhere between the *chinornik* (civil official) and the officer, he is entitled to wear a uniform (as is almost everybody else in Russia), a sword, epaulets and a cockade on the band of his cap; he is also entitled to a salute, but, like our contract surgeon, he is neither "fish, flesh nor good red herring." Whether he is accepted or rejected socially by the officers depends entirely upon himself, but he is never recognized as one of them, though intellectually he is almost inevitably their superior.

I was told that shortly previous to the conflict in Manchuria, General Kuropatkin, then Minister of War, convened a commission to look into the question of reorganizing the Medical Department and placing it upon the status of like organizations in other armies. He recognized that the first step in this direction was a preliminary military training of the *personnel* and had about determined upon reserving a year's service in the ranks as precedent to appointment in the Medical Corps. He also realized that if the Medical Department was to administer its own affairs its officers would have to be trained in administration, and the regulations giving the

senior surgeon command of the field hospital was the first step in this direction. War came before reorganization was effected. Doubtless a good thing, as the experiences in the Far East will determine important points which before would have been tentative, and a better reorganization will result.

I wish it to be distinctly understood that nothing I have said is to be considered as criticism of my Russian colleague; his work speaks for him; it proves him the peer of the physicians of any nation and for it he deserves well of his country, and the commendation of the world.

What does he get? A physician enters the army in the tenth *Chin* grade, "Titular Counselor," assimilated to that of captain and receives 130 rubles monthly. After four years' service he is promoted to the next grade "College Assessor," assimilating that of major (which office no longer exists in the Russian army) and is paid approximately 160 rubles monthly. In this grade he serves two years, when he becomes a "Court Counselor" (lieutenant-colonel), with slightly increased pay. After three years' additional service he receives the grade of "College Counselor" (colonel with approximately 210 rubles monthly). The next grade, "Civil Counselor" (brigadier-general no longer an office in the Russian army), 250 rubles monthly, is reached after an indefinite period of service, and thereafter advancement is made by selection. There are table allowances, in addition to pay proper which about double the salary.

Dr. Gorbacevich, chief medical inspector of the armies, in the Far East has the grade of "Actual Civil Counselor," assimilating major-general, which is the fourth in the *Chin*; he has served thirty years, and Dr. Speranski, the chief medical inspector of the Russian army, is an "Actual Privy Counselor" of the third *Chin*, corresponding to the grade of lieutenant-general. Increased pay and allowances are given for service outside of Russia proper, and army physicians are allowed to accept other opportunities when such do not interfere with their regular duty. They may be transferred to duty with other branches of the public service.

There is compulsory retirement for age in the Russian army which applies to medical men also. Lieutenants must retire at fifty three years, captains at fifty five, majors at fifty eight, and those of higher grades with exceptions at sixty. Should the army physician have attained the office of medical inspector he continues on the active list after this age. The pension for twenty years' service is equal to half pay of the next higher grade and for thirty years' full pay. When retired for disability the amount of pension is determined by the disability. In addition to retired pay the officer as well as the army physician becomes the beneficiary of an official life insurance which is called "imperial pension." The fund for this pension accrues from a deduction of 6% from the annual pay of all officers, and reaches the beneficiary after he has served twenty five years. Should an officer die or

otherwise quit the service before completing this period, the amount actually paid in is wholly repaid him or in part his heirs, the widow getting half and the minor children one fourth.

Upon the completion of twenty-five years' service the officer becomes a beneficiary and receives an annuity for his life, one half of which is continued to widow and one fourth to minor children. I might add here that the enlisted men receive no pension unless absolutely unfitted for work. The Alexander Committee, founded and endowed by Alexander I, has for its object assistance to the needy military *personnel* including their widows and children. In addition to the endowment the funds of this committee are sustained by sequestering the increased amount of pay of the first three months after promotion of all officers, by concerts, private contributions, etc.

We have glanced at the man, let us now consider the machine as I saw it.

The *field* sanitary organization in all armies is essentially the offspring of war and has practically no existence in peace time. It must to the largest extent be organized at the moment of utilization, and like all new machinery is sure to work roughly and unsatisfactorily in the beginning. At the start it is almost always underengineered, for in the throes of war the most enlightened people seem to lose the capacity to multiply, and occasionally the intelligence to apply, their own experience. Then, too, the engine crew is almost entirely unaccustomed to the machine, and must learn it as it is being driven at top speed.

It would seem that Russian soldiers should be too well versed in the theory and practice of war to fail to anticipate the requirements of a military sanitary department in active service and to meet them in the way best suited to their own circumstances. When Russia's armies were mobilized there was probably no question as to the essential features of the sanitary department, all those had been provided for in regulations, and the *military* importance of the department recognized by placing it under the direction of high ranking military officers.

Nevertheless the Russian authorities in this mobilization did not provide a sufficient *military* hospital accommodation at the front, and must have counted largely on the Red Cross for their armies in the Far East, the military hospitals, as will be seen, having beds for but 8 + $\frac{1}{2}$ % of the fighting effective, whereas from front to base at least twice this number is necessary. I know not why this happened unless it was a question of transportation, and very likely such was the case, as Kuropatkin mentioned that one of the large demands made upon the railroad was for the transportation of the Red Cross institutions, which I am inclined to believe was not taken into consideration in early estimates, but was forced by inadequate *military* hospital accommodation, which latter alone was available for some time after the opening of hostilities. As will be shown later, the Red Cross duplicated the Medical

Department units to the extent of nearly 25%, furnishing hospital beds to the number of approximately 30,000.

Even with the Red Cross reinforcement the hospital accommodation would have been barely sufficient had the war continued on the same scale. We know that the percentage of casualties in at least three of the greatest battles was 21.45, and we know that when peace was declared the Russians had 729,000 men on the fighting line. On this basis the wounded of the impending battle would have been over 100,000, to accommodate which there were scarcely 120,000 beds east of Russia and nearly a fourth of these had been furnished by the Red Cross. At best, not over 100,000 beds would have been actually available, as the others were occupied by the current sick, so that a considerable number of sick and wounded might have been forced into improvised shelter, though not for very long. Without the Red Cross there would have been a breakdown in the Sanitary Department.

The scheme of field organization followed the lines which experience has taught to be the most practicable and which I will now endeavor to describe. It was essentially the same as that of the Japanese which is modeled on the German system.

The sanitary organization directly attached to active units has a continuing existence and is practically the same in peace and war. The regulation allowance of *personnel, matériel* and transport therefor is given in Table VI.

As a matter of fact, there were considerable departures in the Far East from the allowances above mentioned, as was to be expected.

The troop dispensaries or "lazarets," as the Russians call them, are in campaign opened only under exceptional circumstances for the care of hospital cases, such being sent to the field hospitals at once, or as soon as possible, so that all of the sanitary resources of the combatant units may be free and ready to accompany the commands to which they belong. A regimental hospital for the treatment of protracted cases is an anomaly in the field; if it is to accompany its unit it cannot entertain such cases, and if it does not accompany it, then it ceases to be a regimental hospital. On the battle field in the East the Russian regimental sanitary *personnel*, 4% of the combatant force, organized advanced dressing stations (regimental, etc., aid stations) to which the wounded were brought by the company bearers and where they received such treatment as they required or the circumstances permitted.

Every Russian soldier carried a first-aid packet. The officers usually attached it to the scabbard of the sword, as did the man who carried such a weapon. Other soldiers were supposed to have a special pocket in the breeches for the first-aid packet, though as a matter of fact this rule was more honored in the breach than the observance, but a place was always found for it somewhere. I heard nothing but praise for the first-aid packet, and the Russians had a very good one, differing

from ours in that it was without a triangular bandage. Moreover, the soldier used it legitimately and thereby received both positive and negative benefit.— positive because it provided an appropriate dressing and negative because it

prevented the use of an inappropriate dressing, which would surely have happened if a proper dressing had not been available.

The vehicles pertaining to the regimental lazaret were placed conveniently near at hand, under such shelter as might be available and were employed in carrying the wounded back to the main dressing station, formed by the division lazaret.

As previously stated, in all armies the organizations in rear of the firing line which pertain to the Sanitary Department, for the most part come into existence only when the army is mobilized—some as a development from existing elements and some *de novo*. The Russian Military Medical Department in the recent war mobilized the following medical units *per division*:

One Division Lazaret (dressing station and ambulance company).

Eight Field hospitals. (Each for 210 patients.)

The Division Lazaret was the central feature of battle-field sanitation; it was the initial point where began the great scheme of evacuation of the wounded, which involved an intricate organization and exact execution. The regulation *personnel* and equipment of the division lazaret is set forth in the following table:

TABLE VII.
PERSONNEL.

| | Dressing Station | Bearers, Ambulance Co. | Transport. |
|-------------|------------------|------------------------|------------|
| Officers | — | 2 | — |
| Surgeons | 5 | — | 2 |

| Carts, 1-horse, | 3 |
| Wagons, 2-horse, | 15 |
| Ambulances, 1-horse, | 9 |
| Horses for mounts, | 1 |
| Horses, spare, | 5 |
| 27 vehicles | |

The 14th Division Lazaret, actually had 322 personnel, 68 carts, 147 litters, 2 field kitchens, and 4 three-hospital tents.

I found considerable variation in the lazarets of different divisions, both in *personnel*, transport and *material*, and I also found a like variety in the views of the surgeons on duty with this organization as to the exact functions of the lazaret and how its work was to be done. It is but fair to say that no doubt of this existed in the minds of those who had been at the front for some time and had opportunity to see a lazaret at work on the battle field, but those who reached the theater of war after Mukden had not this chance.

The Division Lazaret was the medical headquarters of the division, where the Division Surgeon was to be found and from which he supervised the work of his department. The lazaret established a principal dressing station to which theoretically all the wounded of the division were brought, given such professional treatment as might be absolutely necessary, were fed and finally transferred back to the division field hospitals by the transport column or, as we style it, Ambulance Company.

As nothing but outpost affairs occurred while I was in the Far East I saw no battle field work but heard many stories as to the way it was done.

The Russians had at the beginning no recourse but the Fabian policy of fighting and falling back until time was given them to a smolder their forces and create an army. The fighting always occurred along the line of the railroad and this road was the peculiar feature of the war, without it war could not have been carried on, and yet had it not existed there would have been no occasion

for this war. I have been told that the dressing stations were usually established at some Chinese house or shrine, oftentimes little sheltered from fire and that not infrequently the wounded were sent from them directly to the hospital trains upon which they were loaded and carried far to the rear. Others were taken to the division field hospitals, or to the Red Cross field hospitals, and thence to the hospital trains. The Russians managed to get most of their wounded away, and though some field hospitals remained on the ground, under the Geneva Convention, after the army retreated, the numbers of wounded left behind were comparatively small.

One physician relating his experience at a dressing station during the battles of Sha-ho said: "The dressing station was formed at a convenient point and was somewhat sheltered from fire, though an occasional shell would fall near by, and the location was too exposed to permit the wheeled transportation to approach. The *personnel* consisted of 3 physicians, 3 sisters and 15 'sanitarists' [soldiers]. An attempt was made to organize the station systematically, and conduct it as prescribed in regulations. At first but few wounded presented and the required records were kept, but soon the battle became fiercer, the maimed came in by scores and hundreds, and there was hardly time to render professional aid, leaving wholly out of consideration the keeping of records, so the wounded were bandaged as rapidly as possible and passed to the rear. There was much confusion and disorder, and presently the 'sanitarists' shirked, being worked out, but the surgeons and sisters worked on for twenty-four continuous hours until upwards of two thousand cases had passed through their hands. Such as required it were transferred to the hospital trains." The management of a dressing station, I take it, is no small job. The working of such organizations has been carefully provided for in regulations, reported upon in actual service, and graphically described in romantic literature, but must be seen to be fully appreciated.

The collecting of the wounded, the rendering to them of first aid and their transportation to the dressing stations, was the specific duty of the company and division bearers and no other was authorized to leave the ranks for this purpose. I am told that this regulation was not strictly enforced, that often the wounded were accompanied by other than company bearers, and in numbers in excess of the necessities of the cases. I presume this has been so in every war, and will continue to be, yet it is my conviction that specifically designated and marked company bearers should be part of the war organization of every unit, not only for the efficiency of the work but as a deterrent against one cause of unauthorized absenteeism from the firing line. No company bearer was permitted to go behind the regimental aid station, and his work of collecting the wounded was done under the supervision of a regimental line officer. The transport column, or ambulance company, was responsible for the

transfer of the wounded from the regimental aid stations to the dressing station, for which purpose the regimental medical transport might also be used; it had a liberal *personnel* and transport. The variety of vehicles issued to it were from one cause or another gradually reduced to the simplest form, the *deukolka* or cart, of which there were altogether 64, in the 17th Division 19th Corps, for example, each capable of carrying two patients most uncomfortably. Further details regarding sick transport will not here be considered.

I have stated that the Russians organized eight field hospitals *per* division, each capable of accommodating 10 officers and 200 men, — altogether 8+%. Of these four were mobile and four fixed. Of the four mobile hospitals two were assigned to each division under the Division Commander and two were held in reserve, remaining under the control of the Chief of the Sanitary Service, but in immediate touch with the troops, and always ready to supplement or substitute the divisional hospitals.

The *personnel* and transport of a field hospital were as follows :

| | | | |
|------------------------|----|-----------------------|-----|
| Officer, | 1 | Sisters (nurses), | 4 |
| Surgeons, | 4 | Inspectors, N. C. O., | 6 |
| Pharmacist, | 1 | Bookkeeper, | 1 |
| Priest, | 1 | Clerks, | 3 |
| Reader, | 1 | Ward orderlies, | 25 |
| Feldshers, | 10 | Servants, | 34 |
| Supt'd N. C. O., | 1 | Drivers, | 28 |
| Supt'd Asst. N. C. O., | 1 | | |
| Total, | | | 121 |
| Carts, 1-horse, | 4 | | |
| Wagons, 2-horse, | 19 | | |
| Ambulances, 4-horse, | 2 | | |
| Horses, riding, | 4 | | |
| Horses, spare, | 3 | | |

Sept. 3, 1905, Dr. Gorbacevich told me that he had 280 military hospitals east of the lake, exclusive of divisional hospitals.

On that day there were on the morning report : Surgeons, 2,598; pharmacists, 206, and an average of 6 sisters and 115 under *personnel* in each hospital; total, 38,964.

On the march at least one division field hospital invariably accompanied the troops. Both hospitals marched with the medical section of the divisional transport and were opened for the reception of the ill and injured from the main dressing station in battle, or from the regimental lazarets at other times. The divisional hospitals were required to be evacuated at the first opportunity, and never immobilized for any length of time. They could be emptied into the mobile hospitals immediately at hand, or their sick transferred to the fixed hospitals further to the rear. The fixed or "reserve" hospitals, as they were called, were established on the *clape* or at the advanced base in more or less permanent structures. They had the same *personnel* as the mobile hospitals, like them were designated by a number and at any time might be furnished with transport and become mobile field hospitals. In practice they were often combined, thus making a 420 or 630 bed hospital.

In fortresses, hospital accommodation was pro-

vided for 124% of the garrison. If this was insufficient the regulations authorized the organization of fortress temporary hospitals for 20 officers and 400 men.

Convalescent camps for 50 to 200 men were provided for convalescents, weaklings, slightly wounded, and those not requiring regular hospital treatment, and might be connected with a non-divisional or fixed hospital, or be established separately.

Sanitary convoys, railroad and boat ambulances, field dispensaries, and supply depots were liberally provided.

In addition to the medical units above enumerated there were at the disposition of the commander of the army: (1) All permanent hospitals, military and civil, in the region occupied by the army. (2) Foreign and newly opened hospitals in allied and neutral countries in accordance with special conventions. (3) Hospitals belonging to the enemy taken according to the rules of war, and (4) Medical institutions of the Red Cross societies.

I was informed that there were 93,000 beds in hospitals east of Lake Baikal, and 23,000 in the Irkutsk division, while in Russia proper there was practically no limit to the hospital accommodations. Of the 120,000 invalids who passed through Irkutsk I estimate that 100,000 went to Russia and were cared for there; of these about one third returned to the front.

The lessons to be deduced from the experience of the Russian Military Sanitary Department in the Far East, which I have briefly recounted, are too obvious to require recapitulation before so distinguished an audience. Suffice it to say that the sanitary standards of and the unequalled results obtained by Russia in her war with Japan should make it impossible for any nation to accept from her armed forces lower standards or results.

If such are demanded, and they certainly will be, they can only follow from an adequate, well organized, thoroughly equipped and intelligently administered Sanitary Department.

METHOD OF INSTRUCTION IN THE HARVARD MEDICAL SCHOOL.*

BY FREDERICK C. SHATTUCK, M.D.,
Jackson Professor of Clinical Medicine, in Harvard University.

INTRODUCTION.

DURING the past thirteen years three important changes have been made in the method of instruction at the Harvard Medical School.

1. In the year 1892-93, the fourth-year course became compulsory.

2. In 1899-1900 a new arrangement of subjects taught in the first two years was adopted. The first half of the first year was devoted to anatomy, histology and embryology. The second

half to physiology, physiological and pathological chemistry.

The first half of the second year to pathology and bacteriology, the second half to a variety of subjects preparatory to the clinical work of the third and fourth years. (Hygiene, materia medica and therapeutics, theory and practice, clinical medicine, surgery.)

3. With the class entering 1902 began the third great change, namely, the fourth year became entirely elective, a minimum of one thousand hours being required.

This change was thought to be warranted by the raising of the average grade of students, due to the requirement of a bachelor's degree, or its equivalent, for entrance into the school.

ADMISSION OF STUDENTS. 1901-5.

"Candidates for admission to this school must present a degree in arts, literature, philosophy or science from a recognized college or scientific school, with the exception of such persons of suitable age and attainments as may be admitted by a special vote of the administrative board in each case."

We shall endeavor now to follow a student admitted to the Harvard Medical School through his four years of medical instruction. It will, of course, be impossible to go into a detailed description of each and every course offered, but the main points will be emphasized and especial attention paid to the courses in medicine and surgery.

* Examination at end of first half year.

In the first half of the first year his entire time is devoted to anatomy, histology and embryology. In anatomy he has 80 hours of lectures, 180 hours of demonstration and 180 hours of practical anatomy with recitations — a total of 440 hours.

In histology and embryology the number of hours devoted to lectures is 36, those devoted to laboratory work 208, a total of 244 hours. The total number of hours for the first half year being 684, of this number 116 being lectures, section work, recitations and laboratory work having 568. Having devoted his whole time during October, November, December and January to these subjects, anatomy, histology and embryology, he takes a 3-hour examination in

* The exception above referred to applies only to those who, without such a degree, have acquired an equivalent education and training sufficient to enable them to profit by the instruction offered in the school.

* Read at the meeting of the Harvard Medical Society of New York, Feb. 24, 1906.

each subject and enters upon the second half of his first year.

Here again he devotes his whole time to two subjects: physiology, physiological and pathological chemistry.

In physiology the method of instruction is more varied. He has 43 hours of lectures, 174 hours of laboratory experiments, 40 hours of written tests on selected subjects, 26 hours of conference, 15 hours of special demonstration, 15 hours of recitation and 33 hours of discussion of theses, each student being compelled to write one. The total number of hours he devotes to physiology is 346; of this number 43 hours are given up to lectures, the rest to experiments, conferences, demonstrations, recitations, written tests and discussion of theses.

The number of hours of physiological and pathological chemistry which rounds out his first year is 280. Of this number, lectures and demonstrations occupy 64, while laboratory exercises take 216. At the end of his first year he has a 3-hour examination in each of the two subjects, and after a total of 1,310 hours with four 3-hour examinations he has completed his first year and is ready for his second year.

SECOND YEAR, FIRST HALF.

Entering upon his second year at the Harvard Medical School, our student again concentrates his attention upon two subjects during the first half year,—pathology and bacteriology.

The course in pathology, including neuropathology, surgical-pathology and comparative pathology has a total of 477 hours. These hours are divided into lectures, conferences, demonstrations and laboratory work. Ninety-six of his hours he spends in attending lectures or conferences, while 381 are given up to demonstration sections and laboratory work. He has ample opportunity to see and record autopsies, to examine gross pathological specimens, to study microscopical sections of these and other pathological conditions; lantern slides of the various pathological conditions are also shown daily.

He is taught bacteriology by lectures and practical laboratory work. Out of a total of 160 hours, 40 hours or $\frac{1}{4}$ of his time will be spent in attending lectures, while 120 hours, or the remaining $\frac{3}{4}$, are given up to practical bacteriology.

Having devoted a year and a half of his four, year course to anatomy, histology and embryology, physiology, pathological and physiological chemistry, pathology and bacteriology with a total of 1,947 hours, our student enters the second half of his second year. He now begins to branch out, the concentration which has marked his course thus far becomes less apparent (see Chart) and his time for the next half year will be spent in the study of hygiene, materia medica and therapeutics, theory and practice, clinical medicine and surgery. From now on until the end of his third year he becomes a member of a small section of six or eight men, and his time from 11 to 1 is given up daily to his section work in theory and practice, clinical medicine and surgery.

His time is spent at the various hospitals; he is taught bandaging, to examine blood, sputum, feces and stomach contents, to take clinical histories; all of these examinations controlled by some member of the various departments. He also now begins his physical diagnosis; he has in this section work from 11 to 1 during this half year 88 to 120 hours, instruction.

Surgery, 12 exercises 2 hours each. Clinical medicine, 32 exercises of 2 hours each, and the same in theory and practice.

His course in hygiene, consisting of lectures and demonstrations, comprises 48 hours.

In materia medica and therapeutics he also has 48 hours, the course being resumed in his third year.

In theory and practice he attends lectures on selected subjects by Dr. Fitz. 32 in number during the term, while additional clinical lectures in this department to the number of 48 are given.

In clinical medicine he attends 5 clinics weekly, at the Massachusetts General Hospital and City Hospital, a total of 80 hours; these added to his 48 clinics in theory and practice give him 128 hours of clinical lectures during this half year. Especial care is taken at these clinical lectures, his first ones, that type cases should be shown, He is taught to see, to feel and deduce; his observations and his method of palpation are constantly checked by one or more assistants.

In surgery, in addition to his section work of 24 hours, he has 134 hours of systematic lectures, demonstrations and recitations, with 76 clinical demonstrations illustrating the above.

The total number of hours in the second half of his second year is 554 which, with his 637 hours of his first half year gives him a total for the year of 1,191. The only examination which he takes at the end of this second half year is a 1-hour examination in hygiene, as he continues his study of materia medica, theory and practice, clinical medicine and surgery in his third year.

Much has been claimed for this method of

concentration of work during his first two years. It greatly increases the amount of time which can be devoted to each subject, while monotony is avoided by sufficient variety in the correlated groups. That it is the best method of instruction for many students cannot be denied; that it is a good method for all students is open to doubt. Some students can absorb knowledge by bolting, in others more or less slow mastication is necessary.

Plus 1 month as surgical dresser and 7 to 10 days obstetrics.

*Examination at end of first half year.

THIRD YEAR.

Our student having now finished the so-called concentrated portion of his work enters his third year in medicine. He continues his work in materia medica and therapeutics, theory and practice, clinical medicine and surgery, which he began the last half of his second year, and in addition begins the study of pediatrics, genito-urinary surgery, orthopedic surgery, obstetrics, and the various so-called specialties. He has during this year 15 subjects; at the end of the first half of the year he takes examinations in theory and practice, materia medica and therapeutics, surgery and ophthalmology, a total of 9 hours in examinations.

His hours up to 11 are daily spent at clinics in medicine, pediatrics, surgery, neurology, dermatology, theory and practice, at the various

hospitals. His hours from 11 to 1 are devoted to section teaching throughout the year. His afternoons are spent attending lectures or recitations at the medical school, in obstetrics, theory and practice, surgery, pediatrics and the various specialties. In other words he attends clinics two hours daily from 9 to 11, section work from 11 to 1 and lectures at the school from 3 to 6 daily.

During this year our student is compelled to deliver 6 obstetric cases, spending from 7 to 10 days at either the Boston Lying-in Hospital or the Bennet Street Branch, with the necessary daily visits following the confinements; he has to work for 30 days as clinical surgical dresser in one of the various hospitals assigned to him. He has 16 hours of materia medica, 112 hours of theory and practice, 176 hours of clinical medicine including section teaching, 102 hours of pediatrics including section work, 174 hours of surgery including genito-urinary and orthopedic, with 30 days' additional work as surgical dresser in some out-patient department, 128 hours of obstetrics plus the time required to deliver 6 obstetric cases and care for them afterward, 38 hours in gynecology, 48 in dermatology, 28 in syphilis, 48 in neurology, 16 in psychiatry, 30 in ophthalmology, 24 to 26 in otology, 28 in laryngology (his section work in the various specialties averaging from 8 to 10 hours in each), 16 in municipal sanitation. Six hours in legal medicine are also offered.

At the end of his third year, having had 970 hours, plus 30 days surgical dresser work, plus 7 to 10 days for obstetric work, he takes 11 examinations with a total of 17 hours, or, plus the 9 hours at the end of his first half of the third year,—a total of 26 hours of examination. A glance at the section schedules for the months of October and March will show how large a part this work in small classes plays in the education of our student in his third year. (See section schedules.)

DIVISION OF STUDIES.

Fourth-Year Electives

| | |
|--|--------------------------|
| Anatomy | Surgery |
| Histology and Embryology | Genito-Urinary Surgery |
| Physiology | Orthopedics |
| Physiological and Pathological Chemistry | Surgical Pathology |

| Pathology | Gynecology |
| Neuropathology | Dermatology and Syphilis |
| Hygiene | Neurology and Psychiatry |
| Clinical Medicine | Ophthalmology |
| Theory and Practice | Otology |
| Pediatrics | Laryngology |
| Clinical Surgical Pathology | |

FOURTH YEAR

Our student, entering upon his fourth year, can in a measure elect what he will study. He must have a minimum of 1,000 hours. The general plan of instruction of the fourth year is as follows: Courses are offered by the various departments as half courses. A half course occupies the entire day for one month (the all-day plan, or

the forenoons or afternoons for two months (the half-day plan). Each half course has a value of 125 hours. Eight half courses are necessary to satisfy the requirements of 1,000 hours demanded in the fourth year. The two half courses elected for the first two or last two months must be formed on the same plan to avoid conflict.

63, or surgery as did 61; pediatrics was elected by 58, and theory and practice by 46

Let us suppose that the student, now in his fourth year, whom we have been following, chooses to become a general practitioner, or at least decides not to specialize thus early, he could select a course similar to a course we will call A. If on the other hand, he should

| 6 | 7 | 8 | 9 | 10 | 11 | 12 | | | | | | | | | | | | | | | | | | | | | |

intelligently, and doing so will mark him on a scale of 60 for the examination. He also marks him on a scale of 20 as regards his opinion of the general work of the student, a total of 80%. The thesis also required is marked on a scale of 20%, thus the total mark of 100%. Thus it will be seen that most of the marking is done by assistants.

Adams Syndrome, etc. In addition, once a week he attends a clinical pathological demonstration at the Massachusetts General Hospital, at which time all of the organs removed at autopsies for the week are demonstrated; before the pathological condition is revealed, however, the clinical history of each case is taken up, a probable

COURSE B, SUITABLE FOR SURGEON. 1,000 HOURS.

| | Oct. | Nov. | Dec. | Jan. | Feb. | March. | April. | May. | |
|-------------|-----------|-----------|---------|---------|---------------|--------|-------------|------|------------------------------------|
| A.M. 9-1 | Medicine. | Medicine. | Surgey. | Surgey. | G. U. Surgery | | Gynecology | | or Clinical Surgical Pathology. |
| P.M. 2-6 | | | | | Anatomy | | Orthopedics | | or Surgical Pathology. |

In addition to his out-patient work his course in medicine also includes conferences on out-patient records, where a criticism of the records is made, with discussion upon the differential diagnosis, prognosis and treatment, with reports by students asked to look up doubtful points brought out in the discussion.

He has opportunity under the direction of an assistant to control his examinations in blood, sputum, feces, gastric contents, during this work in medicine, by laboratory exercises.

Thesis work: Our student writes a thesis, taking as a subject, assigned by one of the assistants, either some particular case or group of cases seen by him during his work; sometimes ward cases are given out for subjects; he consults weekly with the assistant, who advises him about looking up the literature of the case, the current as well as the textbook, who looks over, corrects the finished thesis and selects the best ones to be read at weekly meetings of the section in the presence of Dr. Shattuck and assistants. Subjects of present interest are often selected, like the X-Ray Treatment of Leukemia, Our Present Knowledge of Etiology of the Stokes-

diagnosis is arrived at and then the true condition as found at autopsy is shown; if the diagnosis was at fault the reason for this is sought for by review of the case.

In addition he attends weekly lectures upon live medical subjects.

In following our student, now taking course A, that suitable for a general practitioner, after completing his three months in medicine he takes up pediatrics; he spends one month in the wards of the Infants' or Children's Hospital, together with some time spent at the South Department of the City Hospital where he studies contagious disease.

In surgery, his next month, he has ward work, — examination of cases, recording of histories, establishing of diagnosis, etherization of patients, dressing of injuries, wounds and fractures, close observation of operations, seeing the progress of the case with the end result. The out-patient department work consists of establishing diagnosis, treatment of cases under direction and recording histories.

His next month is devoted to obstetrics; here he lodges at the Lying-in Hospital, devoting his

FIG. 10. Showing the characteristic attitude of a patient with subdeltoid adhesions or scapulo-humeral spasm when endeavouring to abduct both arms. Abduction on the affected side is mainly accomplished by rotation of the scapula on the chest wall. The angle between the axis of the humerus and the spine of the scapula is practically the same as if the arm were at the side.

time to attending to out-patient cases; he assists at operations, when his duties permit; makes the daily visit with the visiting physician. In the second half of his course he conducts the convalescence of the cases delivered by him during his resident service, making written reports of the cases; he makes daily ward visits and witnesses operations. The character of his work in the last two months depends upon what courses he chooses to elect, as to whether most of his time is spent in clinical or laboratory work. He could take courses in neurology, dermatology, or gynecology, or various of the more strictly speaking laboratory courses, as histology, physiology or clinical surgical pathology or orthopedics or surgical pathology. The character of the examinations in these various subjects varies within wide limits; they are similar in kind to the examination he takes in his medical months. His daily work counts for a great deal more than formerly, as does also ability to apply his knowledge in a practical way; he would have theses in various of his other electives, as pediatrics and surgery.

After finishing his four years, he receives his degree and then tries for one of the hospitals, not, as formerly, taking his hospital at the beginning or at the end of the first half of his fourth year. He is now compelled to complete his four years of medical study before he becomes eligible for hospital appointment.

It would be interesting to follow our student through his hospital service and up to the time he takes his state examinations. We can judge of the result of his training at the Harvard Medical School by looking at the partial list of graduates from various colleges who have during the past years 1900 to 1904 taken their state examinations, the list taken from *The Journal of the American Medical Association*, May 6, 1905. Out of 134 graduates of the Harvard Medical School taking examinations in 12 states there was not a single one who failed to pass his state examination; we could, therefore, infer with probable safety that the student we have been following would be no less well fitted than those who have preceded him. A partial list of medical schools with the number examined, the number of failures and the per cent of failures is as follows:

ON STIFF AND PAINFUL SHOULDERS.

THE ANATOMY OF THE SUBDELTOID OR SUBACROMIAL BURSA AND ITS CLINICAL IMPORTANCE.* SUBDELTOID BURSITIS

BY E. A. CODMAN, M.D., BOSTON.

It is the purpose of this paper to consider certain cases of obscure lesions of the shoulder joint. These cases are not rare—they are common. Every practitioner sees them occasionally and every large hospital out-patient department, I venture to say, has one or more under treatment at all times. These patients complain of pain and stiffness in the shoulder joint and upper arm. A characteristic complaint is the inability to put the arm back of the neck or behind the small of the back. If women, they cannot do their back hair; if men, they cannot button the back of their suspenders.

I think I have said enough to make you recall the type of case to which I refer. You hear them called "rheumatism," "fibrous ankylosis," "paralysis of the deltoid," "peri-arthritis" and other names. I will speak of the symptoms later in detail.

It is my belief that a consideration of the anatomy and pathology of the subacromial or subdeltooid bursa does much to help us understand the cause of these obscure and annoying lesions and suggests more rational methods of treatment than those usually employed.

ANATOMY

I do not know any book on anatomy to which I can refer you for even a fair description of this bursa. You must go to the cadaver and demonstrate it for yourselves. Anatomists have devoted little attention to it, the reason probably being that its thin walls are easily overlooked in the dissecting room and are not readily demonstrated. You will find it alluded to as the subdeltooid or subacromial bursa or you will find it described as two separate bursae. As a matter of fact it should be called by one name or the other to prevent confusion. I prefer to speak of it as the subdeltooid bursa, because the subdeltooid portion is more important clinically, being more exposed to injury. Even in those cases where a septum between the two is found, they are functionally the same. The point is that this bursa is indispensable in abduction and rotation of the humerus.

Look at this diagram (Figs. 1 and 2.) In order to obtain abduction of the arm the greater tuberosity of the humerus must pass under the acromion process. How could this occur unless a joint existed between these two bones, for if there were no joint or bursa there, the greater tuberosity would carry its roof of deltoid muscle in under the acromion and pinch it. It is easy to illustrate this on the cadaver by stitching the roof of the bursa to its base. It is not difficult to feel on one's own shoulder the rotation of the tuberosity beneath the deltoid fibers and to feel it disappear beneath the acromion when the arm is abducted. Anatomists have been quite insistent on a description of the biceps tendon and the bursa about it,

* Read before the Academy of Medicine at Cleveland, March 17, 1906.

and it is perhaps this point which has distracted their attention from the much larger and more important subdeltoid bursa. The biceps tendon and its serous sheath lie entirely beneath the floor of the subdeltoid bursa and are amply protected from injury by the groove in the humerus in which they lie.

The next diagram (Figs. 3 and 4) shows that the bursa is equally important in rotation of the humerus. It represents a horizontal section just below the edge of the acromion, and is intended to show how the short rotators act in taking up the slack of the joint capsule which is practically composed of the tendons of these muscles. It also shows the necessity for the existence of the subcoracoid bursa which lies between the coraco-brachialis and the subscapularis, for since these two muscles move past one another in opposite directions there must be a bursa between them. It is not uncommon to find this bursa in communication with the subdeltoid bursa.

It has been claimed that there is a normal communication between the subdeltoid bursa and the true joint. This has not been my experience; those cases in which I have found a communication I have regarded as pathological cases, for the reason that this communication has been at the point of insertion of the supraspinatus, which is the point most subject to injury. (Fig. 5.) What the actual percentage is, I do not know, but I think it must be small.

I have said that this bursa has very thin walls; I do not think it could be dissected out as an entire sac because it is so firmly attached to the bony parts of its roof and floor, but it can be readily demonstrated by blowing it up through a fine hollow needle. Its base is formed by the tuberosity of the humerus and the tendons of the short rotators which are inserted into the tuberosity. Its roof is formed by the periosteum beneath the clavicle, the coraco-acromial ligament and the acromion and by the upper part of the fibers of origin of the deltoid muscle. Its limits beneath the deltoid muscle vary considerably, but the outline is apt to be trilobar like a clover leaf and to extend below the edge of the acromion for about an inch and a half at its deepest point. On the whole it is circular in outline, concavo-convex in shape and about the size of the palm of the hand. A very pretty way of demonstrating the bursa is to blow it up with air and then cut carefully down upon it and catch the edges of the serous lining as one does in a laparotomy. If the wound is then held open (Figs. 8 and 9), the shiny surface of the base can be seen passing beneath when the humerus is rotated or abducted. Frequently in doing this one is able to see little folds of serous membrane which roll on themselves like the nictitating membrane in a bird's eye. It is these folds which, acting like partitions, give the bursa its lobulated shape.

PATHOLOGY.

The subdeltoid bursa is a serous space and must be subject to many of the same pathological conditions as other serous spaces, such as other bursæ,

the tendon sheaths, the joints, the pleura and the peritoneum. The unprotected situation of the anterior or subdeltoid portion of the bursa makes it especially liable to direct injury or pressure, and from a mechanical point of view it is the weakest point in the complex mechanism of the shoulder joint. Clinically, the obvious causes of inflammation of this bursa may be enumerated as follows:

- | | | |
|-----------|---|---|
| Trauma. | { | <p>A direct blow on the point of the shoulder, <i>e. g.</i>, a fall.</p> <p>A sudden muscular exertion, <i>e. g.</i>, the effort to protect oneself from falling.</p> <p>Pressure, <i>e. g.</i>, a misapplied bandage. Over use, <i>e. g.</i>, as in a baseball pitcher.</p> <p>Unaccustomed use, <i>e. g.</i>, baseball without proper training.</p> |
| Fixation. | { | <p>Following the treatment of the above minor lesions.</p> <p>Following operations on the breast, hand and arm.</p> <p>Following treatment of fractures of the hand or arm, especially fracture and dislocation of the head of the humerus.</p> |
| Sepsis. | { | <p>1. Non-suppurative infection : <i>e. g.</i>, Acute rheumatism. Gonorrhea. Grippe. (Idiopathic cases.)</p> <p>2. Suppurative.</p> <p>3. Tubercular.</p> |

It is not too much to assume that this bursa, like other bursæ, in response to the insult of trauma, overuse, unaccustomed use or infection, may become inflamed, may become over distended with fluid, may be filled with fibrous exudate or that its contiguous surfaces may become adherent.

The anatomy shows that the smooth action of the adjacent surfaces is necessary for abduction and rotation. Is it surprising that after a blow on the point of the shoulder the patient complains of pain on abduction and rotation and that involuntary reflex spasm holds the joint so fixed that the scapula follows all the motions of the humerus? Is it surprising that if fixation of the arm is maintained for a number of weeks, either through misdirected treatment or the unwillingness of the patient to let those two bruised and inflamed surfaces slide on one another, that adhesion between the two takes place?

Suppose again that overuse is the cause of the insult to the serous surfaces. A baseball pitcher is constantly abducting his arm, carrying the tuberosity in under his acromion and then snapping it out again as he throws the ball. There is a point of friction at the highest part of the tuberosity passes under the acromion, and its continued irritation leads to a "glass arm." When adhesion takes place the arm becomes "shoulder bound."

In other cases the irritation may come from sepsis, from gonorrhea, from sudden exertion or

pressure, but we have a right by analogy to assume the same sequence of conditions: an inflamed serous membrane, reflex spasm, sero-fibrinous exudate and finally adhesion of the surfaces. This is the ordinary life history, I believe, of inflammation of the subdeltoid bursa. When, in the severe cases, adhesion has taken place the pain subsides and the symptom is stiffness due to actual mechanical limitation. At this point nature begins her slow cure. As in the peritonium the adhesions melt away and those that have become organized stretch until at length the normal arc of motion is restored. The prognosis will depend on the extent and degree of the original inflammation and the character of the treatment. It is easy to see also that when fixation in the sling position has been long maintained that the neighboring muscles must show secondary changes. Imagine the difficulty the contracted subscapularis must have to get into the position shown in the diagram (Figs. 3 and 4) in external rotation, and see also the consequences to the tendon of the infraspinatus which is too stiff and inflamed to take up the slack of the capsule.

Up to this point the pathology has been assumed from analogous conditions in other structures. The following facts have been obtained by my actual observation:

1. In a case operated on by Dr. F. B. Harrington there was staphylococcus-bearing pus. The lining of the bursa was dark red, velvety, and at least one eighth of an inch in thickness. It closely resembled the appearances usually found in a septic knee joint.

2. In a chronic case of unknown cause operated on by myself, I found an excess of straw-colored fluid. The lining of the bursa was about as thick as blotting paper, slightly reddened, and the cavity contained numerous adhesions, some of which were stretched into bands between the roof and floor of the bursa. These adhesions did not differ greatly from those seen in chronic peritonitis. I have also seen three similar cases of stretched adhesions in dissecting-room specimens.

3. In five cases on opening the bursa at operation I have found firm fibrous adhesions which effectually prevented abduction until torn. In two cases they were too strong to be separated with the finger and had to be divided with scissors. I have also found this condition a number of times in the dissecting room.

In one cadaver which had the typical limitations of subdeltoid adhesion, I made a careful dissection of all the muscles of the shoulder. Even after dividing all the other muscles and the anterior part of the capsule as well, I found that the subdeltoid adhesions alone maintained the limitation of abduction and external rotation. (This specimen was shown at the meeting.)

4. In two operated cases I found a split in the capsule between the tendons of the supra- and infra-spinatus. I have also seen this in the cadaver.

5. In five dissecting-room specimens I found a condition which I believe to be due to a traumatic partial rupture of the tendon of the infraspinatus.

The condition is illustrated in this diagram. (Figs. 5, 6 and 7.)

6. I have seen a considerable number of x-rays of cases of trauma to the shoulder in which there was evidence that a chip of bone was torn from the tip of the tuberosity at the point of the insertion of the supraspinatus. In one of these cases I operated and found the roof of the bursa adherent over the point of fracture, but the periosteum forming the base of the bursa was not actually torn through, although the fragment could be felt beneath it.

7. In one case operated on and in several cadavers I have found a small area of bare bone on the tuberosity at the base of the bursa. In two other specimens the fibrous tissue on the base of the bursa was shredded, almost exposing the bone.

SYMPTOMS

Clinically, we find cases of all degrees of severity, from mere discomfort in raising the arm to firm ankylosis. To me it seems most convenient to separate four types, although border-line cases occur frequently.

Type I. Acute or Recent Cases.—The essential characteristic of this type is that the joint is locked by reflex spasm (Fig. 10.) The inflamed surfaces no more enjoy friction than do the pleural surfaces in acute pleurisy or the joint surfaces in acute hip disease. Hence active or passive rotation of the humerus cannot be performed without pain except to the extent permitted by the movement of the scapula on the chest wall. There is, however, *always* some motion between the scapula and the humerus both in abduction and rotation; there is *never* complete ankylosis. It is characteristic of inflammation of the subdeltoid bursa that a small amount (about 10°) of painless motion persists in the true shoulder joint. In other words, anatomically the humerus can be moved somewhat without calling into play the inflamed portions of the surfaces of the bursa. A patient with acute subdeltoid bursitis will willingly follow you about the room if you take hold of his hand even without a jin jitsu grip, rather than allow you to rotate or abduct his arm.

Outside of this peculiar limitation due to the anatomical situation of the bursa we have also the usual signs and symptoms which accompany inflammation of any bursa or joint, except that these signs are somewhat more difficult to make out because they must be felt through the deltoid muscle.

Local tenderness will sometimes be definite enough to allow accurate mapping out of the limits of the bursa. This is especially true in cases of inflammatory origin where the whole bursa is involved, but in traumatic cases from a blow on the point of the shoulder or a tear in the tendon of the supraspinatus the tenderness will be greatest at one point. This point is almost always on the greater tuberosity just external to the bicipital groove (Fig. 5.) When the arm is in the straight position this point forms the most prominent part of the shoulder. It is ana-

tomically the weakest point in the shoulder because it is not protected by acromion or clavicle and over it the fibers of the deltoid are particularly thin. Normally this particular point is somewhat sensitive, as you may demonstrate on yourselves. It is at this point too where the greatest stress comes when the supraspinatus is acting as an abductor of the arm, and *vice versa* when the arm is forced down against the action of this muscle.

Pain is a constant symptom and is especially annoying at night. Patients complain that they cannot get into a comfortable position. A curious feature of the pain is its location. Almost invariably it is felt in the distribution of the external or internal cutaneous nerve down the arm from the point above spoken of to the external condyle, passing to the outer or inner side of the biceps muscle. I cannot explain why this is so, unless it is due to involvement of the musculo-cutaneous nerve in its passage through the coraco-brachialis muscle. Possibly spasms of this muscle or inflammation in its substance might cause pressure on the nerve. Perhaps it is comparable to the sacral pain from pelvic disease or shoulder pain in biliary inflammation. Frequently the patient thinks the seat of the trouble is at the insertion of the deltoid muscle.

Demonstrable effusion is not uncommon but is somewhat disguised by the overlying tissues. I have known the pain to become less when the effusion appeared. Frequently, even when effusion cannot be demonstrated, there is a puffy feel much like that which is frequently found in subacute inflammation of the knee joint.

To sum up Type I, we may say that its essential characteristic is scapulo-humeral spasm. Left to themselves the patients maintain the sling position, and I am sorry to say that the average physician encourages them in this for a long time. The result is that the condition tends to become chronic.

Type II.—The characteristic of this type is actual adhesion instead of muscular spasm. Where one begins and the other ends is hard to determine. Full surgical anesthesia is the best test.

In these cases the symptoms are the chronic edition of Type I, except that the extreme type is *painless* fibrous adhesion with atrophy of the shoulder muscles. Some cases complain of no pain whatever and seek advice simply for the limitation of motion. This is not the rule, however, for there is usually some complaint of pain. It is in this stage when the influence of the character of the individual on the course of the disease is most pronounced, for the man who can persist in the use of his tender and atrophic muscles in spite of the soreness has a great advantage over the hypersensitive neurasthenic who has not the courage to stretch his painful adhesions. In some cases the nervous element is so strong that the case passes for neuritis, and much has been written about reflex joint atrophy by neurologists. In some cases these secondary changes in the nerves and muscles almost amount to a real paralysis and simulate lesions of the brachial

plexus or progressive muscular atrophy. Contractures of the fingers are not uncommon in the very severe cases and the forearm may resemble the condition found in Volkman's paralysis.

Even where these alarming secondary changes have taken place, I believe that the primary cause is in the subdeltoid bursa and that proper treatment will eventually bring about cure.

Type III.—The essential characteristic of this type is pain in certain motions, but the ability to carry out the full arc of motion of the joints persists. The pain is felt only in certain positions or motions but is nearly always in that point of abduction at which the tip of the tuberosity passes under the acromion. Sometimes it is called forth by rotary or pushing motions. Sometimes the patient will be unable to produce it when he wishes to demonstrate it to you. Sometimes for days at a time he is annoyed by it and again it will appear to improve.

I have as yet operated on but one case of this type, because the symptoms are seldom severe enough to demand operative interference. I have alluded to this case above as having a thickened serous membrane with occasional adhesions from floor to ceiling. I believe that other cases would show that the trouble was due to such local conditions as those which I have described in the cadaver,—bits of synovial fringe, swelling of the "necrotizing folds," frayed tendon or rough areas of bare bone. In the cadaver these irregular areas are usually found at the above-mentioned point of least resistance, *i. e.*, on top of the greater tuberosity just external to the bicipital groove at the insertion of the tendon of the supraspinatus. These cases when they become worse may pass into Type I or Type II.

Type IV.—Severe traumatic cases in which rupture of the supraspinatus tendon takes place or the facet of bone to which it is attached is torn off. These cases are often seen with subcoracoid dislocation and would more appropriately be discussed with fractures or as a separate paper. The reason that I speak of them here is that they are really ruptures of the base of the bursa and not an uncommon cause of subdeltoid adhesions. One theoretical symptom (since the supraspinatus is put out of action) should be the persistence of passive and loss of active abduction. I am not ready to state this as yet, however, because in most cases the pain is so great that spasm prevents even passive motion and later adhesion takes the place of spasm. When rupture of the tendon does take place it probably is only partial and a Y-shaped attachment still remains to perform part of the function. (Fig. 5.) In a similar way the quadriceps may extend the femur when the patella is broken if the lateral expansions of its tendon are not torn. Nevertheless, I believe that the active function of the supraspinatus is important in elevation of the arm.

DIAGNOSIS.

The most important consideration in diagnosis is the question of whether the true joint is involved or the bursa alone. Cases of pure subdeltoid

bursitis always admit of a few degrees of painless abduction, flexion and extension and internal rotation, even when the scapula is held firmly fixed. When the true joint is involved the spasmoid fixation is nearly absolute. Palpation of the joint from the axilla is also painless in subdeltoid bursitis, while in disease of the true joint, signs of tenderness are elicited.

The relative positions of the humerus and scapula are decidedly different in the two cases if there is distention with fluid. This can be beautifully shown on a dissected specimen by blowing up the joint and the bursa alternately with air. When the joint is distended the angle between the humerus and inner border of the scapula is obtuse; when the bursa is distended it is acute.

The x-ray is a valuable test. Where the articular surfaces of the bones show signs of disease the true joint must be involved.

It is my belief that nearly always when the joint is diseased the bursa is also, but that the reverse is not true. I believe that it will be found that most minor lesions of the shoulder joint involve the bursa and few involve the true joint. This might be expected *a priori* from the mechanical structure of the two, for it is hard to conceive of a better protected, more simply constructed joint than the true joint, or a more exposed, more delicate or more complicated structure than the subdeltoid bursa. On the other hand, severe diseases as tuberculosis or sepsis usually involve them both and the same may be said of severe trauma.

I have intentionally not gone into the diagnosis of other shoulder lesions, such as fractures, dislocations, rupture of the biceps tendon, deep axillary abscess, caries sciea, muscular rheumatism, rheumatoid and osteoid arthritis acromioclavicular dislocation, circumflex paralysis, etc. Subdeltoid bursitis is far more common than any one of these and yet it is usually left out when the others are considered. I venture to say that there are some in this audience who have had it themselves!

TREATMENT.

Type I. The acute cases.—The indications would seem to be to obtain relief of pain and to give physiological rest during the inflammatory stage and when this has passed, to prevent adhesion of the inflamed surfaces.

Some years ago Dr. Geo. H. Monks, of Boston, showed at a meeting of the Suffolk District Medical Society a splint for the treatment of "painful shoulders." The splint held the arm at right angles to the body in internal rotation and abduction. Some cases which he reported showed that he was dealing with the same lesions of which I am speaking, and the relief he described from his splint was striking. I have used his splint for the relief of pain in these cases with good success. A practical substitute is to seat the patient sideways at a table and let him rest his arm on a pillow. This gives great relief. As soon as the pain will allow it, gentle passive

motion should be begun to prevent adhesion. Above all do not allow the patient to maintain his arm in the sling position. Do not put on a Velpeau bandage. It has seemed to me that counter irritants have about as much tendency to promote adhesion as to restrain it. I regret to say that a few years ago I recommended the very treatment which I now condemn.¹

Type II. Chronic adherent cases.—These are the most common cases and, as I have said, vary according to the severity of the original inflammation, the treatment given during the acute stage, and the age, extent and density of the adhesions.

Twenty-four years ago Dr. J. J. Putnam, of Boston, in speaking of these cases as "peri-arthritis," suggested manipulation under ether, and reported gratifying results. The usual treatment in Boston has been according to Dr. Putnam's suggestion in the more severe cases, and passive motion, baking, counterirritants, etc., in the milder cases. On the whole, the results have been poor as far as time and pain are concerned, although ultimate recovery at length occurs. In cases which are etherized and manipulated, the adhesions may be felt to tear, sometimes with alarming violence, so that one suspects fracture of the humerus or rupture of the internal lateral ligament of the elbow. It is my belief that this tearing takes place in the subdeltoid and subcoracoid bursae and possibly also in the older cases in the substance of the contracted shortened subscapularis muscle. The peculiar sensation under the operator's hand, as if the internal lateral ligaments of the elbow joint were tearing, I think may be due to the transmitted vibration of the coraco-brachialis muscle which is stretched like a bow string from the coracoid process to the center of the humerus. As external rotation tears the subscapularis from beneath it, the effect is like that of a fiddle bow on the strings.

The disappointing part after this rupturing of the adhesions is that when the effect of the ether has passed off we find our patient again in the acute stage. Scapulo-humeral spasm again fixes the joint and the patient must show more than ordinary courage if he will permit passive motion again before the adhesions reform. As a rule he hugs his arm in the sling position. It occurred to me that in allowing the patient to thus hold his arm in a sling position, *i. e.*, abduction and internal rotation, we were allowing the raw surfaces which were before adherent, to be again in apposition and that this reunion was favored. Why then should we not carry them as far apart as possible so that each will be opposite a healthy serous surface. This can be done by a modification of the Monks' splint which will hold the arm in abduction and external rotation. (Fig. II.)

In this connection I want to emphasize an anatomical point which is of great importance, although I do not find it in the textbooks. *Complete abduction (abduction of the humerus necessitates external rotation.* Flex your elbow to

¹ BOSTON MEDICAL AND SURGICAL JOURNAL Vol. cl. No. 14 April 7, 1904

a right angle, rotate your humerus inward and try to abduct. When your humerus arrives at the horizontal it will no longer move on the scapula, for the base of the tuberosity impinges on the acromion. Now rotate the humerus outward and you will find that the arm will go into full abduction because the tuberosity rolls out of the way and the concavity of the surgical neck takes its place and does not impinge on the acromion.

FIG. 11. Showing the abduction splint in position, the patient standing. It is held by a figure eight bandage which crosses behind the shoulders and by a belt about the hips. The arm is at rest.

DESCRIPTION OF SPLINT.

The frame of the splint which I use is made of iron wire (diameter one quarter inch), stiff enough to maintain its form and to carry the weight of the arm securely. Sufficient cotton wadding to thoroughly pad it is bandaged over it and the whole covered with cotton or linen cloth. The general shape is shown in the photograph. It should be just long enough to extend from the axilla to the seat of the chair on which the patient sits. It is best held in position by a belt around the pelvis and a figure eight flannel bandage about the shoulders crossing back of the neck. A pad should be placed in the opposite axilla to prevent excoriation of the skin by the bandage.

During the first twenty-four hours and afterwards, if worn at night, the arm should also be lightly bandaged to the projecting part of the splint. Additional security is given by the application of a swathe which may be pinned to the bandage in the axilla.

The corollary of this observation is that in breaking up our adhesions we must not forget to break those that prevent external rotation. I have shown that these might be in the subcoracoid bursa as well as in the subdeltoid. In the position obtained by my splint it would be impossible for the raw surface on the tuberosity to adhere to the healthy under surface of the acromion, and even if it did, when the splint was removed gravity would aid the patient to break any adhesions.

The practical results of this treatment have been good. After the splint has been on for twenty-four hours the bandage on the arm may be removed and without changing the position of the splint the arm can be held up straight in complete abduction with little or no pain. The hand can be placed back of the head and held there by the patient. I have kept the arm on the splint except for daily exercise for periods varying from two days to two weeks. I think that one week is enough and that during the second week the splint should be worn only an hour a day. After this it is necessary to insist that the patient puts his arm through the full arc of motion once a day or more. I have been much aided in the after-treatment of my cases by the use of the Zander apparatus at the Massachusetts General Hospital under the direction of Dr. Max Böhm. These exercises have been of great help in assisting the patient to maintain the mobility of the joint and to strengthen the atrophied muscles. If one has not access to a Zander apparatus the same result can be accomplished by judicious passive movements and active exercises.

It is obvious that even if the adherent surfaces are broken apart and allowed to heal opposite healthy surfaces that we still must cope with the stiffened and atrophied short rotators which take weeks or months to return to their normal strength. My only claim for the use of my splint is that it greatly shortens the period of restoration of function. By preventing the adhesions from reforming it allows us to break the vicious circle and to begin at once to exercise the muscles.

In certain severe cases I have felt that I could better make sure of breaking the adhesions by an actual cutting operation. I feared the manipulation under ether would be more apt to rupture the muscle substance of the contracted subscapularis than to break the subdeltoid adhesions (in fact, in cases of long standing, I believe this rupture of the muscle may occur). In six cases I have made an incision into the bursa (Figs. 8 and 9) on the point of the shoulder between the fibers of the deltoid and have torn the adhesions with my finger before using the leverage with the arm. In two cases it was necessary to divide the adhesions with scissors. In others, after the adhesions of the subdeltoid bursa had been ruptured, I had to break those in the subcoracoid bursa by using the leverage of the forearm in outward rotation. It is during this motion that the peculiar sensation of rupture of the internal ligament of the elbow takes place.

Be it understood, however, that I do not recom-

mend a cutting operation in these cases to a surgeon who has not recently familiarized himself with the anatomy of the bursa. So far, I have seen no ill consequences follow it, for the reason that the postoperative use of the splint has prevented the reformation of adhesions. As a rule, I recommend merely manipulation under ether followed by fixation on the abduction splint.

Type III.—I have no essential improvements to offer on the usual methods of treatment applied to these cases. If they are severe I consider that exploration in the hope of finding a fringe or other irregularity of the bursal surface is justifiable. I have operated on but one case of this kind and was encouraged by the result, although this case was otherwise complicated and was in a particularly unfavorable subject.

Type IV.—Cases of this type when seen soon after the injury might be treated on Dr. Monks' splint or my modification; when seen late in the adherent stage, they should be etherized and put on the splint as in Type II.

If one could make the diagnosis with certainty of rupture of the tendon of the supraspinatus, incision and suture might be considered.

CONCLUSION.

On a number of previous occasions I have made observations on anatomical and surgical subjects which I imagined original. Later I have found that the ground had been covered by others, frequently by some of the famous physicians of my own city. In this case after the observations were made on which this paper is founded, my attention was called to the above mentioned article by Dr. Putnam,² written twenty-four years ago and giving an excellent clinical description of these cases as "peri-arthritis," although not the same explanation of the causes. Eight years later Dr. Monks³ presented to the same society a splint for the treatment of the same cases. The idea of this splint was to relieve pain by maintaining the arm in abduction. At the meeting at which Dr. Monks showed his splint, Dr. Maurice H. Richardson asked Dr. Monks if he had noticed that in these cases the scapula moved with the humerus, and questioned whether the trouble might not be due to adhesions of the subdeltoid bursa. Dr. Monks had not noticed about the scapula, but thought that possibly the bursa had something to do with the disability.

It is evident that my paper is but a combination of these three ideas. If the trouble is due to subdeltoid adhesions (Richardson), the logical treatment is breaking the adhesions (Putnam) and relieving pain by the use of an abduction splint (Monks).

A superficial examination of the literature shows that some of these ideas have also been brought forward by others. Hyperemia of this bursa has frequently been reported. The best article I have seen is by Kuster,⁴ but even he fails

to appreciate the influence of the subdeltoid adhesions on rotation; in fact, he refuses to make a diagnosis of subdeltoid bursitis unless the ability to rotate is present. In italics he says: "Dagegen ist die passive Rotation stets ganz oder fast ganz frie und schmerzlos; und auf dies Symptom lege ich den Hauptnachdruck."

As far as I have been able to find yet, I may claim that my anatomical observation that external rotation of the humerus is necessary for complete elevation of the arm is original. So, also, is the idea of preventing the reformation of adhesions by a splint which holds the arm in abduction and external rotation, thus bringing raw surfaces opposite healthy ones. I hope some of you may be induced to try this treatment, for I am sure that in my own hands it has been most encouraging. If the splint is properly applied, there should be no pain during the day. The discomfort at night is the greatest drawback but is worth enduring for the sake of the result obtained.

Perhaps if you are successful in thus limbering up the motions of the shoulder you may be able to apply this same principle to other articulations, for adhesion of the bursa about them may be the cause of most stiff joints!

I believe it is possible to make new bursa where the normal ones have become obliterated.

DESCRIPTION OF PLATES.

Fig. 1 is a diagram from a frozen section. Notice the deltoid and its origin from the edge of the acromion. Notice the subdeltoid bursa with its roof made by the under surface of the acromion and by the fascia beneath the upper portion of the deltoid. Its base is on the greater tuberosity and the tendon of the supraspinatus which separates it like an interarticular fibro-cartilage from the true joint.

Fig. 2 illustrates the condition which would be found in complete abduction, the tuberosity having passed under the acromion and the point (B) having passed the point (A). The elastic deltoid has taken up the slack on one end and the supraspinatus at the other. It is obvious that the floor of the bursa as it lies on the tendon of the supraspinatus and the tuberosity must be a smooth, even, rounded surface. As a matter of fact, the first time one cuts into this bursa one is almost startled to find how much the floor of it looks like the cartilaginous surface of the bone!

It is obvious that if the surfaces of the bursa between the points A and B in Fig. 1 were adherent, it would be impossible for the joint to pass into the position shown in Fig. 2.

Figs. 3 and 4. A diagrammatic representation of a horizontal section through the head of the humerus to indicate the lateral extent of the bursa and the necessity for its existence to allow the greater tuberosity to rotate beneath the deltoid. Notice also how the tendon of the supraspinatus is stretched around the head of the bone in internal rotation and how the tendon of the subscapularis is stretched around the head in the opposite direction in external rotation. This stretching occurs not in the tendons themselves, which are very short, but in the muscles which, by their construction take up the slack of the capsule of the joint. In fact, the capsule of the joint is really made up of the tendons and muscular bellies of these short rotators. It can be easily imagined how a simultaneous spasm of these muscles would lock the joint, for, in the

normal motion one must relax as the other contracts. Notice also the cross section of the coraco-brachialis and the necessity for the subcoracoid bursa which lies between it and the subscapularis. Since the two muscles work at right angles to one another the bursa is indispensable.

Fig. 5. This diagram is intended to illustrate the condition found when the tendon of the supraspinatus is torn. The head of the humerus is seen from the outer side with the tendons and portions of the muscular bellies of the short rotators still attached to it. There is a small tear in the tendon of the supraspinatus near its insertion on the greater tuberosity. The rupture is not complete because the Y-shaped expansion of the tendon still holds it in fair position. As explained in the text, this lesion is at the point where the shoulder is most prominent.

Figs. 6 and 7. Contrast the smooth contour made by the tuberosity and the overlying tendon in normal condition with the irregular contour found when the tendon has been ruptured. Sometimes instead of ruptures of the tendon taking place the portion of the tuberosity to which it is inserted is torn off.

Figs. 8 and 9 illustrate the appearance when an incision into the normal bursa has been made. The extremely thin superior layer of the bursa is caught with sutures and the smooth shining base is seen in the middle. The base can be moved by rotation of the arm without moving the superior layer. In the lower portion of the wound is seen one of the "nictitating folds."

THE COMPLICATIONS OF ACUTE PNEUMONIA.

BY HENRY JACKSON, M.D., BOSTON.

I REPORT the complications noted in 1,320 cases of acute croupous pneumonia at the Boston City Hospital. In 150 of the cases I carefully reviewed the records myself, but in 1,170 I simply took the complications reported in the card catalogue, therefore the report cannot be considered as absolutely correct, as the card catalogue is not made by physicians. Further, the paper does not deal with the exact pathologic findings of the pathologist, but rather with what may be called the clinical complications of the disease. Therefore I make no record of the condition of the kidneys or of the heart, except in a few instances in which acute endocarditis was a prominent feature of the primary disease.

The complications directly connected with the lung are as follows: Empyema, 22 cases; abscess lung, 4 cases; gangrene, 3 cases; pleurisy with large effusion, 23 cases; unresolved pneumonia, 5 cases.

The complication of organs not directly connected with the lung: Pericarditis, 22 cases; phlebitis, 6 cases; meningitis, 3 cases; joint disease, 1 case; neuritis, 2 cases.

In the consideration of the complications of pneumonia the main interest centers in the complication of empyema, the great importance of this complication being that its prompt recognition is essential in saving much suffering to the patient if not in saving his life. One of the most common mistakes that we see in consultation is the failure to recognize empyema; the patient is supposed to have unresolved pneumonia.

Though empyema occasionally appears during

the course of the pneumonia, it is most usual in the course of the first week after the crisis. In these cases the empyema was first shown in the majority of cases by a rise in temperature without apparent cause on the second or third day after the crisis, or the temperature never fell absolutely to normal. In none of the cases did the empyema appear later than six days after the crisis. In the vast majority of cases a rise in temperature during convalescence means empyema, abscess or tuberculosis. The temperature may be elevated in unresolved pneumonia but the opposite is the rule. The most important early clinical sign of empyema is the absence of tactile fremitus over the area of the pus formation and the modified egophonic voice sounds. In such cases aspiration is obligatory, and aspiration with a large needle.

Unresolved Pneumonia.—As Dr. Williams has especially pointed out by examination with the x-ray, we know that absolute return to the normal occurs only a long time after perfect return to health. We do not expect to find the lung normal by physical examination in less than a week or ten days. But in a very few cases complete consolidation is found to exist many weeks after the onset of the pneumonia, and to such cases, after the careful elimination of all other pathologic processes, we give the name of unresolved pneumonia or delayed resolution. Only five such cases do I find recorded in the hospital cases reviewed, a number suspiciously small and in marked contrast to the large number of cases of empyema. In only one of these cases was there fever persisting throughout the course of the consolidation. This was a case of my own, a little girl of eight years, who entered with the history of an acute pulmonary disease. There was a complete consolidation of the whole left lung which continued for weeks. In spite of the evidence of consolidation and absence of signs of fluid, only by negative aspiration was I convinced that it was not a case of empyema. I then made a probable diagnosis of an acute tubercular pneumonia, which was overthrown by a perfect recovery after many weeks passed in the hospital. The small number of cases of "unresolved pneumonia" bears out my previous assertion that such a condition is probably empyema, possibly tubercular, and that only the established fact that neither of these conditions exists warrants a diagnosis of pneumonia unresolved.

Aside from several cases in which a small abscess cavity was found post-mortem, two clinical cases of abscess of the lung following pneumonia are noted. In both, the diagnosis was made by the expectoration of a very large amount of pus on several occasions though perfect recovery followed. As recovery is rare in such a condition, I give one case.

Girl, seventeen, entered the hospital, Jan. 10. Pneumonia lower left lung. Crisis Jan. 18. Irregular temperature, Jan. 25 to Feb. 9, with continuance of signs of consolidation. Feb. 10 spit up a pint of pus; the same Feb. 11; no bacilli of tuberculosis. After

this date gradual improvement and no fever. March 6 discharged well. X-ray showed a slight shadow in lower left lung.

In two other cases the diagnosis of abscess was made during life by the finding of emphysema, irregular temperature, and the expectoration of much fetid pus. Both were confirmed by autopsy, one in the apex and one in the base of the right lung.

In twenty-three cases there was a large pleuritic effusion, demonstrated by tapping.

Pericarditis.—Twenty-two cases of pericarditis are tabulated. These cases are taken from the card catalogue of the clinical records, and therefore are not to be reckoned as an accurate estimate of all the possible pathologic findings that we would expect from a tabulation of post-mortem statistics. Pericarditis is recognized as a disease often obscure and in some cases impossible of diagnosis. Eighteen of these cases were diagnosed, usually by the evidence afforded by a to and fro friction sound, though in a small number pericarditis was recognized by the evidence afforded by increased area of the heart dullness and faint heart sounds. As in four cases advanced pericarditis, with and without fluid, was found post-mortem, in which no record was made of signs which might suggest such a condition, it is evident that in all probability the disease was much more common than is suggested by my statistics.

No suggestion is offered by these cases as to the probable or possible cause of the involvement of the pericardium by the pneumococcus, either in the age of the patients, their previous condition of health or the location of the pulmonary process. Pericarditis is an early complication of pneumonia, as in all the cases where the diagnosis was made the signs were found in sixteen on entrance and within two days in the two other cases. In the other cases there is no reason, from the history of the cases to consider that pericarditis was a late complication causative of death. Herein this complication presents a very marked difference from empyema, which in the large majority of cases appears late, after the crisis, and at times when convalescence appears to be established.

In ten of the cases a post-mortem was made giving us accurate data as to the condition of the other organs. In one case there was extensive involvement of the valves of the heart, an acute ulcerative endocarditis being found of the aortic and tricuspid valves. In three other cases there were a few acute granulations on one of the valves. Pleural effusion was found in four cases and purulent effusion in two cases. Aside from these pathologic findings, there was found only the acute pneumonia. These findings do not suggest that the pericarditis was a manifestation of any acute pneumococcus septicaemia which had involved many organs.

In ten cases the pericarditis was dry, in four purulent, and in eight serous, estimating as serous all the cases which presented evidence of increase of the size of the heart, yet ended in recovery, and the cases that showed enlargement but were not

proven to be purulent by aspiration or autopsy. Pericarditis is a very serious complication of pneumonia; fifteen cases died, seven recovered. Of the seven that recovered in only two did the size of the heart warrant the diagnosis of an increase in the fluid sufficient to give rise to diagnosis by percussion. That is to say, in five cases a pericardial friction rub was heard which in no way affected the course of the disease, but the demonstration of fluid in the pericardial cavity makes the prognosis very grave. As demonstrative of the obscurity of pericarditis I quote one case.

A man fifty-three years of age entered the hospital Jan. 3. He had been sick for one week. Pneumonia was found in the right base, and a pericardial friction rub was heard over the heart. On the fourth day the temperature fell to normal and remained so; his condition was very poor. No enlargement of the heart area was recorded. He died one week after the crisis.

Seven hundred and fifty cc. purulent fluid was found in the pericardial cavity; 1,250 cc. purulent fluid in the right pleural cavity; an abscess cavity in the right lower lobe with a resolving pneumonia.

It is of course certain that some or all of these conditions should have been diagnosed, but as a matter of fact no definite diagnosis was made according to the hospital record.

Phlebitis.—This is apparently a rather rare complication of pneumonia. In distinction from other diseases which are the result of the pulmonary infection, it occurred in my series of cases in individuals who were not very sick and showed no signs of a general pneumococcus septicaemia. In most of the cases the course of the disease was mild and convalescence more rapid than in phlebitis associated with typhoid fever. In none of the cases were the patients very sick, and all recovered except a case of cerebral thrombosis, where death was the direct result of the localization of the pathologic process. Six cases are noted, five in the femoral and one in the left lateral sinus. So far as the history of the cases shows no possible cause can be suggested for the occurrence of the phlebitis.

CASE I. Man, fifty-four years of age. Entered the hospital on Feb. 10. He had had pain in the right side and cough for three days. There was found a pneumonia of the lower right lobe. The temperature dropped on the seventh day. On entrance the right leg was swollen and slightly tender, the veins of the leg were prominent and a distinct hard vein could be felt along the inner side of the thigh. For ten days after the first fall in temperature there was a little fever. On Feb. 28, eighteenth day, the leg was practically normal. The man was discharged well on March 31.

CASE II. Woman, nineteen years of age. Entered the hospital on May 9. Five days before entrance there was a chill followed by pain in the right side. There was a pneumonia in the right middle and lower lobes. The temperature fell by crisis on May 13. On May 23 pain developed in the left thigh and leg. Leucocytes, 13,800. The leg was moderately swollen, tender and pain on motion. Very slight fever. Patient discharged well on July 9.

CASE III. Man, thirty-five. Entered the hospital

Nov. 9. He gave a history of chills with fever on several days. The diagnosis was obscure at entrance, as no pulmonary trouble was found. Spleen not enlarged and no plasmodia found. On the fourth day in the hospital a pneumonia was discovered in the right lower lung. The temperature was irregular, falling gradually by lysis. On Nov. 24 there was much pain with tenderness and redness in the right leg from thigh to foot. Later the pain became severe. Dec. 7 there was pain in the left leg which was swollen and tender. He was up in a chair on Dec. 19, and was discharged practically well on Jan. 2.

CASE IV. Man, forty-one. Entered the hospital Nov. 8. He had had irregular fever and chills for ten days. There was a pneumonia in the left lower back. No tubercle bacilli were found. Nov. 23, pain and tenderness left thigh and leg. The femoral vein was felt as a swollen cord. There was a moderate fever Nov. 23 to Nov. 29. Dec. 6, lung clear; no pulmonary symptoms. He was discharged well on Dec. 9.

CASE V. Man, twenty-eight. Entered the hospital Jan. 1. On Dec. 26 he had a chill accompanied by vomiting, cough and pain in the right side. There was pneumonia in the right lower lung. The pneumonia was complicated with delirium tremens. Temperature fell by crisis on Jan. 3. On Jan. 10, pain in right thigh and knee. The leg was swollen and tender. Temperature 99-100. In a few days the leg was much swollen. On Jan. 23 when the right leg was better, similar symptoms appeared on the left with a rather higher temperature. During February there was a reduction of the pain, but both legs were much swollen. In March less swelling, and April 6 the patient was discharged practically well. This was the only case in which the severity of the phlebitis was in any way comparable to the similar condition when occurring in typhoid fever.

CASE VI. Cerebral thrombosis. Man, forty. Entered the hospital Feb. 2. On Jan. 29, cough; followed in one day by dyspnea and pain in the lower part of the left chest. On entrance there was intense bronchial respiration with dullness in the left lower back which later spread to the upper lobe. Feb. 5, heart action feeble with a low temperature. Feb. 9, pulse weak and temperature subnormal. Feb. 13, respiration shallow; rapid failure and death.

Autopsy: Heart not abnormal. Whole left lung solidified. Brain: The veins of the pia over the posterior part of the left cerebrum were much injected with abundant diffuse hemorrhages into the substance of the pia. On the left side was a firm, grayish yellow thrombus in the vein of the fissure of Rolando, with similar thrombi in other veins.

No clinical symptoms were noted suggestive of the diagnosis of organic cerebral disease.

In two of the cases there was a phlebitis of both femorals. In only one case, number four, was the course of the pneumonia at variance with the ordinary type.

Meningitis.—Three cases are reported. In only one of the cases were signs present which warranted the diagnosis of acute organic cerebral trouble. It is certainly possible that a review of autopsy diagnoses might show that a meningitis was less rare than is suggested by the clinical records. Acute and often violent delirium is certainly common in severe cases of pneumonia which end fatally.

CASE I. Man, sixty-three. Entered the hospital April 22. On April 20 he had severe headache and later fainted; he was unconscious but a short time.

April 21, less pain in the head, vomited, and delirium came on. On entrance there was a pneumonia in the right lower lung. April 26 and 27 the pneumonia spread throughout the right lung. No signs were noted diagnostic of cerebral trouble, and only the acute headache in the prodromal period might have made such a diagnosis probable. On April 28 there was suddenly an attack of violent muscular twitching, the eyes were rolled upwards and to the left. Death.

Autopsy: Solidification of the whole right lung. The pia over the left occipital lobe and the posterior part of the left parietal lobe was considerably thickened. There was much thick yellow fluid. A similar condition, though less marked, was noted in the right hemisphere. Pneumococci were found in the lung and pia.

CASE II. Woman, forty. Entered the hospital May 14. She had a chill on May 10. Pneumonia was found at the right base on entrance. The temperature fell by crisis on the 19th of May. On May 31 there was a rise in temperature with pain and tenderness in the right ear. The ear drum was incised immediately and the drainage was free. In spite of free drainage she gradually failed, became unconscious on June 4 and died. Though no autopsy was obtained, the diagnosis seems permissible.

CASE III. Man, twenty-nine. Entered the hospital Nov. 9. Since Nov. 3, general pain, fever, cough and sweating. Dyspnea; no chill. At entrance there was a pneumonia in the front and back. Nov. 11, a marked crisis. On Nov. 12 there was slight dullness on the left back with bronchial respiration. Nov. 17, rise in temperature, chill, vomiting. He seemed very sick and weak. Delirium developed. In spite of the marked severity of the general condition the pulse was slow. Nov. 21, external strabismus of left eye. Death.

Autopsy: On the mitral valves acute vegetations with loss of substance. Consolidation due to acute pneumonia in both lungs. Old tubercular process at one apex. Brain: Dura thickened. In sulci yellow fibrino-purulent material, most marked at the base. Pneumococci present. "General pneumococcal septicemia."

This case demonstrated in an interesting manner the value of a slow pulse as an indication of organic cerebral trouble when it is found in a patient whose general condition is bad, where we would naturally find a very rapid pulse were the rate not modified by the cerebral process.

Two cases of peripheral neuritis are reported in some detail on account of the rarity of this lesion in connection with pneumonia.

1. Woman, forty-eight. No alcohol; no syphilis. Entered March 26. Two chills before entrance. Pulmonary examination negative; much pain and tenderness in the arms and legs; knee jerks absent. March 29, pneumonia right lower lobe. April 7, lungs clear. The oculist reported a paralysis of third nerve right and sixth nerve left with slight atrophy of the nerve. She was discharged practically well.

2. A man, seventy. Very severe double pneumonia. At the end of the first week of convalescence paresis of both legs which gradually increased to an almost complete loss of power. After many weeks a complete restoration of muscular power. In this case tenderness was slight and pain hardly noticed.

THE class of 1909 of Cornell University on May 18 presented to Dr. Austin Flint a silver loving cup in memory of his retirement from the chair of physiology on account of reaching the age limit. — *Medical Record*.

Massachusetts General Hospital.

CLINICAL MEETING.

CASE OF TUMOR OF SPINAL CORD, CORRECTLY DIAGNOSTICATED; OPERATION; MARKED IMPROVEMENT.

BY HENRY C. BALDWIN, M.D.

A. O'D., single; aged twenty-nine.

Aug. 26, 1905, I was asked to see a patient who was said to have ataxic paraplegia, and who gave the following history. In January, 1904, she noticed that her right foot was numb and cold. This numbness increased until the entire leg was affected, and the leg became rigid. The right leg seemed as strong as the left leg, but she could not bend it at the knee and she dragged the toe. The following December the left leg became affected and rigid, and in about six weeks, that is, some time in February, 1905, she became unable to walk at all. She lost control of the sphincters of the bladder and rectum at this time. Some time in April she noticed that the palm of the right hand was not so full as formerly, and later the left hand became somewhat affected. At the time that she noticed the slight wasting of the hand, there was some numbness on the outside of the arm in the ulnar distribution.

She was well nourished and had good color. There was marked contraction of the pupil of the right eye and narrowing of the right palpebral fissure, which she had noticed for the previous year. There was no involvement of any cranial nerves. There was wasting more marked on the right side than on the left, in the ulnar and median distribution of both hands and arms, and there was disturbed sensation in the ulnar distribution. Both legs were rigid, and for the most part in the position of flexion. She was troubled with frequent jumpings of both legs, which caused her a good deal of annoyance. At times the legs would be crossed. There was curvature of the spine with a convexity towards the left. The patient complained of sweating and flushing on the right side of the body. On testing sensation, there was anesthesia in both legs, and this anesthesia extended to the region midway between the umbilicus and the breasts. Above this point sensation was practically normal except in the ulnar distribution as stated. There was no disturbance of sensation to heat and cold when complete anesthesia was absent.

In both supraclavicular regions there were small nodules the size of a hen's egg. There was also a nodule in the right thigh. The diagnosis was made at this time of tumor pressing on the cord probably multiple. The patient was sent into the hospital for observation and examination of tumors.

The patient was asked about pain and said that she had had no pain from the beginning of her trouble.

Examination of the tumor removed from the right thigh showed it to be a fibro-sarcoma. Immediate laminectomy was urged. The opinion that the lesion was multiple, one tumor being located between the sixth and eighth dorsal vertebrae, and the other tumor between the fifth cervical and the first dorsal, proved to be incorrect.

A laminectomy Sept. 18 by Dr. C. L. Scudder in which the fifth, sixth and seventh dorsal vertebrae were opened, showed normal appearing cord at this level. On Nov. 7, a second laminectomy was performed by Dr. Scudder, the fifth, sixth and seventh cervical and first dorsal vertebrae being opened. An extra-dural tumor was found growing from the side of the fifth cervical vertebra. It was encapsulated and was removed. Microscopically it is a fibro-sarcoma.

The tumor, for the most part, was situated anteriorly to the cord, and this situation accounts for the absence of pain, which is unusual, pain being considered one of the principal symptoms of tumor of the cord. The tumor extended downward, and was about the size of a peach stone. The cord posteriorly did not look much compressed, but it was flattened and compressed, especially on the right side and anteriorly, to such a degree that the question of any improvement from the operation seemed doubtful.

In both operations the dura was opened and afterwards stitched together.

The patient had no unusual symptoms after either laminectomy, and made a good recovery. Following the second operation there was hiccoughing for a period, which showed irritation of the phrenic nerve.

Sensation had returned in both legs within a week after the second operation. Early in December the patient moved the toes of her left foot, and a little later she regained complete control of the sphincters of the bladder and rectum, and began to move the toes of her right foot. The rigidity of the legs has gradually disappeared, and she can now straighten out her left leg and partially straighten out the right leg. Both legs have increased in size. The right hand and arm have grown larger, and she can now sew and write, which she could not do at the time of the operation.

Sensation is perfect everywhere. The narrowing of the right palpebral fissure and the contraction of the right pupil have improved now that the irritation of the first dorsal nerve no longer exists. The patient can stand on her left leg by holding on to something, and will probably soon be able to walk with crutches.

The patient has already improved far beyond the expectation at the time of the operation, and this recovery has been sooner than was looked for. There are undoubtedly some degenerative changes in the cord which will prevent perfect recovery, but there will be further improvement.

In 1898 Schlesinger,¹ in a monograph on "Tumors of the Spinal Cord and Vertebrae," reported four hundred cases of tumor of the spinal cord found in autopsies; over one fourth of these being sarcoma. This was the number found in over 35,000 autopsies, and it is noted that tumor of the cord bears the relation to tumor of the brain in the ratio of one to thirteen.

In 1899 Putnam and Warren² collected thirty-three cases of tumor of the spinal cord that had been operated on up to that time.

In 1903 Starr³ collected fifty-eight cases of tumors of the spinal cord where operation had been performed.

In 1905 Harte⁴ analyzed 92 cases of operation for tumor of the spinal cord. In 72 cases tumors were found in fact the nature of the growth was not stated, 11 were cases of adhesions and 5 of syringomyelia.

Since Harte's paper was written Walton and Paul⁵ have reported one successful and one unsuccessful case of operation for tumor of the spinal cord. Warrington has reported one successful case of operation for tumor of the cervical spine and two cases not included in Harte's lists were reported by Lumsden and successful

operations by Ballance at the National Hospital for Paralyzed and Epileptics in London.

Tumors in the cervical region are less common than elsewhere. Putnam and Elliott⁷ (Boston) report one case of tumor of the second and third cervical vertebrae. This case was successfully operated upon, and seems to be the highest localized case on record. Putnam, Krauss and Park⁸ (Buffalo) report a case of tumor at the level of the third cervical vertebra. The tumor which is now reported lay at the level of the fifth cervical vertebra. Woolsey,⁹ Oppenheim,¹⁰ Henschen,¹¹ Walton and Paul¹² and Cushing¹³ each report a case of tumor lying between the sixth cervical and first dorsal vertebrae.

Among the reported cases both tumors are in the cervical region, and this case is the third highest localized tumor.

Regarding the mortality, in the series of Putnam and Warren 16 died within a few days of the operation, and two within six months. Seven are reported as recovered, and improvement is noted in the remainder.

In the series reported by Starr, 32 died; 16 cases recovered from the operation and improved; 10 recovered from the operation, but did not improve because of the degenerative processes in the cord that had occurred previous to the operation.

In the series reported by Harte 43 died and 49 recovered; 29 are reported as cured; 17 improved, and 3 unimproved.

Undoubtedly to-day by improved technique the mortality from the operation is greatly reduced. The success of the operation, so far as the recovery of the patient is concerned, depends upon its early performance, as degenerative changes in the cord occur in consequence of continued pressure upon it.

SCABIES.

BY JOHN T. BOWEN, M.D.

I wish to show several cases of scabies, chiefly for the purpose of emphasizing the frequency of this affection and the failure to recognize it on the part of the general practitioner. During the last two years scabies has been second on the list of skin diseases treated at the Out-Patient Department of the Massachusetts General Hospital, eczema as usual occupying the first place. During the last year there were 315 new cases of scabies.

These figures refer simply to the individuals who presented themselves, for in the majority of instances there was a history of many other members of the family being affected. The disease is now so prevalent that the social status and cleanliness of the individual by no means preclude the possibility that he has contracted the disease. The cases shown demonstrate the predilection points of scabies, namely, the

dermatitis and scratch marks on the hands and especially between the fingers, in the folds of the axillae and on the penis and breast. One of the patients shown was a young man who worked in an iron foundry. A squad of workmen, of which he was one, were accustomed to change their clothes in the same room, and of these a large number were affected with the disease.

RECENT RESEARCHES ON THE PATHOLOGY AND ETIOLOGY OF JUVENILE SPINAL DEFORMITIES. (LATERAL CURVATURE OF THE SPINE.)*

BY MAX BÖHM, M.D.

The question: "Which is the cause or, rather, which are the causes of juvenile spinal deformities, called commonly lateral curvature of the spine?" is an old problem. An enormous amount of time and intelligence has been spent in the study of this question. I only need to quote here names such as Hueter, Volkmann, Albert, Eulenburger, Nikoladoni, Mikulicz and others in the past. And the interest taken in this question in the present is still more alive than ever. You all know the name of this excellent scholar, Schulthess, in Zürich, the leader in the scoliosis research work; furthermore, men like Riedinger in Würzburg, Wullstein in Halle, Schanz in Dresden, and last, but not least, Lovett in our city.

Many theories have been advanced—too many; for the great quantity only proves that none of them has been fully satisfactory. And if I introduce to-night a new feature into the etiology of spinal deformities, I dare it only on account of well-founded facts, on account of pathological findings. The study of the pathology of juvenile spinal deformities is a somewhat difficult matter, since those cases come extremely seldom to autopsy; and the scoliotic specimens, found in museums, show the secondary changes prevalent, the primary conditions hidden, and thus are not very suitable for pathological studies. So the idea suggested itself to use radiographic means, and indeed after the necessary technical improvements were made, the x-ray proved highly satisfactory, in certain ways even better than autopsy, for it showed the conditions as they exist in the living body, that is to say, under the influence of muscular action and elastic tissues.

The cases I examined represent two types of lateral curvature. (Demonstration of cases.) The first type, as represented in this girl (Ev. S.), is the characteristic triple curve, left lumbar, right dorsal, left cervical. No distinct primary curve could be made out. The second type may be seen in these two cases (A. B. and Br. T.). There is a decidedly primary left lumbar curve present with compensation in the other regions of the spine.

The two different types can be studied more

Tumor pressing on cord. (See also p. 100, and p. 101, of this volume.)

thoroughly in the clinical records and measurements. From the history let me only mention that no heredity as to spinal curvatures could be made out and no signs of rickets were present. I wish to emphasize especially the fact, that the deformity in all the cases was first noticed between the tenth and fifteenth years of age.

Of every case a careful x-ray examination was made. This consisted in taking two or three guide pictures of the whole spine, in order to get a rough idea of the deformity present and, chiefly, in order to enable us to count exactly the number of ribs and the number of vertebrae present in the different regions of the whole spine. Then the detail pictures were taken of certain parts of the spine, which seemed to offer abnormal conditions.

and 5 lumbar vertebrae are present. This and various other combinations lead to the occurrence of the so-called "Übergangswirbel," transitional vertebrae, on the boundary of the different regions of the spine.

To use our above-mentioned instance of a spine, containing 11 dorsal, 6 lumbar vertebrae on the left, 12 dorsal, 5 lumbar vertebrae on the right; this phenomenon gives rise to a transitional vertebra on the lumbodorsal boundary, to a dorso-lumbar vertebra, showing left lumbar, right dorsal character. The same may occur in the cervicodorsal region, on the lumbosacral and finally on the sacrocoxygeal boundary. It is known to the anatomist, that correlations exist between all these "Variations," (Dwight, Adolph). We shall to-night give all

FIG. 1. After Durr. Sacro-lumbar. Übergangswirbel.

The results were surprising for each case offered abnormalities as to the division of the spine, as to the numbers of vertebrae, which make up the different regions of the spine; all the cases showed "numerical variations," as the anatomical term is. Before I demonstrate to you the x-rays, let me give you a short résumé of the anatomical character of the anomalies, we have to deal with.

If, normally, the human spine has 7 cervical, 12 dorsal, 5 lumbar, 5 sacral and 4 coxygeal vertebrae, we find that a certain percentage of men show so-called numerical variations; for instance, 11 dorsal, or 4 lumbar vertebrae and so on. This may take place symmetrically but it may also occur asymmetrically, i. e., it may concern only one half of the spine (left or right or both halves but in a different way). We may have, for instance, on the left side of the spine 11 dorsal and 6 lumbar vertebrae, while on the right side the normal conditions of 12 dorsal

and 5 lumbar vertebrae are present. This and various other combinations lead to the occurrence of the so-called "Übergangswirbel," transitional vertebrae, on the boundary of the different regions of the spine.

To use our above-mentioned instance of a spine, containing 11 dorsal, 6 lumbar vertebrae on the left, 12 dorsal, 5 lumbar vertebrae on the right; this phenomenon gives rise to a transitional vertebra on the lumbodorsal boundary, to a dorso-lumbar vertebra, showing left lumbar, right dorsal character. The same may occur in the cervicodorsal region, on the lumbosacral and finally on the sacrocoxygeal boundary. It is known to the anatomist, that correlations exist between all these "Variations," (Dwight, Adolph). We shall to-night give all

these are the conditions that interest us the most at present.

In studying these affections and their relation to deformities of the spine, the question comes up at once: How often do we find these numerical anomalies in the spine and especially in the lumbosacral region? Exact knowledge of their frequency is necessary in order to find out whether in our cases the anomalies are only incidental or represent the cause.

FIG. 3. — Oblique-oval pelvis and lumbar scoliosis with lumbosacral "Zwischenwirbel." From Welcker (1881).

The statistics of Bardeen are of great help to us. Let me give you shortly the results of his and other statistics.

(1) About 4.74 % of all human adult beings have 23 presacral vertebrae; about 4.3% have 25 presacral vertebrae.

(2) A lumbosacral vertebra occurs in .99%, a sacrolumbar vertebra in 1.41% of all human beings.

FIG. 2.

(3) If the number of presacral vertebrae is normal, the sacrum contains, in 4.07%, 6 vertebrae; in 1.51%, $\frac{5}{2}$ vertebrae (*i. e.*, one sacral half has 5, the other has 6 vertebrae); in .45%, $\frac{4}{2}$ vertebrae (*i. e.*, one half 4, the other 5).

N. B. The division into sexes and the affection of both sides may be seen in the original.

The next question must be: Do the anatomical specimens show lateral curvatures of the spine, when variations in the lumbosacral region are found?

You see here some photographs from anatomical works, that show you the influence of the lumbosacral variations in deforming the spine. Another interesting question is: Which is the genesis of our anomaly?

It can only be understood on the ground of embryology. We are fortunate in having excellent researches on the development of the spine, done by Bardeen, anatomist in Missouri, formerly of Johns Hopkins University. The following description is a very short account of his work as far as it is here concerned. At the end of the second week the embryonic body shows fourteen spinal segments (myotomes), which increase gradually and reach at the end of the fourth week the number of 35 to 36. Through resegmentation of the sclerotomes and regressive fusion in the coccyx this number is reduced finally to the number of vertebrae found in the adult. Now, at the third week, it is impossible to discriminate between the lumbar, sacral and coccygeal region of the spine, since all these vertebrae at this time look alike. The ileum is at this moment opposite the twenty-first to twenty-sixth segment, which means the later lumbar region of the spine. Gradually the ileum travels downwards till it finally reaches, at the end of the sixth week, its definite place, *i. e.*, the first, second and third sacral vertebrae. As soon as the ileum approaches we see a revolution in these later sacral segments. Their costal elements — the later wings — begin to grow and get finally so perfectly developed that they form a marked distinction to the lumbar segment. Thus it is the ileum which determines the regions in the caudal part of the spine. Now as Wiedersheim has shown, the ileum is phylogenetically as well as ontogenetically younger than the free extremity, and its development in a certain way depends upon the development of the free extremity. So we may say that the normal development of the regions of the caudal part of the spine depends in its last cause upon the development of the free lower extremities. The genesis of the Zwischenwirbel is now clear. If the ileum in its way downward is troubled, it may remain higher and thus produce a sacral vertebra, where we should expect a lumbar one. It may, on the other hand, travel lower than normally and thus lumbarise a vertebra which in normal development would show a sacral character. This may be symmetrical and then we have in the first case a spine with only 23, in the latter case a spine with 25, presacral vertebrae. This anomaly, if it takes place asymmetrically, produces different degrees of Zwischenwirbel with more or less sacral character on one and lumbar character on the other side.

Which are now the causes of the disturbances, which interfere with the normal travelling of the ileum? We know very little about it as far as facts are concerned, and two different theories

have been advanced: The one accepts intrauterine disturbances, the other supposes phylogenetic influences. It seems very plausible that intrauterine troubles as, *e. g.*, abnormal position of the limbs, intrauterine pressure, etc., either directly on the ileum or indirectly on the leg of the fetus could result in such anomalies. Indeed, we sometimes find anatomically, in connection with lumbosacral and sacrolumbar vertebrae, differences in the length of both lower extremities and differences in the size of both ilia. And clinically I could make corresponding findings in our scoliotic cases, as you can see in the measurements of the extremities and in the x-rays of the pelvis. Besides this theory which considers the numerical variations of the spine and especially the lumbosacral variations as due to individual incidents during the earliest period of fetal life, there is another theory which explains these conditions in a phylogenetic way.

This theory, first advanced by Emil Rosenberg in 1876, raised considerable interest and was generally considered as epoch-making. Rosenberg's theory is briefly: In the class of primates the phylogenetic development of the spine tends towards shortening, *i. e.*, the spine of a certain species shows the *less* presacral vertebrae, the *higher* the order, on which it is placed on account of its general system. While, for instance, certain semi-apes have 27 or 28 presacral vertebrae and certain anthropoid apes have 25, man has in common with the gorilla only 24 presacral vertebrae. Thus a segmentary shortening of the spine has phylogenetically taken place.

Starting from this point of view, Rosenberg went over to ontogenetic researches and found these conditions corresponding to pylogeny. He stated that the fetal spine as to its presacral segments is longer than the adult spine, that consequently a shortening of this part of the spine must have taken place during embryonic life. Rosenberg explains this shortening by travelling of the ileum from the twenty-sixth to the twenty-fifth segment of the spine, its definite place. This differs from Bardeen's embryological statements, who found a downward traveling of the ileum. If now the ileum remains lower, so Rosenberg continues, we will get an abnormally long spine, an atavistic abnormality; if it travels too high, we have to deal with the reverse: a futuristic or epigonistic anomaly.

Rosenberg's theory is, in Germany, generally accepted, although Weleker and Holl have opposed it. In fact it has been made the starting point for similar researches, thus Ruge proved that not only the spine, but the whole human trunk has phylogenetically passed through a state of "metamerie shortening."

In other countries Rosenberg's theory found many adherents, although many important objections were raised (Paterson). In America both authors who studied the question, Dwight and Bardeen, either refused it entirely or accepted it only in part.

It seems to me the question, Is the cause of

the numerical variations of the spine an individual or phylogenetic one? is a misleading question. For there is no reason why both theories should fight each other. They may co-exist and we should wait for definite facts brought forward by the adherents of the one or the other theory. And as I can demonstrate to-night, we have now an open field for the study of this question, since we are no more tied up to the museum material but have by the help of the x-rays an unlimited material. After these theoretical explanations let us return to our cases and allow me to demonstrate to you the x-rays of them.

You see here the x-rays of the four spines, belonging to the first type of cases, taken in the above-mentioned manner. I am sorry to say that the cervical spine has not yet been taken; but otherwise the spines are complete.*

Case I has cervical ribs, 1. more developed; 11 dorsal vertebrae with normal dorsal ribs; the next vertebra shows lumbodorsal character, inasmuch as on the left side the rib is missing and on the right rudimentary and the superior articular process show lumbar character. Then 4 true lumbar vertebrae follow. The next vertebra is lumbosacral, *left* sacralised, *right* showing lumbar character. Five true sacral vertebrae follow.

Case II has elongated transverse processes on the seventh cervical, 11 true dorsal, 1 lumbodorsal, bearing rudimentary ribs; 4 lumbar vertebrae, 1 lumbosacral vertebra, 5 sacral vertebrae.

Case III has 12 true dorsal vertebrae, 5 lumbar vertebrae, 1 lumbosacral vertebra (*left* sacralised), 5 sacral vertebrae.

Case IV has 12 dorsal vertebrae, 6 lumbar vertebrae (the first shows on the *right* a trace of a rib), 1 lumbosacral vertebra (the transverse process are bifid and contain each a foramen), 4 sacral vertebrae.

In the next case the presacral spine is normal except that the lower ribs (eleventh and twelfth) are abnormally long and show the same character as those above (*not* floating). The variation is here in the sacral and coccygeal parts.

Case V. The first sacral vertebra shows transverse processes, extended upwards and thus indicating that it is imperfectly sacralised. The last lumbar vertebra disappears as to its body below the level of the sacrum, indicating that it rests on an asymmetrical foundation, apparently on an asymmetrically developed first sacral vertebra, its left inferior articular process is extended downward and apparently fused to the arch of the following vertebra.

In a sixth case of a slight lumbar curve I had just the chance to get an x-ray of the last lumbar vertebra, which gives evidence of a double transverse process on the left side.

A special technical care is required in taking the x-rays and only radiograms have been used, in which the point of interest was *absolutely centered*, since the slightest deviation of the

*As proven by later examination the cervical region contains in all cases the normal number of vertebrae.

compression cylinder produces distorted pictures. Furthermore, the explanation of the pictures offers considerable difficulties: for the possibility existed that we had to deal with x-ray deceptions. From this point of view several experiments were made by Mr. Dodd; for instance, pictures were taken with the patient lying in different positions, on the stomach and so forth.

Finally, the possibility had to be considered that the peculiar position of the fifth lumbar vertebra between a flexible and a fixed part, shapes it in a scoliotic spine in such a peculiar way. Thus we x-rayed a case of poliomyelitic lumbar scoliosis, a curvature in which the fifth lumbar vertebra is exclusively secondarily or mechanically involved. You see the appearance is entirely different. You do not find that this vertebra disappears below the level of the top of the sacrum. A résumé of the radiological or pathological conditions in our cases is thus the following:

Not a single case shows normal numerical conditions, but each shows numerical variations. The first four cases which represent clinically one type show the numerical variation in the presacral part, the other shows the variations in the sacrum and coccygeal part of the spine.

Now it seems to me not to be a very bold undertaking to make the following conclusion: We find numerical variations in the above-mentioned percentage (see statistics); if now *each* case of lateral curvature shows these variations in some form or the other, there must be a closer connection between this clinical affection and the above-mentioned anatomical condition. I should be inclined to call this connection the indirect cause, since it is clear that these variations in themselves cannot be the direct cause. Now we have to look for the direct cause. This is to be seen in the asymmetrical attachment of the extremities (pelvis and free extremity) to the spine and the subsequent, but still primary, asymmetry of the sacral wings. (Cases I, III and V.) Whether a lumbodorsal or a cervicodorsal vertebra can show a symmetry and thus produce a deformity, whether, furthermore, abnormalities in the spinal joints and other abnormal conditions, which sometimes accompany the numerical variations, may give rise to deformities of the spine,—all these are questions which in the future would have to be studied. Only one point shall be mentioned to-night. It was first Tenchini and Dwight who independently demonstrated that in connection with numerical variations of the spine the size of the affected region changes in this sense: that in a numerically enlarged region—take a lumbar spine with 6 vertebrae—the height of each vertebra *decreases*, and *vice versa* in a numerically diminished region the height of each vertebra *increases*. They speak in this sense of a “volumetric compensation.” Papillault confirms Tenchini’s statement and so does Rosenberg. The latter author uses this phenomenon for his theory in the following way: An epigonistic (futuristic) spine is shorter as to the number of vertebrae, but larger as

to the height of each vertebra; an atavistic spine reverse. In looking up this subject in anthropological literature I found an article of Klaatsch, who compares European spines with spines of Australian aborigines and finds the latter decidedly smaller as to the size of the vertebrae. (See photograph A, No. 4.) Further

FIG. 4.

1 and 3, European. 2 and 4, Australian. From Klaatsch, Heidelberg.
5 and 7, European. 6 and 8, Australian. From Klaatsch, Heidelberg.

anatomical measurements are necessary; but suppose these above-mentioned statements are true and we apply this theory now to spines with asymmetrical variations, to cases where both halves of the spine are in an unequal state of phylogenetical development, so to speak, we would have to expect differences in the height of the halves of the vertebrae, which must lead to deformities. This is just a hypothesis that I give you to-night, simply as a point which needs our consideration and exact study. However the deformity may result on the basis of the numerical variations, there can be no doubt that our cases are deformities of true congenital character. This is a surprising fact, since, as we clinically stated, the deformity started in all the cases between the tenth and fifteenth years of age. This seems to me another interesting point of the research work; that we found, as far as I know for the first time, true congenital affections, which do not manifest themselves directly after birth, but ten to fifteen years later. Thus I should like to call our cases *scoliosis congenitalis tarda* in order to discriminate them from those well-known congenital spinal deformities which show directly after birth. The question now is: “Have we any sufficient explanation for the fact that this deformity develops so late?”

Naturally, we will think first of the fact that the sacrum in its different parts does not get

fused together until about the twenty-fifth year of age. But this explanation seems not entirely satisfactory and we have to consider the point I already mentioned,—the "volumetric compensation." If this should take place, it could develop only in a later period. For all the researches we have on the postnatal development of the human spine point out that the different vertebrae do not show their typical proportions, size and shape directly after birth but in a later period, practically at puberty (Acby, Langer, Ravenel, Rotch and Dwight). Consequently, deformities based upon the differences of these factors must manifest themselves at the same period. With this newly gained knowledge,—that congenital deformities may show up in a later period,—we will have to revise our knowledge of scoliosis and also other deformities which have some relation to scoliosis and which belong into the same class, for instance, coxa vara, etc. (Belastungsdeformitäten.)

I am unable to say to-night how many of our juvenile spinal deformities are based upon numerical variations, how large this factor is in the etiology of scoliosis; this remains to be proven on a greater material.

I would not finish my paper without having said my heartiest thanks to all those who gave me their help and assistance. In the first place I have to thank Dr. Goldthwait and Dr. Osgood for the great interest they took in my work during the past two years and for the chance they gave me to carry it out by placing at my disposal all the curvature material which came along. Furthermore, my thanks are due to Professor Dwight for anatomical instruction. Dr. Painter and Dr. Brackett had the courtesy to allow me to use some of their material. One glance at the x-rays exhibited to-night will show you what excellent work has been done in this line. This is due to the tireless energy and intelligence of Mr. Dohli; without his kind help I could not have carried out my intentions. Finally, my assistant, Miss Stephens, helped me a great deal in the clinical measurements. To all these my heartiest thanks.

APPENDIX.

Since the above paper was read I have had a chance, by closer study of Dr. Dwight's collection of spines, showing numerical variations, in the Warren Museum of the Harvard Medical School, partly to modify, partly to confirm, my opinion on the relations of juvenile deformities and numerical variations of the spine. My present standpoint — based upon clinical and anatomical examination — is, briefly, the following: Numerical variations of the spine lead by no means in every case to spinal deformities, but may give the occasion to such in a way as above partly stated.

As to the connection between lumbosacral variations and spinal deformities, which I studied especially, my theory is the following: The deformity in its traveling downward may not only vary in its attachment to the spine as to the height of attachment, but also as to the direction, i. e.,

it may be rotated, etc., may finally vary as to its size, the latter in connection with the whole lower extremity. While in the first case a numerical variation of the spine will be the consequence, in the second and third cases a pelvic deformity will result, such as oblique oval pelvis, etc. (known as congenital to obstetricians). Combinations of the three anomalies are frequent. (See Fig. 1.) If these anomalies take place asymmetrically the pedestal of the spine, namely, lower extremities, ilei and sacral wings (costal pieces) will primarily become asymmetrical during embryonic life (first six weeks). When the child begins to walk and gradually becomes adapted to the erect position the bodies of the sacral vertebrae will develop asymmetrically, and this secondarily, due to the abnormal static conditions, caused by the primarily asymmetrical pedestal. Thus the foundation of the spine will become asymmetrical, and finally, in the course of the development, the free, presacral spine must adapt itself to the asymmetrical base. The visible expression of this adaptation is the deformity, which according to this theory cannot develop and manifest itself until the time at which the features of the erect position are gained,—about the puberty.

M. Böhm.

ASCITES FOLLOWING ADHERENT PERICARDITIS AND PERIHEPATITIS.

BY E. G. CUTLER, M.D.

Mrs. E. G., aged thirty-two, with history of rheumatic fever at the age of seven and again at twenty-two, was found in November, 1905, by Dr. Fitz to have mitral stenosis and insufficiency, adhesive pericarditis, perihepatitis and ascites. The noteworthy fact was the limitation of the transudation to the peritoneal cavity chiefly, the rest of body and extremities being but little affected. The patient left the hospital much relieved, Jan. 25, 1906, but returned again April 3, 1906, because of abdominal distention, cough, dyspnea. April 4, she was tapped and twenty-six and a half pints of slightly turbid, greenish tinged fluid of 1.017 specific gravity and 0.9% albumin was removed. She was much relieved and has somewhat improved in general condition. The upper part of the abdomen, hypochondria and epigastrium has been markedly tender. As evidence of adherent pericardium there is systolic retraction and diastolic protrusion at the apex and systolic retraction on both sides of the ensiform cartilage, also in the back over the eighth, ninth, tenth and eleventh ribs, most marked on inspiration. There is retraction of the upper part of the epigastrium on full inspiration, and no shifting of apex on right and left lateral decubitus. This pathological condition has given rise to the symptoms and signs observed in portal obstruction.

A MEMORIAL TABLET FOR THE LATE DR. GEORGE RYERSON FOWLER. At eight o'clock, on Sunday evening, May 27, a memorial tablet for the late Dr. Fowler was unveiled, with appropriate ceremonies, at the Pharmacy building of the Medical Society of the County of Kings. — *New York Medical Journal*.

FRACTURE OF SKULL PROBABLY INVOLVING THE BASE. RECOVERY AFTER OPERATION. ANALYSIS OF THE APHASIA.

BY G. L. WALTON, M.D.,

Physician to Neurological Department, Massachusetts General Hospital,

AND

G. W. W. BREWSTER, M. D.,

Surgeon to Out-Patient Department, Massachusetts General Hospital.

THE following case presents several points of interest to the surgeon and the neurologist. In the first place it shows the importance of considering not only the symptoms but also the violence of the blow in determining the probability of fracture of the skull. In the second place it reminds us that hematoma does not preclude, but may obscure, underlying fracture. In the third place it shows the importance of exploration in case of deepening unconsciousness, even though the fracture involves the base and the condition of the patient is desperate. Finally, it shows the degree to which the brain may be involved and the tolerance it shows for manipulation even in a region concerned in the complicated mechanism of speech.

SURGICAL ASPECT OF CASE.

DR. BREWSTER.

Realizing that the interest in the report of this case, beyond recording a recovery, lies in the neurological observations, I should hesitate to say anything from a purely surgical point of view, was it not for this opportunity of expressing my belief in the importance of the co-operation of neurologist and surgeon, and to emphasize the subsequent conclusions. The problem presented to the surgeon was whether operation offered any chance of relief. With the history of a serious head injury with immediate unconsciousness, a period of improvement, followed by a deepening unconsciousness, a slowing pulse and no localizing symptoms of pressure, the outlook seemed hopeless. As there was a well-defined hematoma in the left parietal region extending forward over the temple and down to the zygoma, it was decided to turn back a flap including the hematoma in order to determine the condition of the underlying bone. It was impossible to demonstrate a fracture by palpation.

Under ether anesthesia a "U" incision was made down to the bone, and the area underlying the hematoma was freed of periosteum. A crack was then seen running from the middle of the frontal region backward and downward in a curved direction an inch in front of the external auditory meatus. No depression could be found, and the crack was so fine that it was not immediately seen. A small trephine opening was then made at approximately its middle, and enlarged upwards and downwards by means of rongeur forceps. There was no evidence of extradural hemorrhage or fragments of bone displaced from the inner table. The dura was tense and did not pulsate. It was incised and gave vent to dark blood. On exploring with the finger in a downward direction a large cavity filled with blood was given an outlet from which the hemorrhage became so profuse that it was necessary to pack in a long strip of gauze. Even then it did not seem possible to control the bleeding, and the wound was partly sutured and a firm dressing tightly bandaged

over it with as much speed as possible, fearing a death from hemorrhage on the operating table.

Although there was a great deal of staining in the first twelve hours the subsequent history unexpectedly proved to be that of an uncomplicated recovery. The pulse almost immediately showed the relief of the pressure slowing. The patient took liquids without difficulty after twelve hours. Consciousness was so slow in returning that in spite of the good general condition no hope of a recovery was admitted for at least three days.

The original packing was removed on the second day and replaced by a small wick. This was taken out on the third day, and the wound allowed to close. There was no wound infection and the healing was steadily progressive and in no way unusual.

The extent of the injury and the source of the hemorrhage can only be conjectured. The blood had the appearance of venous origin, it flowed from the opening within a steady stream and dark in color. There was no sign of arterial spurting nor of bright arterial blood.

It seems probable that there was no laceration of the brain substance and no fragments were seen to escape from the exploratory opening. It seems reasonable to deduce from the progressive symptoms before operation and the recovery following that hemorrhage and its consequent pressure may be controlled even though the source is not determined.

The favorable outcome of this case may serve to encourage a willingness to undertake a class of operations which certainly must always result in a very high mortality. It also serves to emphasize the following conclusions which are already expressed by other writers and not intended as original:

1. In serious head injuries it is clearly indicated to turn back a flap when there is a doubt about the condition of the skull beneath.

2. It may be possible to control an intradural hemorrhage and relieve pressure, which would result fatally without operation.

NEUROLOGICAL ASPECT OF CASE.

DR. WALTON.

The patient, a brakeman, was brought to the hospital unconscious; with history of striking a bridge while on a rapidly moving train. After recovering consciousness he became in a few hours dull, though when roused he would still answer questions intelligently, correctly and without speech defect. The knee-jerk, Achilles, plantar, abdominal and cremasteric reflexes were normal and alike on the two sides. All motions of the face and extremities were alike and of equal strength on both sides. There was no bleeding from the ears or nose, but a few hours after the injury he vomited bloody matter. The lids were black and enormously swollen and the swollen conjunctival sac projected between them.

His first attempts at speech after the operation resulted in jargon, the patient failing to name even simple objects.

On the tenth day the speech had improved sufficiently to permit of its recognition as transcortical with some involvement of the word hearing center. He was able to show the teeth, protrude the tongue and close the eyes at command, showing that this center was not entirely

destroyed, but he did not understand the order to squeeze the hand. Asked to name a watch he said, "Brass; don't mean brass." Shown a coin, he said it was "nearly square," making at the same time a circle with his hand. Asked to say the days of the week answered, "Yes, sir; well, it is Friday, March 20, 1898." When started on the days of the week, named them correctly. That the mind vision center and the writing center, and probably Broca's center with their connections were comparatively intact was shown by the fact that he could read correctly from a magazine, understood gestures and the uses of objects and could copy practically without error. He signed his name as follows:

W R Royall
Broadway
Dr. Bloodsont.

Voluntary speech was at this time greatly improved. He said, "I have been through a terrible sight. You distrust me, but I knew nothing at all until yesterday." The conclusion to be drawn from this form of aphasia is that the lesion was largely limited to the temporal lobe.

On the eleventh day (March 31) the speech had still further improved and a detailed examination was made to determine the character of the aphasia. The method of Bastian was followed. As this author points out, we cannot determine exactly the fibers and centers implicated in a given case or the degree of their involvement, but we can do so with sufficient accuracy to classify the aphasia and to show where the bulk of the injury falls. It will be seen that the injury in this case falls chiefly upon the center for auditory memories in the temporal lobe with its afferent and efferent fibers. This is the type commonly met in abscess of otitic origin. (See report of case by Jack and Walton in *Boston Medical and Surgical Journal*, Vol. CLIV, No. 26, Dec. 26, 1901.)

For convenience of reference a diagram is appended showing the important centers concerned in speech and their connecting fibers. The continued lines show the common paths. The dotted lines show those less constantly in use. For perfect speech the integrity of all is essential.

Systematic Test by Bastian's Method

(a) *Preliminary qualifications.* (1) He is right-handed. (2) There is no paralysis of the face and limbs. Every movement of the hand is

perfect. There is no astereognosis and no lack of facility in handling the tape measure and other objects. (3) He apparently has a good common school education.

Diagram showing: (B) Broca's center for glossokinesthetic memories (memories of movements of the tongue etc. to be reproduced for speech); (A) Auditory memories for words; (V) Visual memories. The chiro-kinaesthetic center (center for memories of movements made in writing) is also indicated in writing is also indicated. (W) Lines and arrows indicate afferent and efferent fibers connecting these centers. The probable seat of the lesion includes (A) with its afferent and efferent fibers.

(b) *Activity of auditory word center and glossokinesthetic (Broca's) center with afferent, commissural and emissive fibers.* (4) The hearing is quite defective, the voice must be raised in order that he hear at four feet. (5) He appreciates ordinary sounds as the ticking of a watch. (6) He comprehends simple speech as the command to put out the tongue, but fails to understand the command to touch the left ear with the right forefinger. He understands simple words as thermometer, but when asked what the thermometer is for he says, "Go and large." Asked what one does with it, answers, "Why, it is larger and smaller." Makes motions showing that he understands what it is for. Apparently understands what the word "explosion" means, making an explosive motion with his lips and saying, "It is in a mine." When asked to copy the numerals $5 + 5 = 10$, he understands the order but writes 14 for 10. Asked what a slate pencil is answers, "You can make it or make a piece of chalk." (7) Spontaneous speech is impaired even for ordinary conversation. Substitutes words but puts in very few meaningless words. In the Lord's Prayer substitutes words and says, "I cannot do it, really." (8) He can name the days of the week and says the alphabet and numbers from 1 to 20 without being started, he says the months of the year. (9) He can repeat short sentences uttered before him. (10) He recognizes times and 11 can whistle Yankee Doodle without being started, adding, "I can whistle very good."

(c) *Activity of the visual word center and chiro-kinaesthetic center with their afferent, commissural and emissive fibers.* (12) His sight is good. There is no homonymous hemianopia. (13) He recognizes printed words but repeats them imperfectly, for example for F. L. Jack he reads Frederick C. Jackson. He appreciates and understands everything that he reads in the paper as he indicates by gestures. (14) He recognizes

letters and numerals. (15 and 16) He can read what he has copied and realizes that his spontaneous writing is unintelligible. The spontaneous writing is very poor. A specimen is appended of his attempts to write "Around the rugged rock, the tree grows" and the

*away from
around the
there the
through
Thundel, muddled
muddled
Thundel, muddled
muddled*

days of the week. (17) He recognizes common objects. (18) He recognizes gestures. (19) His attempts to write spontaneously are very poor, even worse than his attempts to speak. (20) He can write his own name with a mistake of one letter. The days of the week he cannot write. (21) He copies what is set before him nearly correctly. (This case corresponds to two reported by Pitres in that the patient could copy but not write spontaneously. He could not even write to dictation that which he could say with ease, a fact which tends to favor the view of Bastian that there is a cheiro-kinesthetic center — denied by Dejerine — which acts independently of Broca's center, but whose activity may be impaired by loss of conduction from the auditory center to the visual center, or perhaps directly to the cheiro-kinesthetic center.) (22 and 23) He copies numerals easily and does simple calculation. (24, 25, 26 and 27) Not tested on reading or writing music.

(d) *The associated activity of three centers with commissures between the auditory and visual word centers or other sets of afferent and efferent fibers.* (28) He reads sentences aloud. (29) Names words and vowels at sight. (30) Does not name at sight the objects thermometer and knife, but does pin. (31) Can point to common objects whose name he hears, including the thermometer. (32) On dictation writes practically jargon. (33) Can write individual letters and numerals. (34) His ability to play instruments was not inquired into.

On the eighteenth day after the accident (April 7) improvement had continued; spontaneous speech was greatly improved. Some sentences he completed without error, for ex-

ample, "When I get up and am on my feet I will talk all right." He generally makes his wants clear but fails in conversation. He is a little slow in carrying out complicated directions. He names the tune which is whistled before him "Rocky Doodle Dandy." He can carry the air of "Swanee River" but cannot start it. His ability to name objects is much improved. He names "magazine" correctly but calls a thermometer "mometer." Though he copies without error, when asked to write the days of the week he fails completely. When they are dictated to him he partially succeeds in writing them.

On the twenty-third day he was up and about, practically well. At this time he could make his wants known and carry on simple conversation fairly well but with frequent loss of substantives.

This improvement was continuous and on the thirtieth day he conversed with comparative ease. He can name and spell the days of the week perfectly, but still fails to write them perfectly.

CRUSH OF CORD FROM SPINAL FRACTURE.

BY G. L. WALTON, M.D.

I wish to show this picture (see plate) of a spinal cord crush at the level of the sixth cervical vertebra. The principal interest lay in the beautiful manner in which it illustrated complete disintegration at the level of the crush coinciding with an external appearance of normal cord. This is, perhaps, the most frequent finding on operation. In this case the operation (by Dr. E. A. Codman) showed an apparently healthy cord, though the paralysis, sensory and motor, was complete. It was assumed, however, from the symptoms that the cord had been crushed. Death followed within a few days, and the autopsy showed that while the surface of the cord was not ruptured at the spot of injury, a split had occurred at a somewhat lower level with extensive hemorrhage.

There was entire loss of reflexes, as is usual in complete transverse lesion at any level of the cord, contrary to the earlier teaching.

The third of the cross sections shows the condition of the cord at the level of the crush.

Medical Progress.

PROGRESS IN THERAPEUTICS.

BY FREDERICK T. LORD, M.D., BOSTON.

TREATMENT WITH PASSIVE HYPEREMIA.

The cupping glass and suction apparatus, constriction of the limbs for venesection and the control of hemoptysis are methods which have been in use since times long past.

Ambroise Paré was probably the first to use passive hyperemia for ununited fracture. Similar treatment was again recommended by Nicoladoni¹ in 1875. Bruns² and Thomas,³ in 1886,

¹ Nicoladoni: Wiener med. Woch., 1875, Nr. 5, 6. u. 7.

² Bruns: Deut. Chir. Lief. 27, 1886, S. 597.

refer to the method and report cases thus treated. Again, in 1887, Helferich⁴ found passive hyperemia useful in favoring callus formation.

August Bier of Bonn has extended the use of passive hyperemia to many other conditions, and in his recent book,⁵ the source of this review, carefully describes the technique, the effects of and indications for its application.

TECHNIQUE.

The part to which the constriction is to be applied is first protected by a few turns of gauze bandage. A broad rubber band is then wrapped about the part tight enough to produce moderate stasis. No pain, discomfort or paresthesia should result from the application. It should be loose enough to be forgotten during the performance of ordinary occupation.

At first the subcutaneous veins of the back of the hand, then the larger veins of the forearm, begin to swell. The skin gradually becomes bluish, with a red color of the palm and the extensor surface of the elbow. In the skin of the palm and more sparsely on the back of the hand there are numerous circumscribed small white flecks. On careful observation a delicate venous network can be seen. After about three hours the skin of the forearm is generally blue-red, the fingers, elbow region and back of the hand bright red. The white flecks and veins gradually disappear. After longer application the limb becomes edematous.

In his earlier work Bier recommended the application of a bandage to the peripheral parts of the limb, but has lately discarded this. When possible the site of application should be frequently changed.

In diseases of the extremities suitable for this treatment a rubber band about 6 cm wide is applied at any point above the site of the lesion. In affections of the hip no satisfactory apparatus has yet been made. For disease of the shoulder a rubber tube is used in place of the rubber band. This tube is maintained in its proper position by slipping it under a handkerchief tied about the neck. In the production of stasis about the head, a rubber band from 2 to 3 cm. in width may be used, the neck being protected, as in the extremities, by a gauze bandage. In disease of the testicle a rubber tube may be applied about the scrotum, including one or both testes. A suspensory should be worn during the application.

RELIEF OF PAIN.

The most striking effect of passive hyperemia is the relief of pain. Though the explanation of this is not clear, it may be due to diminished sensitiveness of the nerves under the serous infiltration.

BACTERICIDAL ACTION.

The experiments of Notzel⁶ seem to show that stasis of a limb in animals prevents death after the injection into the congested part of an otherwise

fatal dose of anthrax and virulent streptococci. Of sixty-seven rabbits subjected to local passive hyperemia and then injected with these organisms, only sixteen died. All controls and also the same animals, again injected a few weeks later, but unsubjected to passive hyperemia, died after the injections.

Laqueur⁷ found that *in vitro* the bactericidal power of blood from the region of stasis hyperemia possessed increased bactericidal power over the normal.

The increased bactericidal power of passive hyperemic blood is ascribed by Wessely⁸ to the presence of albuminous substances and antibodies, by Buchner⁹ to an increase in the number of leucocytes in the congested region, by Cornet¹⁰ for tuberculosis to the retention of the products of bacterial metabolism, which stimulate connective tissue formation, by Hamberger¹¹ to the bactericidal action of an increase of carbonic acid.

Bier points out that such favoring influences obtain only when the passive hyperemia is of moderate grade and that suppuration and erysipelas may follow tight and long-continued constriction of an extremity, as he has seen in his own work.

INFLUENCE ON ABSORPTION.

The experiments of Klapp¹² seem to show that active hyperemia is capable of increasing the absorption into the circulation of certain substances. In his work he selected milk sugar for the injections, because of its practically complete excretion in the urine and the readiness with which the amount can be quantitated by polarization. Injections into the hind legs of dogs showed that excretion was much more rapid in sixteen of eighteen trials when the leg was subjected to the influence of a hot-air apparatus. In experiments on himself and students, he found that hyperemia from hot air regularly increased the quickness of absorption, but that the increase was somewhat less striking than in dogs.

The relation between passive hyperemia and absorption is less clear. Klapp's researches show that during the application of the constriction absorption is delayed as might be expected. With the removal of the constriction, however, absorption takes place much more rapidly than normal. The end result, therefore, in short periods of passive hyperemia may be a more rapid absorption than normal. In the use of passive hyperemia for long periods, as Bier frequently recommends we may suppose that absorption is slowed. The results of experimentation are somewhat conflicting. Czylharz and Donath¹³ found that a dose of strychnine, otherwise lethal in two to five minutes, after injection into the hind leg of guinea pigs, failed to kill the animals when the limb was previously constricted with an

⁶ Notzel: Archiv. f. klin. Chir., 60, 141, 1. Heft.

Esmarch bandage. All the animals remained well when the constriction was removed after from one to four hours. Kohlhardt¹⁴ failed to confirm this observation concerning strychnine, but found that an otherwise fatal dose of cocaine hydrochlorate failed to poison rabbits when injected into a limb subjected to constriction longer than one hour.

Bier regards the edema following constriction as of favorable moment, diluting the poison and thus protecting the system from too concentrated a dose. A longer contact with the protective body tissues may render toxic material less harmful.

RESOLVENT ACTION.

Bier believes that hyperemia, both active and passive, is capable of resolving proliferated joint tissue and tendon nodes. He cites his experience with a patient who presented thick, easily palpable and visible nodes on the extensor tendons of the fingers of both hands, following gonorrheal rheumatism. He had been treated in many ways, but never with hyperemia. Hot air was used on one side and a constricting band on the other with disappearance of the nodes. A favorable effect is also mentioned in other cases. The softening of urethral strictures after the use of bougies is ascribed to hyperemia from inflammatory irritation. The passive hyperemia of the genital tract during pregnancy softens vaginal cicatrices. The relief of pain and stiffness in infected joints after active and passive hyperemia is evidence of solvent action.

NOURISHING EFFECT OF HYPEREMIA.

An opportunity to study the effect of long-continued passive hyperemia is afforded by cases of venous thrombosis arising spontaneously in the course of various infections. The condition of the affected limb after such a disturbance has been noted by Berger,¹⁵ Lesage,¹⁶ Eulenberg,¹⁷ Goldscheider,¹⁸ and Redlich.¹⁹ An increase in the size of the muscles of the limb is practically a constant finding. There is usually dilatation of the superficial veins and slight edema. The increase in size of the muscles was unaccompanied by a corresponding increase in strength, and in all but Lesage's case the unaffected limb was the stronger. A true muscular hypertrophy following passive congestion is therefore doubtful.

In the use of passive hyperemia as a therapeutic agent, Bier has never noted any muscular hypertrophy.

An increase in the length of the bones of the extremities after long standing venous hyperemia has been noted by Broca,²⁰ Krause,²¹ Nicoladoni,²² Israel²³ and Hitzig.²⁴ Helferich²⁵ has

utilized passive hyperemia to lengthen a limb shorter than its fellow and with satisfactory result. Schüller²⁶ likewise obtained an increase in the length of extremities after long standing artificial passive hyperemia, but in combination with massage, baths and diet. Animal experimentation and experience in pathology show that after passive hyperemia there is often a marked increase in the connective tissue of an affected organ. Bier regards the number of cases with an increase of bony growth following passive hyperemia as too small to expect much from the method. His own experience in many cases led to no striking results.

REGENERATION.

The proliferation of connective tissue following passive hyperemia may be regarded as evidence of regeneration.

Burn's²⁷ experiments with animals seem to show that bony growth may be increased by passive hyperemia. Artificial fracture of the diaphysis of both tibiae in dogs was followed by more rapid formation of callus in the leg to which a constricting band was applied for an hour and a half a day.

TREATMENT OF SPECIAL CONDITIONS.

Tuberculosis.

Tuberculosis of the joints: Bier believes that active hyperemia is harmful in the treatment of tuberculosis. Passive hyperemia is the method of choice, but does not exclude surgical intervention in cases which are doing badly under this method. Passive hyperemia may be satisfactorily used in out-patient clinics.

Technique: The use of passive hyperemia is especially difficult in tuberculosis and needs close observation on the part of the physician. A strong venous hyperemia is induced by means of the broad elastic band, which must be applied so that it does not cause pain. The limb should remain warm, the pulse plainly palpable in the peripheral parts. The elastic band is allowed to remain in place at first from one to at most three hours. During the application the limb is not immobilized. Both closed and open tuberculosis are thus treated. When there are cold abscesses or fistulae, the strictest asepsis is observed. Collections of pus may be incised and their evacuation favored by cupping glasses or vacuum apparatus. Scraping with the curette and probing must be avoided.

Contra-indications: Beginning amyloid, severe pulmonary phthisis, large cold abscesses and faulty position of the limb are contra-indications to the method.

Results: Bier discusses the results of treatment with passive hyperemia in cases which came under his observation between April 1, 1904, and Aug. 1, 1905. Though the method was in use long before this time, the technique was undeveloped and all cases were not similarly treated. Cases treated after August, 1905, are not included

to insure a sufficient period of observation. *Tuberculosis of the joints of the hand:* Seventeen cases were under treatment. Four showed fistulae and ulceration at the time of first observation. Abscesses were incised in five cases while under treatment. Fifteen cases (88%) were regarded as cured. The result was satisfactory in all of these; in three there was no limitation of motion. Two cases improved, one had fistula; the other, a severe case, underwent numerous operations. The average duration of treatment was twelve months. *Tuberculosis of the elbow:* Eleven patients were treated. Five had fistulae from the start. In eight, abscesses were incised under observation. Eight patients (72.7%) were cured, two of them fistulous cases. Normal mobility was secured in none of the cases. In all, however, motion was satisfactory. The worst case showed an excursion of from 50 to 115 degrees. Three were improved, all of them fistulous cases. The average duration of treatment was nine months. *Tuberculosis of the foot:* Thirteen patients were treated. Eight had fistulae when they came under observation. Abscesses had to be incised in six. Eight were cured, four of them fistulous. Perfect motion was secured in three, satisfactory motion in all. Three were improved. There was no improvement in one, and in another an amputation was done outside the clinic. The average duration of treatment was ten months. *Tuberculosis of the knee:* Bier regards the knee as less suited for passive hyperemia than other joints with tuberculosis. In most cases an operation is needed to prevent stiffness in a faulty position. In eight cases an operation was done after a short trial of passive hyperemia. In five cases, however, the method was used, and of these two were beginning to show fistulae and a third was already fistulous. Three patients were cured, two with full motion. In one the joint was stiff, but in good position. Two improved, both with stiff joints. *Tuberculosis of the shoulder:* Only one case was treated. In this, cure was complete with perfect motion.

Both Henle²⁴ and Halse²⁵ report favorable results with passive hyperemia in joint tuberculosis. Though the method has been generally thought inefficient and even dangerous, Bier believes that poor results are due to bad technique and that operation is less often necessary than with other methods.

Bier believes passive hyperemia to be an efficient method of treating not only tuberculosis of the joints, but also of the testes, the tendon sheaths, glands, the subcutaneous cellular tissue and the skin.

Acute Inflammation and Suppuration of the Extremities

Technique: In the treatment of gonorrheal inflammations, of acute simple and relapsing osteomyelitis, lymphangitis, freshly infected wounds and phlegmonous inflammation of the tendon sheaths, the technique in the applica-

tion of passive hyperemia is quite different from that in tuberculosis. While in tubercular inflammation, the stasis bandage is applied for only a short daily period and the production of edema is avoided, in these acute non-tubercular infections the elastic band is applied for from twenty to twenty-two hours a day and the limb elevated during the remaining two to four hours to diminish the edema. Similar care is taken in these cases to impede only the venous return. Discomfort should be avoided. The constricted limb should be warm and the pulse strong. Pain should be lessened. Its diminution is a good index of the efficiency of the method. Following the application, there is usually an increase in the redness, swelling and edema of the diseased region. The whole limb, even, may become red to the limits of the bandage, but with the continuance of treatment these symptoms should subside. If abscesses appear they should be incised. As the case improves, the period of application is shortened until finally the bandage is used only from one to several hours a day. During the early part of the treatment, the constricted limb should be carefully watched. The bandage may become loose with time and need to be tightened. On the other hand, a strong blue color to the limb indicates that it has been too tightly applied. The constriction should not be applied too close to the diseased region. When the fingers are affected, it may well be placed on the upper arm. Its site should be frequently changed to avoid injury to the underlying tissue.

If surgical intervention is necessary, the incisions should be small. After operation, the bandage may be re-applied after from two to three hours. The evacuation of pus may be aided by expression and flushing with normal salt solution. A large absorbent dressing favors the evacuation of pus. Drainage and the use of tampons are believed to be harmful, doing unnecessary injury to the diseased region.

Effect on temperature: Though the bandage often fails to affect the temperature, yet, in some cases, it is noted that the temperature quickly falls after its application or sinks to rise again when it is removed.

Gonorrheal Arthritis

Bier has treated all forms of gonorrheal arthritis with his method, obtaining the best results in the most severe cases with stiffness or ankylosis of the affected joints. He knows no method of treatment which accomplishes such rapid results in any disease as hot stasis in gonorrheal arthritis. The prompt relief of pain is one of its most striking features. Often after one hour of application, a point the movement of which was followed by excruciating pain can be passively manipulated without discomfort. Both passive and active motion should be begun as soon as is possible without pain. If as rarely happens pain is not at once relieved, the bandage may be removed for from one half to one hour, then replaced.

²⁴ Henle. *Beitrag zur klin. Chir.* 20 Bd. 711

²⁵ Halse. *Munch. med. Wch.* 1903, Nr. 22

Unfortunately no list of the patients thus treated is included, but Bier illustrates the success of the method by several cases in detail.

Acute Articular Rheumatism.

Of ten cases of acute articular rheumatism, the method gave prompt relief of pain in all. In a disease with such a variable course, positive conclusions cannot be made concerning the effect on its duration, but Bier states that those joints to which passive hyperemia was applied healed more quickly than others in which the method was not used.

Phlegmonous Inflammation of the Tendon Sheaths.

Twenty-two cases were treated. Of these, fourteen recovered without permanent injury to the tendons, an unusually favorable result. The result in eight cases was less fortunate, for in these there was necrosis of the tendons.

Osteomyelitis.

Passive hyperemia is combined with operative interference. Puncture is made with a stout trocar and the abscess washed with normal salt solution or one or more incisions are made. Neither drains nor tampons are advised. In fourteen acute cases, cure was effected in six. There was slight necrosis in five, extensive necrosis in two. Death from pyemia is recorded in one case. The fatal result was not ascribed to the method.

Cephalic and Cervical Inflammation.

Acute suppurative of the middle ear, mastoiditis, acute cerebrospinal meningitis, acute parotitis, lymphadenitis, alveolar abscess, periorbitis and osteomyelitis of the maxilla are regarded as suited for treatment with passive hyperemia. Constriction of the neck is made below the larynx and is maintained for from eighteen to twenty-two hours. The face becomes somewhat swollen and turgid. As a change in the position of the bandage is impossible, the underlying skin must be carefully protected. Relief of symptoms and more rapid resolution of inflammation is claimed.

Recent Literature.

Case Teaching in Medicine: A Series of Graduated Exercises in the Differential Diagnosis, Prognosis and Treatment of Actual Cases of Disease. By RICHARD C. CABOT, A.B., M.D. (Harvard). Instructor in Medicine in the Harvard Medical School and Physician to Out-Patients at the Massachusetts General Hospital. Pp. x. 214. Boston: D. C. Heath & Co., 1906.

In this book Dr. Cabot makes use of the so-called case system of medical teaching which has come into general recognition since Dr. W. B. Cannon's original work on the subject. As an introduction to seventy-eight actual cases Dr. Cabot makes certain pertinent remarks regarding the method, its advantages for the

student, for the teacher, the method of using the cases, general suggestions and a statement of the character of the cases which he has collected. In these remarks there is a succinct statement of what the method is expected to do and has done in the hands of competent teachers. Undoubtedly, the plan of presenting an actual case and bringing out a discussion of it on the part of the students is an interesting and, therefore, a useful method of imparting medical knowledge. The students may always be depended upon to do their part provided the teacher does his. One must, however, be a good teacher in order to accomplish satisfactory results. If the cases are well chosen, as in this volume, and the teacher does not allow the discussion to run too far afield, the method cannot fail to be stimulating and instructive. In preparing this book Dr. Cabot has chosen various cases coming within the domain of internal medicine, some of them simple and some complex. Following the clinical history, which is often intentionally left incomplete, are certain questions, and answers to those questions which are useful after the case has been thoroughly discussed. The book is printed only on the left-hand page making possible note-taking opposite to the case under consideration. The diagnoses are given at the end of the volume. Certain typographical errors occur, as is apt to be the case in a first edition. Among the most conspicuous of these is a misspelling of the word Argyll, in speaking of the Argyll-Robertson pupil. The press work is satisfactory and the volume is furthermore of interest as being the first book of a medical character published by the D. C. Heath Company of Boston.

In the practical use of the case method of medical teaching it should not be forgotten that its application to medicine was due to the efforts of Dr. W. B. Cannon who some years ago saw the possibility of applying to medicine a method long used with success in law. We regret that Dr. Cannon's name is not mentioned in connection with a method which he first showed to be of wide applicability.

A Laboratory Guide in Bacteriology: For the use of Students, Teachers and Practitioners. By PAUL G. HEINEMANN, Sc.B., Fellow in Bacteriology, The University of Chicago.

Although a number of laboratory guides in bacteriology have been issued within the last few years, none can be more heartily commended for actual use in class work than this volume. It is based upon the course in bacteriology given at the University of Chicago. The best technical methods are presented, and they are clearly described. There are good illustrations of nearly all the apparatus employed. Cultural and morphological features of the different bacilli that the student can readily learn by observation are omitted. The book is well arranged with the object of training the student's powers of observation, and of stimulating him to consult the original sources.

eleven other societies are to be here during the month of June alone.

The list of these societies is as follows: The American Medical Association, June 5 to 8, under the presidency of Dr. William J. Mayo, of Rochester, Minn.; The American Academy of Medicine, June 2 and 4, under the presidency of Dr. D. C. Hawley, of Burlington, Vt.; The American Neurological Association, June 4 and 5, under the presidency of Dr. Henry R. Stedman, of Boston; The American Association of Life Insurance Examining Surgeons, under the presidency of Dr. H. W. Dewey, of Tacoma, Wash.; The American Proctologic Society, June 5 and 6, under the presidency of Dr. Lewis H. Adler, Jr., of Philadelphia; The American Urological Association, under the presidency of Dr. F. C. Valentine, of New York; The American Gastro-Enterological Association, under the presidency of Dr. H. W. Bettmann, of Cincinnati, Ohio; The American Medical Editors' Association, June 4 and 5, under the presidency of Dr. H. Waldo Coe, of Portland, Ore.; The American Public Health Association, under the presidency of Dr. F. F. Westbrook, of Minneapolis, Minn.; The National Confederation of State Examining Boards, June 4; The American Association for the Study of Alcohol Inebriety and Other Narcotics, June 5, 6 and 7; and the Massachusetts Medical Society, June 12 and 13, under the presidency of Dr. Arthur T. Cabot, of Boston.

The membership in these various societies naturally coincides in great measure with that of the American Medical Association, hence the opportunity of combining various meetings has no doubt led to this somewhat extraordinary array of societies coming to Boston at this time. It is apparent that this city offers much of interest quite apart from its work in medicine, and it is also evident, from the plans which have been made, that amusement and recreation will form a goodly part of the meetings which are about to take place. This is as it should be. It would be unfortunate were our minds so taken up with purely professional problems that no time could be left for the social side. It would be equally unfortunate were the time to come when these meetings should so far neglect their reason for existence that recreation took a foremost place. There is, however, small danger of this, and the aim of the Boston management has been to combine in just measure, and, we trust, with a measure of success, the strictly scientific side of the program with a due amount of relaxation.

THE FOREIGN GUESTS.

A MEETING of the American Medical Association would be far from complete were it not possible to have the medical profession of other countries represented at its sessions. This year will be no exception to the rule which has previously obtained that many distinguished foreigners will grace the meeting by their presence and their contributions.

Among the first to be mentioned should be Sir William Macewen, regius professor of surgery at the University of Glasgow, and a surgeon of the very foremost rank. Dr. Macewen is now fifty-eight years of age. He was born in a small town in Scotland, studied at Glasgow University, and began his surgical career in a subordinate position at the Glasgow Royal Infirmary. His career has been one of constant accomplishment, and, although he is probably best known for his work on the surgery of the brain and cord, his contributions in general have been of the highest order. His remarks at the meeting will be followed with the closest attention by many who have long known him through his work.

Prof. Alfred Dührssen is a leader among German gynecologists. The scene of his activity has been Berlin where he at present conducts his own polyclinic. He is still a comparatively young man, and will be cordially welcomed to this country by many of the younger generation who have had the good fortune to make his acquaintance as students. Another gynecologist of distinction who will be present at this meeting is Prof. A. von Rosthorn, of Heidelberg, where he has attained to the rank of "Geheimrath." He is a teacher of distinction, a faculty possibly gained in a measure by an earlier association with Billroth. Dermatology is represented by Prof. Max Joseph, of Berlin. Dr. Joseph conducts a popular private polyclinic with an exceedingly large clientèle.

Surgery will have further representation through the presence of Prof. Friedrich Trendelenburg, of Leipsic, and Dr. Theodore Tuffier, of Paris. Professor Trendelenburg is at present chief of the surgical clinic at the University of Leipsic and is perhaps popularly known best through his contribution to surgery in calling attention to the so-called "Trendelenburg posture." Dr. Tuffier is a leader among French surgeons. He was an ardent supporter of Lister's early theories and did much toward introducing antiseptic methods into French practice. His recent work on spinal anesthesia has more recently brought him again into prominence.

Dr. Tullier is, however, more than a surgeon, inasmuch as he is a patron of the arts and a collector of great enthusiasm. Prof. Max von Frey will represent physiology. He is at present professor of physiology at the University of Würzburg. He was formerly an assistant of Ludwig and later was associated with Justus Gaule.

Others who will attend the meetings are Dr. Wesley A. Mills, of McGill University, Dr. James Bell, Dr. George A. Peters, Dr. Alexander Primrose, Dr. George A. Armstrong, Dr. Francis J. Shepherd and Dr. Richard A. Reeve, all from Canada, and the latter president of the British Medical Association. British Columbia and New Brunswick will also be represented in the persons of Dr. Samuel W. Tunstall, of Vancouver, and Dr. Murray MacLaren, of St. John's.

THE NERVOUS SYSTEM IN RELATION TO DIABETES.

At the recent meeting of the Section of Medicine of the Fifteenth International Congress at Lisbon Dr. F. W. Pavy, of Guy's Hospital, London, contributed an important paper on the pathogeny of diabetes. After discussing at considerable length the pathological anatomy and what is known of the mechanism of sugar production, he committed himself definitely to a recognition of the important part which the nervous system plays in the development of the disease. He holds that the evidence from various sides is now too definite to admit of doubt that cerebral action is intimately related to the affection. The common occurrence of diabetes in so-called neuro-pathic persons and its greater severity among those of this disposition are arguments of some value in this direction.

The mechanism by which this influence of the nervous system is affected is presumably through the little understood vaso-motor system of nerves. Dr. Pavy is of the opinion that the chain of evidence regarding the part played by the vaso-motor system is sufficient to render possible the assumption that diabetes is primarily a neurosis implicating a particular area of that system.

However forcible the arguments Dr. Pavy presents may appear to the general reader, we may at least see in his work a valuable tendency to associate closely organs and processes which at first glance seem to have small relation to each other. As we observe the gradual development of our knowledge of disease, we see more and more an

effort to make clear the exact relationship of the nervous system to the most varied disorders under investigation. No doubt this tendency, like any other, may be carried to an extreme, but the recognition of the influence of the nervous system on bodily function is a distinct step in progress. As we have before had occasion to state, one of the strongest arguments for the prosecution of specialism in the practical as well as in the theoretical branches of medicine is the impetus it gives to look below the surface and to trace relationships which would otherwise pass wholly unobserved. The entire matter, in its broadest aspects, of the relation of the nervous system to the onset of disease, constitutes a subject which the students of immunity must sooner or later face, and which no doubt when systematically studied will lead to practical results of value. Such a paper as this of Dr. Pavy is a step in this direction.

THE AMERICAN MEDICAL ASSOCIATION SUPPLEMENT.

As a supplement to this issue of the Journal, we publish details of the management of the several committees acting under the general committee of arrangements. In order to make clear the entire organization of the committee of arrangements we reproduce a diagram illustrating in graphic form the exact relationship of the various subordinate committees to the central committee of arrangements and to each other. It is hoped hereby to offer the visiting members of the association a quick and easy method of securing such information as they may need regarding those in authority in the various departments of the general organization. This is naturally not intended in any way to take the place of the various bureaus of information but rather to aid in directing members to the proper sources of authority.

MEDICAL NOTES.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.

For the week ending at noon, May 30, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 12, scarlatina 29, typhoid fever 13, measles 67, tuberculosis 27, smallpox 0.

The death rate of the reported deaths for the week ending May 30, 1906, was 19.28.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, May 26, 1906, was 214, against 202 the corresponding week of last year, showing an increase of 12 deaths and making the death-rate for the week 18.75. Of this number 97 were males and 117 were females; 205 were white and 9 colored; 141 were born in the United States, 67 in foreign countries and 6 unknown; 45 were of American parentage, 147 of foreign parentage and 22 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 51 cases and 4 deaths; scarlatina, 40 cases and 2 deaths; typhoid fever, 13 cases and 2 deaths; measles, 80 cases and 1 death; tuberculosis, 47 cases and 26 deaths; smallpox, 2 cases and no deaths. The deaths from pneumonia were 28, whooping cough 4, heart disease 27, bronchitis 8 and marasmus 4. There were 15 deaths from violent causes. The number of children who died under one year was 41; the number under five years 60. The number of persons who died over sixty years of age was 54. The deaths in public institutions were 57.

There were no cases and no deaths reported from cerebrospinal meningitis during the week.

AMERICAN NEUROLOGICAL ASSOCIATION. — The annual dinner of the American Neurological Association will be held Monday evening, June 4, at the Hotel Somerset, presided over by Dr. Henry R. Stedman, of Boston.

LUNCHEON, AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION. — Dr. E. G. Cutler will entertain the American Gastro-Enterological Association at luncheon at the University Club on Monday, June 4.

DINNER IN HONOR OF FOREIGN GUESTS. — The foreign guests of the American Medical Association will be entertained at dinner at the Hotel Brunswick, Monday evening, June 4. Preceding the dinner, a reception will be held between the hours of seven and eight.

BREAKFAST TO PROF. MAX JOSEPH. — On Tuesday, June 5, Dr. C. G. Cumston will entertain at breakfast Prof. Max Joseph, of Berlin, who will speak in the sections on cutaneous medicine and surgery and on hygiene and sanitary science.

FIELD DAY, BOSTON CITY HOSPITAL. — The annual field day of the Boston City Hospital will be held Saturday, June 9, at half past two,

at the Riverside Recreation Grounds. In case of rain the festivities will be postponed to Monday, June 11.

RECEPTION AT THE BOSTON CITY HOSPITAL. — The trustees of the Boston City Hospital have invited the general and section officers and foreign guests of the American Medical Association to visit the hospital June 7, from twelve to one o'clock, to meet his Honor Mayor John F. Fitzgerald and the trustees of the hospital. Luncheon will be served at one o'clock.

NEW ENGLAND MEMBERS OF HOUSE OF DELEGATES, AMERICAN MEDICAL ASSOCIATION. — The members of the House of Delegates of the six New England States are as follows: Maine, Dr. E. M. Fuller, Bath; New Hampshire, Dr. J. W. Gile, Hanover, and Dr. W. T. Smith, Hanover; Vermont, Dr. M. R. Crane, Rutland; Massachusetts, Dr. L. H. Fitz, Dr. E. H. Bradford, Boston, Dr. J. L. Hildreth, Cambridge, W. P. Bowers, Clinton, Dr. F. G. Wheatley, North Abington; Rhode Island, Dr. John Champlin, Westerly; Connecticut, Dr. George R. Shepherd, Hartford, and Dr. Henry L. Hammond, Killingly.

NEW YORK.

NEW YORK BAY POLLUTION BILL. — The New York Bay Pollution Bill has now been signed by Governor Higgins, as well as Mayor McClellan, and therefore the creation of the new commission is an assured fact. The bill goes into effect immediately.

RETIREMENT OF A POLICE SURGEON. — In consequence of failing health, Dr. Stephen Guernsey Cook, for twenty years a police surgeon and for a considerable portion of that time president of the Board of Police Surgeons, has handed in his application for retirement. The city ordinances provide that after fifteen years' service a police surgeon may retire on half pay, which is \$1,500 a year.

A NEW DEPARTMENT AT COLUMBIA UNIVERSITY. — Miss Adelaide Nutting, at present superintendent of nurses at the Johns Hopkins Hospital, Baltimore, and also president of the American Federation of Nurses, has been selected to inaugurate at Columbia University a department for the training of women to take charge of public and private institutions.

RED CROSS HOSPITAL. — The corner stone of the New York Red Cross Hospital, on Central Park West, was laid on May 22, with public ceremonies. William T. Wardwell, president of the institution, purchased the lot, 100 by 90

feet, on which the building is to stand, at a cost of \$90,000, and he has also contributed another \$10,000, making his total gifts to the hospital \$100,000.

AMENDMENT TO CHILD LABOR LAW.—Governor Higgins has signed an important amendment to the child labor law, protecting children from the dangers of night work. This amendment provides that no minors under sixteen years of age shall be employed in factories or mercantile establishments after 7 P.M.

DISPOSAL OF GARBAGE.—In consequence of the burning of the plant, on Barren Island, of the Sanitary Utilization Company, which for some time past has been disposing of the city's garbage under contract, it becomes necessary for the Street Cleaning Department temporarily to have the garbage again towed out to sea in scows and dumped. Before the company took the contract and erected its plant the summer resorts along the New York and New Jersey coasts suffered greatly from the garbage and refuse washed up upon the beaches. It is stated, however, that the scows will now be taken so far out to sea that there will be no danger of a recurrence of this nuisance. The Street Cleaning Commissioner, Dr. Woodbury, had an interview with Admirals Evans and Brownson of the Navy, and both officers assured him that, from their knowledge of the tides, they felt justified in saying that if the garbage were dumped twenty miles at sea, southeast of the Goshue channel, there would be no possibility of defilement of the beaches.

Correspondence.

A FURTHER NOTE ON A NEW METHOD OF USING THE ROENTGEN RAYS: THE CONSIDERATION OF PRIMARY TREATMENT OF SOME EARLY CASES OF BREAST CANCER BY THESE RAYS.

Boston, May 21, 1906.

Mr. Editor: It is universally acknowledged that the most important step towards an intelligent use of the x-rays as a therapeutic agent is the ability to give a definite dosage. This may be done both as regards quantity and quality of the rays by means of the fluorometer devised by me in connection with a series of *fluorometer plates* and described elsewhere.*

I have found this method helpful in treating tubercular adenitis, tubercular sinusitis, enlarged prostate, cancer of the breast, lymphosarcoma, etc. The therapy of the one case of schirous carcinoma, reported by me, is the subject of the present, the microscopical examination of which is

death (from other causes) showed that the diseased cells had disappeared. Other cases of cancer of the breast have done well by the use of this method when the clinical diagnosis indicated operation, which had been declined. A testicle in a man about fifty years old, which was much enlarged owing to a new growth, was reduced to smaller size than normal under treatment by this method.

The noteworthy point in these cases is that though the exposure has sometimes been one and one-half hours in duration with the tube at a distance of ten inches from the skin, not even the slightest reddening of the surface has been caused, because the easily absorbed rays were excluded by the aluminum plates. In other words, by means of this method the penetrating rays, which also have efficiency as a therapeutic agent, can be used in much larger doses than would be possible were the easily absorbed rays not shut out. Formerly the amount of penetrating rays that could be used was dependent upon the quantity of easily absorbed rays that the skin could bear without being burned.

The rays of great penetrating power, estimated by their action upon barium-platinum-cyanide, exert less chemical action than those of low penetrating power. This is true also, I believe, of their action on a photographic plate, therefore if the efficiency of the rays as a therapeutic agent is due to the chemical change they bring about, a somewhat larger amount of highly penetrating rays may be used, as compared with that necessary for easily absorbed rays in superficial cases, to offset this lower degree of chemical action, in addition to the larger amount needed, because the light diminishes when the distance from the source increases. It follows from this that the amount of easily absorbed rays and of penetrating rays issuing from a tube cannot be measured accurately by the same scale if based on a chemical reaction, therefore many of the methods used are at fault.

While the small group of patients with cancer of the breast alluded to above does not prove that the x-rays are the best means of treating very early cases, it does seem wise to give further consideration to their use as a primary means of treatment in early new growths of the breast, when we realize, first, that the penetrating rays undoubtedly have efficiency as a therapeutic agent, second, that we can use them alone by excluding the easily absorbed rays and that if the dose can be measured, and third, that metastases may perhaps be avoided by very early treatment. The rays should be directed upon the breast from two or more sides and those regions also should be included in the treatment in which the glands that might be affected were the disease to progress. Subjecting the heart and other normal organs to the action of the rays should be avoided. I believe that there are cases of early new growths in the breast which may well be treated by the x-rays alone, provided the method which I have indicated is fully carried out. Further study of the subject is of course necessary. The fact that in numerous cases of operation for breast cancer the x-rays have been successful only locally is not a proof that they may not be used successfully as a primary treatment in some early cases, in these numerous, perhaps have died already, I think, of metastases. With operation we find the metastases and recurrences locally. If in some cases, specifically, the x-rays used very early can be of the character mentioned, in some sort of the disease the will be a greater cure than they are now.

Very truly yours,

LESLIE H. WILLIAMS, M.D.

Casa de la Salud, Mexico.

Mr. Editor: Dr. David W. Williams, of Boston, has been successful in the treatment of cancer of the breast by the use of the x-rays. He reports that he has treated a number of cases, which he had previously failed to cure by operation, by the use of the x-rays. He states that he has been successful in curing a number of cases of cancer of the breast, which he had previously failed to cure by operation. He states that he has been successful in curing a number of cases of cancer of the breast, which he had previously failed to cure by operation.

Mr. Editor: I have been reading Dr. Williams' paper on the use of the x-rays in the treatment of cancer of the breast, and I am very much interested in the results. I have been successful in curing a number of cases of cancer of the breast, which he had previously failed to cure by operation.

Very truly yours,

LESLIE H. WILLIAMS, M.D.

REGISTRATION.

BOSTON MEMBERS OF THE AMERICAN MEDICAL ASSOCIATION.

IMPORTANT NOTICE.

The Bureau of Registration at Mechanics Hall will be open Monday morning, June 4, at 8.30 A.M. Boston members are urged to register at the earliest possible moment, in order to avoid congestion which will otherwise occur on Tuesday.

Committee of Arrangements,
R. B. GREENOUGH, Secretary.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING MAY 23, 1906.

BAIHACHE, P. H., surgeon. Granted leave of absence for one month from June 9, 1906. May 21, 1906.

STONER, G. W., surgeon. Granted leave of absence for three days under paragraph 189 of the regulations.

STONER, G. W., surgeon. Directed to proceed to Liverpool, England, and other points in Continental Europe for special temporary duty, upon completion of which to rejoin his station at Ellis Island, N. Y. May 16, 1906.

MCINTOSH, W. P., surgeon. Granted leave of absence for ten days from May 25, 1906. May 22, 1906.

BROWN, B. W., passed assistant surgeon. Granted leave of absence for two months from July 2, 1906. May 16, 1906.

RODMAN, J. C., acting assistant surgeon. Granted leave of absence for five days from May 29, 1906. May 22, 1906.

TOWNSEND, P., acting assistant surgeon. Granted leave of absence for five days from May 22, 1906. May 22, 1906.

WELDON, W. A., acting assistant surgeon. Granted leave of absence for thirty days from July 15, 1906. May 19, 1906.

BOARD CONVENED.

A board of medical officers was convened to meet at Baltimore, Md., on May 19, 1906, for the purpose of making a physical examination of an officer of the Revenue-Cutter Service. Detail for the Board: Surgeon L. L. Williams, chairman, Assistant Surgeon W. H. Frost, recorder.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING MAY 26, 1906.

H. D. WILSON, surgeon. Detached from the Naval Hospital, Portsmouth, N. H., and ordered to the "Dixie."

J. P. TRAYNOR, passed assistant surgeon. Ordered to the Naval Hospital, Portsmouth, N. H., for additional duty.

A. H. ALLEN, assistant surgeon. Ordered to the Naval Hospital, Naval Home, Philadelphia, Pa.

(Orders issued by the Commander-in-Chief of Asiatic Station.)

J. M. EDGAR, surgeon. Detached from the "Monadnock" and ordered home.

F. S. NASH, surgeon. Detached from the "Rainbow" and ordered to the "Monadnock."

EXAMINATION.

EXAMINATION FOR APPOINTMENT IN THE MEDICAL CORPS OF THE ARMY.—A preliminary examination of applicants for appointment in the Medical Corps of the Army will be held at various military posts throughout the United States on July 31, 1906. Full information in regard thereto may be obtained from the Surgeon General of the Army, and applications must be filed prior to June 30. Thirty years is the prescribed maximum age, and persons whose age exceeds that limit are not eligible for examination.

RECENT DEATHS.

DR. WALLACE CLEVELAND CLARK, of New York, died on May 19. He was graduated from the medical department of the University of the City of New York in 1882.

DR. JOSEPH SIDNEY CRANE, of New York, died on May 20, in the eighty-fifth year of his age. He was a native of Massachusetts, and was graduated from the medical department of the University of Pennsylvania in 1844. Before the Civil War he practised in Columbia, S. C.

BOOKS AND PAMPHLETS RECEIVED.

Materia Medica and Therapeutics. An Introduction to the Rational Treatment of Disease. By J. Mitchell Bruce, M.A., LL.D. (Hon.) Aberd., M.D. Lond. New and enlarged edition. Revised throughout. Chicago: W. T. Keener & Co. 1906.

Transactions of the National Association of United States Pension Examining Surgeons. Fourth Annual Meeting, Chicago, Ill., July 7 and 8, 1905. Vol. III.

The Practical Medicine Series. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the General Editorial Charge of Gustavus P. Head, M.D. Vols. I and II. Series 1906. Chicago: The Year Book Publishers.

The Nature and Treatment of Cancer. (Some Methods of Hypodermic Medication in the Treatment of Inoperable Cancer.) By John A. Shaw-Mackenzie, M.D., Lond. Third edition, revised and enlarged. London: Baillière, Tindall & Cox. 1906.

Manual of Diseases of the Ear, Nose and Throat. By John Johnson Kyle, B.S., M.D. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1906.

The Autotoxicoes. Their Theory, Pathology and Treatment. By Heinrich Stern, Ph.D., M.D. Chicago: G. P. Engelhard & Co. 1906.

Transactions of the American Roentgen Ray Society. Pittsburg, Pa. 1906.

On Leprosy and Fish-Eating. A Statement of Facts and Explanations. By Jonathan Hutchinson, F.R.S. and F.R.C.S., LL.D., Glasgow, Edinburgh, Cambridge and Oxford; D.Sc. Leeds and Hon. M.D. Dublin. Illustrated. London: Archibald Constable & Co., Ltd. Chicago: W. T. Keener & Co. 1906.

On Carbohydrate Metabolism (A Course of Advanced Lectures in Physiology delivered at the University of London, May, 1905). With an Appendix on the Assimilation of Carbohydrate into Protein and Fat followed by the Fundamental Principles, and the Treatment, of Diabetes Diabetically Discussed. By F. W. Pavy, M.D., LL.D., F.R.S., Illustrated. London: J. & A. Churchill. Philadelphia: P. Blakiston's Son & Co. 1906.

An Essay on the General Principles of the Treatment of Spinal Curvatures. By Heather Bigg, F.R.C.S. Ed. Illustrated. London: J. & A. Churchill. Philadelphia: P. Blakiston's Son & Co. 1905.

The Subconscious. By Joseph Jastrow. Boston and New York: Houghton, Mifflin & Co. 1906.

Original Articles.

THE ORIGIN AND NATURE OF THE BLOOD PLATES.

BY JAMES HOMER WRIGHT, M.D., Sc.D.

Director of the Pathological Laboratory of the Massachusetts General Hospital; Instructor in Pathology, Harvard University Medical School.

A prolonged study of the comparative morphology of the blood corpuscles of a wide range of animals has shown me that all of the many theories hitherto proposed concerning the origin and nature of the blood plates are untenable and erroneous.

In this paper I shall not set forth my reasons for coming to this conclusion, but I shall confine myself to a brief statement of my own opinions concerning the origin and nature of these bodies and a summary of the facts and observations upon which my opinions are based.

By means of a staining fluid, devised by me for use in the staining of blood films according to the method of Leishman, which gives the so-called Romanovsky polychrome staining, I have been enabled to stain characteristically the blood plates in sections of fixed tissues and organs so that they may be positively recognized and may be clearly distinguished from other histological elements. The description of the method of obtaining suitably stained sections with this fluid is reserved for a later publication.

After an extensive study of sections of bone marrow and other tissues in which the blood plates are thus characteristically stained, I have convinced myself that the blood plates are detached portions of the cytoplasm of those giant cells of the bone marrow and spleen which have been named "megakaryocytes" by Howell to distinguish them from the multinucleated giant cells of the marrow — the so-called osteoclasts or polykaryocytes (Howell).

This idea of the origin and nature of the blood plates is based upon the following observations:

In the sections, the blood plates (Figs. 7, 11 and 12) present the following characteristics. They appear as small bodies of generally circular outline, of a variable diameter but usually less than that of an erythrocyte, a striking characteristic is the presence in the central part of each plate of an aggregation of more or less closely packed, minute, red to violet-stained granules which may be so closely packed together and so deeply stained as to form an opaque, homogeneous, sharply outlined mass giving an appearance suggestive of a nucleus. In this central portion of the plates of some animals small rounded, unstained, vacuole-like areas are often present. The marginal portion of the blood plate is translucent, blue-stained and, though sometimes having a smooth edge, it usually presents at the periphery indentations and short projections of irregular shape giving the edge an irregular or

jagged or fimbriate outline. There is thus to be distinguished in the blood plate two portions, namely, a central, granular, red to violet-staining portion and a marginal, homogeneous, hyaline, blue-staining portion. The diameter of the central portion and the width of the marginal portion vary, the latter being usually narrower than the diameter of the former.

The giant cells present the following peculiarities which are of importance for the subject of this paper:

The cytoplasm making up the central and usually the greater portion of the giant cell is crowded more or less densely with closely set, minute, red to violet granules, for the most part like those of the central portions of the blood plates, while at the periphery it is hyaline and blue-stained. This hyaline peripheral portion forms a definite narrow zone of somewhat variable width, but is very narrow as compared with the diameter of the whole cell and has a smooth or finely ragged or fimbriate edge. In appearance it suggests the ectosare of an amoeba. The majority of the giant cells are of spheroidal form, but a minority are of varied and irregular shape by reason of the distortion of their cytoplasm into processes and pseudopod-like prolongations of varying length, form and width, so that they present all the varieties of form and outline shown by a motile amoeba (Figs. 1, 2, 6, 10 and 13).

Some giant cells may be observed in which nearly all of the cytoplasm is in form of pseudopod-like processes extending peripherally in various planes from a small central mass of cytoplasm surrounding the nucleus (Figs. 1 and 14). In these distorted giant cells the central red to violet granular portion of the cytoplasm is continued into the pseudopod-like processes to form in them a central portion and the peripheral, hyaline, blue, marginal zone also continues on to these processes as a hyaline marginal zone with a smooth or finely ragged, or fimbriate free edge (Figs. 1, 2, 4, 6, 10, 13 and 14). These pseudopods of the giant cells may have in some instances a greater length than the diameter of the field of an oil immersion objective. Their width is never less than the diameter of the smaller blood plates. They may be seen sometimes projecting far into the lumen of a blood vessel through its imperfect wall (Figs. 4, 6, 10 and 13). Some of them are seen unconnected with any giant cells (Figs. 3, 5, 7, 8, 9, 11 and 12) and such free pseudopods have been found not only in the blood channels of the marrow and spleen but also in the capillaries of the lungs.

A comparison of the pseudopods, especially the slender ones, with the blood plates shows the most striking similarity in composition and structure (Figs. 5, 7, 8, 11 and 12). The material constituting the granular, red to violet-stained central portion of both the granular, red to violet-stained central portion of the plates is indistinguishable in general appearance. It is also contained in small rounded or rounded vacuole-like spaces like those seen in the central portions of the plates (Figs. 5, 7, 11 and 14). The hyaline

A Rapid Method for the Differential Staining of Blood Films and Malarial Parasites, by James Homer Wright, M.D., *J. Am. Med. Research*, vol. vi, p. 136, January, 1917.
Pathological Technique, by MacGill and Wright, 3rd edition, p. 370. Saunders, Philadelphia, 1914.

marginal zone of the pseudopod is also just like the marginal hyaline portion of the plate in texture, staining, width, and outline of its edge.

Moreover, in a few pseudopods, of a width corresponding to the diameter of the blood plates, one or more short lengths of the central, red, granular portion may be seen to be marked off by constrictions or to be definitely separated and to appear as rounded masses or segments of the same diameter and with the same appearances as the central portions of the blood plates (Figs. 1, 2, 3, 4, 5, 7, 8, 9, 10, 11, 12 and 14). Such separate, rounded masses thus are completely surrounded by the hyaline material constituting the marginal zone of the pseudopod and the appearances are thus produced of a typical blood plate with its hyaline marginal portion continuous with the hyaline marginal portion of the pseudopod; or of a pseudopod formed out of a short chain of blood plates by the continuity of their marginal portions.

Furthermore, there may be observed short bud-like pseudopods springing, either directly from giant cells or from other pseudopods, with rounded, central, granular portions, either separate from, or continuous with, the central granular portion of the main mass of cytoplasm (Fig. 13). The smaller of these bud-like pseudopods are also in every respect like blood plates, except that they are obviously a part of the cytoplasm of a giant cell.

In brief, the two constituents of the cytoplasm of the pseudopods and of the bud-like processes of the giant cells are identical with the two substances making up the blood plates in staining reaction and texture and they are similar in their arrangement with reference to each other. Furthermore, all grades of transition exist between bud-like processes of giant cells in process of detachment (Fig. 13), or slender pseudopods showing signs of dividing into smaller parts by transverse division and the blood plates (Figs. 1, 2, 3, 4, 5, 7, 8, 10, 11, 12 and 14).

In view of these facts the inference seems to be justified that the blood plates are detached portions of the cytoplasm of the giant cells. This idea derives additional support from the following considerations:

1. That the giant cells do lose their cytoplasm. This is shown by the relatively small amount of cytoplasm of some of the giant cells exhibiting amoeboid forms, and by the occurrence of degenerate looking-giant cell nuclei with little or no cytoplasm connected with them (Fig. 4.) The appearances seem to clearly indicate that this loss of cytoplasm occurs chiefly by the detachment of buds or plate-like fragments or segments from pseudopods, or of whole pseudopods, rather than by disintegration and liquefaction, evidence of which may be seen in some giant cells.

2. The number of giant cells and pseudopods in which the appearance of plate formation is present is only a small proportion of the whole number of giant cells and is not greater than could be expected at any given moment in view of the numbers of the blood plates.

3. The direct observation by me of protoplasmic movements of identical character, both in the hyaline marginal zone of the giant cells and in the hyaline marginal zone of the blood plates on the warm stage of the microscope. These movements have been described by Detjeen and others for blood plates. I have seen the hyaline marginal zone of the giant cells and of the blood plates constantly changing its outline, sending out and withdrawing short processes of various shapes. The so-called amoeboid movement of the blood plates is not surprising, because it is known that detached fragments of living protoplasm may exhibit independent movement.

In this connection I may state that I have seen a few giant cells change their form very markedly, sending out and withdrawing pseudopods, such as are seen in the sections. This seems to show that the presence of pseudopods and protoplasmic prolongations of giant cells and even of whole giant cells in blood vessels, as I have seen in the sections, is not a passive act, due to local conditions of pressure in the tissue, but is a manifestation of the vital activity of the giant cell.

4. According to my own and others' observations, bodies that are undoubtedly and obviously blood plates are found only in the blood of mammals, and mammals are the only creatures that have giant cells in the blood-forming organs. I have found undoubtedly, characteristically staining blood plates in the blood of all of a considerable variety of mammals including the opossum and camel, and I have found giant cells in the blood-forming organs in all mammals, including the opossum, in which I have sought for them. The so-called spindle cells or fusiform corpuscles of the birds, amphibia, reptiles and fishes have been claimed by some writers to be the morphological equivalents of blood plates, but my studies of the blood of these vertebrates have not led me to accept this view.

5. It would seem from my own observations and from the studies of others that the blood plates make their first appearance in embryonic mammalian blood at about that stage of development when the giant cells have first appeared in the blood-forming organs. This point, however, is not as definitely established as I could wish.

6. A comparison of the results of the enumeration of blood plates, obtained by Helber and by Pratt in certain pathological conditions, with the histological findings in the bone marrow in the same diseases suggests a relationship between the blood plates and the giant cells. Thus in pernicious anemia and lymphatic leukemia the blood has been repeatedly found to contain abnormally few plates, while the marrow in typical cases of this disease, as far as can be inferred from the reports in medical literature and from my own observations, undergoes profound changes in the character of its cellular constituents with resulting very marked diminution in the number of the giant cells. On the other hand, in post-hemorrhagic anemia, the blood

plates are increased in number and there is also increase in the amount of red marrow with good evidence that the number of giant cells in the blood forming organs are relatively and absolutely increased in number.

In so-called myelogenous leukemia the blood plates are also increased in number and in the cellular accumulations of this disease giant cells do not seem to be an uncommon finding, although but little attention has been paid to them by pathologists. In view of the enormous increase in the marrow elements in this disease it must be obvious that the presence among them of a relatively small proportion of giant cells means a great absolute increase in the number of such cells in the body.

My acknowledgments are due to Dr. Oscar Richardson, assistant pathologist, for relieving me of much of the regular work of the laboratory during the period in which I have carried on this study.

DESCRIPTION OF PLATE.

The photomicrographs were made by Mr. L. S. Brown in the Pathological Laboratory of the Massachusetts General Hospital from sections of the bone marrow, spleen and lung of the rat, the blood plates of which animal are especially large. The magnification in all the figures is approximately 1500 diameters.

Fig. 1. Giant cell with a pseudopod projecting into a small blood channel of the bone marrow. A blood plate in process of pinching off is seen at the free extremity of the pseudopod. The granular portion of the cytoplasm is densely stained. The hyaline margin of the pseudopod is only faintly shown.

Fig. 2. Giant cell with a pseudopod projecting into a blood channel of the bone marrow. Other pseudopods either free or attached to the cell are also shown. Two small rounded bodies near the pseudopods in the vessel are either blood plates or cross sections of pseudopods.

Fig. 3. Detached pseudopod in a capillary of the lung in process of segmentation into blood plates.

Fig. 4. A small pseudopod segmenting into plates and still attached to a nearly naked giant cell nucleus in a blood vessel of the spleen.

Fig. 5. Blood plates and detached pseudopods in a blood vessel in the spleen.

Fig. 6. A giant cell with pseudopods, two of which stretch far into a small blood channel of the marrow. The continuity of one of them is not visible in the figure.

Fig. 7. Blood plates and a detached pseudopod in process of segmenting into blood plates. The vacuole-like unstained areas in the central portions of the pseudopods and of the plates are shown. Two leucocytes are present.

Fig. 8. Detached pseudopods showing segmentation and transitions to blood plates. These lie in a small blood vessel of the marrow.

Fig. 9. Small detached pseudopod showing indications of segmentation in a lung capillary.

Fig. 10. Giant cell in the marrow with pseudo-

pod protruding into a blood vessel through its thin wall. The free portion of the pseudopod has segmented so as to form a short chain of three blood plates connected together by their hyaline marginal portions.

Fig. 11. Thrombus-like mass of blood plates in a vessel of the marrow. Among the plates two detached pseudopods, one of which shows signs of beginning segmentation. Vacuole-like unstained areas are seen in some of the blood plates and in one of the pseudopods.

Fig. 12. A detached pseudopod, several blood plates, a few erythrocytes and three leucocytes in a blood vessel of the spleen. The hyaline marginal zone, both of the pseudopod and of some of the plates, is fairly well shown.

Fig. 13. A giant cell of the spleen with a pseudopod projecting into the lumen of a small blood vessel through its wall. At the free extremity of the pseudopod two plates are seen in process of formation.

Fig. 14. Giant cell in a blood vessel of the spleen with its cytoplasm nearly all arranged in pseudopods and more or less detached from the nucleus. Some blood plates are seen either free or in continuity with the pseudopods. Vacuole-like unstained areas are shown in the mass of cytoplasm at the left of the nucleus.

INFLAMMATION OF THE FRONTAL SINUS.*

By HAROLD PEYTON MOORE, M.D., BOSTON.

HEADACHE is a symptom which in a great many instances receives the most off-hand diagnosis as to its cause and the most off-hand treatment. The case is much like that of the crying baby and the soothing syrup. There is a sure remedy always at hand. It is on every dressing table and on the show case by every soda fountain. We are taught that cause and effect always go together and so should be studied together. In the common symptom of headache, however, the effect often engrosses our attention to the exclusion of the cause. It is a truism, of course, but one which I shall take the liberty of repeating, that an illuminating diagnosis of the cause of recurring and chronic headache requires a most thorough, sustained and systematic physical examination plus a keen cross examination of the patient's personal and family history and a judicial weighing of the testimony thus secured. This means that the broad knowledge and sound good sense of the general practitioner must at times be supplemented by the examinations of the man doing special work, and it means that both should work together, and that the specialist in medicine like the specialist in finance should try to keep out of "fads and fancies."

The subject of this paper is acute and chronic inflammation of the frontal sinuses. The chief symptom of disease of the frontal sinuses is headache. I ask your permission to make what I have to say a little informal and in the line of a lecture.

* Read before the Lawrence Medical Club, April 24, 1906.

Charts and specimens from the Anatomical Laboratory, City of Harvard Medical School.

stration. I shall discuss the subject in the following order: The development and the anatomy of the frontal sinus; the surgical routes to the frontal sinus; acute inflammation of the frontal sinus, its diagnosis and treatment; chronic inflammation, its diagnosis and treatment.

The frontal sinus is one of a chain of accessory cavities which surround the nasal cavity and enlarge its capacity. All the sinuses are formed in the same way. The nasal mucous membrane possesses the peculiar ability of growing in various directions into cartilage and into bone and there expanding to make the cavities which we know as the sinuses. The antrum alone is present at birth. The formation of the other sinuses begins soon after birth, but active growth does not take place in them until the period of second dentition. The reason for their formation is a little problematical. The best explanation for their presence is that they serve to lighten the bones of the face. The reason that they increase in size at the time of the second dentition is that they do so in order to give the permanent teeth enough room. At this time the superior maxilla enlarges and with it the antrum. The frontal sinus enlarges in order to keep the symmetry of the face. This theory accounts nicely for the enlargement of the antrum and the frontal but is not so applicable to the sphenoid. In animals all the sinuses including the sphenoid contain turbinates covered with olfactory epithelium. This is seen beautifully in the dog. There are no turbinates and no olfactory epithelium in the sinuses of man.

There are two frontal sinuses, a right and a left. They are separated by a median partition which corresponds to the sagittal suture of the skull. The sinuses are placed in the middle and inferior part of the front face of the frontal bone. All recent studies demonstrate that the sinuses are anterior ethmoid cells which have grown upward from the ethmoid region and separated the two plates of the frontal bone. There is always an intimate relation between the frontal sinuses and the ethmoid region since one is but the continuation of the other.

SIZE.

The development of the sinus begins after birth. At eight years it extends above the root of the nasal bone one quarter of an inch. The adult sinus measures vertically from three fourths of an inch to an inch, and horizontally from the median line one inch, that is, it reaches to the middle of the upper rim of the orbit. The capacity of the adult sinus is about one dram and a half. Owing to deviation of the septum between the sinuses the two are seldom of the same size. The prominence of the superciliary ridge is but a poor guide to the size of the sinus.

VESSELS.

The veins of the sinus are in relation with the superior longitudinal sinus of the brain, and the lymphatics connect with the sub-arachnoid space. There is a plentiful supply of nerves which makes the sinus very sensitive.

THE FORM OF THE SINUS.

There are two varieties of the frontal sinus,—the small sinus and the large.

THE SMALL SINUS.

The small frontal sinus is one where the ethmoidal cell which makes it has developed but little, but, instead, has remained at the top of the ethmoid labyrinth as the highest ethmoid cell, without pushing further upward and separating the two layers of the frontal bone. Such a sinus is contained within the upper inner angle of the orbit just above and a little behind the inner canthus of the eye.

THE LARGE SINUS.

What may be taken as the normal sinus is one which comes out of the orbit on to the brow. Normally in the median line the height varies between three quarters of an inch and an inch. In large sinuses the vertical measurement may be two inches.

The large sinus is often still further enlarged by prolongations,—a prolongation outward over the superciliary ridge and a prolongation backward over the orbit.

THE OUTWARD PROLONGATION.

Usually the sinus extends outward from the median line one inch, that is, to the middle of the orbit. Where there is a large outward prolongation the outward limit may be two inches, from the median line, or the malar bone.

THE BACKWARD PROLONGATION.

The backward prolongation runs back over the orbit on the inner side of the sinus to end blindly about one-half inch from the rim of the orbit. Usually it is one eighth of an inch high.

THE SEPTUM OF THE SINUS.

Normally the septum of the sinus is a thin triangular plate of bone placed vertically between the two sinuses. Very rarely are there perforations in it. I have found but one undoubted perforation in at least four hundred heads. No matter how much the upper part of the septum may deviate the base is nearly always in the median line.

INCOMPLETE OR PARTIAL SEPTA.

In addition to the median septum which is complete, the frontal sinus often has partial or incomplete septa. These have two seats of predilection,—at the summit of the sinus and in the backward or the orbital prolongation. Partial partitions are found in about 10% of all sinuses. In about 5% of cases there is found a nearly complete partition. I have never seen but one of these at a time. Such a partition must be recognized or it will vitiate the operation which is undertaken for the cure of disease of the sinus.

The study of the relations of the sinus is the study of the sides which compose it. There are three such sides and the canal which connects the sinus with the nose.

ANTERIOR WALL.

Taking bodies as they run in the dissecting room in one third of them, the frontal sinus is of the undeveloped variety; that is, it does not come on to the brow at all but is confined within the upper inner angle of the orbit as the highest ethmoid cell. For surgical purposes such a sinus has no anterior wall. In two thirds of the cases the sinus comes on to the brow from three fourths to one inch. If, therefore, you do not know the size of the sinus, the only sure place to reach it is within the orbit at its upper inner angle, and next to this place you are sure to find the sinus at the root of the corresponding nasal bone.

THE POSTERIOR OR THE CRANIAL WALL.

The posterior wall of the sinus is the front wall of the cranial cavity.

THE FLOOR OF THE FRONTAL SINUS.

In surgical anatomy, next to the anterior wall the floor of the sinus is the most important wall. Given a normal sinus of the large variety the floor is in relation from without inward with the roof of the orbit, the roof of the ethmoid labyrinth and the roof of the nasal fossa.

The relationship with the roof of the ethmoid labyrinth is constant. If the sinus is small the relationship with the roof of the orbit and with the roof of the nasal fossa may disappear.

The relationship between the floor of the frontal sinus and the ethmoid cells is very important. The anterior ethmoid cells make the floor of the sinus, and often mould into it. By this they may obstruct the drainage of the sinus. When an ethmoid cell moulds into the floor of the sinus it is easy to break through the roof of this and make a large opening down into the ethmoid region of the nose. The floor of the frontal sinus is either funnel shaped or saucer shaped.

The dangerous area of the sinus is the posterior internal angle of the floor, since here the cribiform plate comes into close relationship. All strong curetting of the sinus, therefore, should be done in an outward and downward direction, never backward and inward.

The sinus empties into the middle meatus of the nose by a canal about half an inch long. This starts from the posterior part of the floor from an eighth to a quarter of an inch from the median septum. In trying to find it from within the sinus, the tendency is to tug the septum of the sinus. If the floor of the sinus is funnel shaped the probe is guided at once into the duct, but if the floor is of the saucer shape variety the probe must be moved outward away from the septum before it will drop into the duct.

CATHETERIZING THE SINUS.

The duct of the sinus empties into the middle meatus to the outside of the anterior end of the middle turbinate. It is usually impossible to

catheterize the sinus without first gaining room by the removal of the anterior end of the middle turbinate. Not only does the turbinate hinder catheterization but any enlargement of it tends to block the canal. All intranasal work for the purpose of bettering the drainage of the frontal sinus is focussed about the anterior end of the middle turbinate. The frontal sinus is placed directly over the antrum so that in one half of the cases a probe can be passed from the frontal sinus into the antrum below. Pus, of course, could find its way more readily than the probe. From its anatomical position, therefore, the antrum is often only a cesspool for the frontal.

THE PULLEY OF THE SUPERIOR OBLIQUE MUSCLE.

The superior oblique muscle is attached just within the upper inner angle of the orbit to the inside of the supra-orbital notch. This muscle lies in wait for the operator in all operations on the sinus within the orbit. If it is disturbed it gives temporary double vision, and occasionally permanent trouble. It is attached to the periosteum of the orbit. If it is necessary, this can be elevated carefully without giving lasting inconvenience, but the pulley of the muscle will not tolerate rough dissection.

THE MUCOUS MEMBRANE.

The mucous membrane of the frontal sinus is a continuation of the mucous membrane of the nose, but is not as thick. This difference is due to the fact that the mucous membrane of the sinus has few glands and no cavernous tissue.

I have given the anatomy somewhat in detail because the surgery of the sinus has undergone complete revolution in the last few years owing to the increased knowledge of the surgical anatomy.

THE METHODS OF ENTERING THE SINUS.

1. In a fair proportion of cases, after removing the anterior end of the middle turbinate, a catheter, can be passed into the sinus. This may follow the canal, but in the majority of instances it enters an ethmoid cell which moulds into the floor of the sinus and breaks through the roof of this into the cavity of the sinus. To pass a larger instrument than a catheter into the sinus by this route is to my mind unsurgical, because it is working in the dark.

2. Where the sinus comes on to the brow, it can be entered just above the root of the corresponding nasal bone. The nearer the nasal bone the opening is made the greater the resulting deformity from pitting of the scar.

3. The third method of entering the sinus is from the upper inner angle of the orbit. The incision for this starts from the inner end of the eyebrow and runs down the side of the nose along its outer border. The linear scar which this leaves is, of course visible, whereas the scar of the second method is confined to the eyebrow and is hidden by it unless it is sunken. This third method of entering the sinus is very valuable because it enables the operator to remove the

inner part of the floor of the sinus thus making a large opening from the sinus into the nose and at the same time to deal with any or all of the ethmoid cells. Chronic disease of the frontal is practically always associated with chronic disease of the ethmoid region, and the two have to be dealt with at the same time.

X-RAY PLATES.

X-ray plates give very valuable information in dealing with sinus disease. The first thing which must be known in operating on the sinus is its location and size. In other words whether the sinus is of the small type and confined within the orbit or whether it is of the usual large type and comes on to the brow. The plates show this and show further how far above the root of the nasal bone the sinus can be entered without opening the cranial cavity. If it is possible to enter well above the root of the nasal bone the deformity which results from pitting of the scar is reduced to a minimum and at times entirely obviated.

The plates show further how many septa the sinus has and their position, they show the presence and size of the orbital prolongation, the extent of the basal relationship between the floor of the sinus and the ethmoid cells, and so settle the question of the possibility of making a large opening from the sinus into the nose; and finally the plates will in a majority of cases show the presence of pus. In settling these points transillumination is unreliable.

ACUTE INFLAMMATION OF THE FRONTAL SINUS.

Acute inflammation of the frontal sinus is very common after a cold or the coryza of influenza. The bacillus of influenza has been demonstrated in acute and chronic inflammation of the antrum so that it is highly probable that the same would be true of the frontal in disease of sinus could we get at it as readily as we can the antrum. Acute inflammation of the frontal sinus does not as a rule go on to the formation of pus. The conditions in the sinus are probably the same as the conditions in the nose, namely, congestion and edema of the lining mucous membrane with an exudation of serum and a blocking of the drainage duct. These conditions persist for a few days or for a few weeks. Complete resolution generally follows.

Symptoms.—The symptoms may be simply a feeling of weight and uneasiness over the brow, something like the feeling in the temporal region when the Eustachian tube is closed; or, in addition, there may be dull persistent pain which is increased on lowering the head and tenderness under the upper inner angle of the orbit. Anything more than a very transient edema over the brow or over the inner part of the upper lid indicates that pus is forming. A few cases have been reported where the upper lid has dropped from involvement of the third nerve. I have had no such case.

Diagnosis.—In making the diagnosis of acute inflammation of the frontal sinus supra-orbital

neuralgia must be ruled out. Occasionally, the two conditions cannot be separated with certainty. In neuralgia the tenderness usually extends up on the brow in the course of the nerve to the scalp, and there is a history of neuralgia in other branches of the fifth nerve or in other parts of the body. In the nervous neuralgia patient, one should be slow in operating, especially should be slow in resorting to any external operation. In all cases of sinus disease, sometimes in acute cases, but always in chronic cases, syphilis is the "nigger in the wood pile." In my house-office days, it used to be said that every negro should be treated first for syphilis. In acute inflammation of the frontal sinus due to syphilis, if the history does not give the clew, the increase of the pain at night may furnish it.

Treatment.—The frontal sinus must be made to drain. This can be done in many cases by the use every three hours of a spray of adrenalin oil. Unless the patient has an idiosyncrasy to this drug it will keep the middle turbinate in a shrunken condition and make the lower opening of the duct as patent as possible. In addition it is very useful to pack the middle meatus with cotton saturated with the oil hoping that by leaving the tampon in place a short time the astringent effect of the drug will penetrate further along the course of the duct, perhaps into the sinus itself. If the middle meatus is roomy enough air, preferably warm, can be blown into the sinus; this gives great relief.

Combined with the use of adrenalin or rather preceding its use the nose should be cleansed with warm normal salt solution from a Birmingham douche. Cold or heat applied to the brow over the sinus will dull the pain. In the beginning of the trouble, pnenacetin, bromide, or morphia are required for the severer paroxysms. Unless this line of treatment lessens the symptoms in a short time the anterior end of the middle turbinate should be removed.

The theory of this is, that it allows the sinus to drain. In acute cases it is only rarely that pus flows from the sinus after this is done, but the clinical fact remains that this procedure quickly brings improvement. Often it is the only thing which will. If the acute inflammation does not resolve but passes into the tedious course of chronic suppuration of the sinus, if you have taken off the anterior end of the middle turbinate early you have the satisfaction, such as it is, that you left no stone unturned which might have prevented the disease from becoming chronic.

CHRONIC SUPPURATION OF THE FRONTAL SINUS.

Chronic suppuration of the frontal sinus gives a much darker picture than the one given by acute inflammation of the sinus. Acute inflammation may be an affair of a few days and a trivial complaint; chronic suppuration, on the contrary, is an affair of months, years or a lifetime and can never be classed as trivial. Its tedious course and the increasing invalidism which it produces gain for it a dignified standing among diseases.

There has been a great revival of interest in chronic suppuration of the frontal sinus of late owing to the trying out of certain new operations for its cure. For many years disease of the frontal sinus has masqueraded as supra-orbital neuralgia. For many years also, pus which had broken into the orbit from the frontal sinus was classified as orbital abscess. If any part of the nose or its accessory cavities was assigned as the origin of the pus it was the ethmoid region. In many cases this was true, but in many more cases the unrecognized source of the pus was the frontal sinus.

We have operations enough and to spare for dealing with suppuration of the frontal sinus; just what ones can be spared for good will be settled in the near future. Our knowledge of the etiology of chronic suppuration of the frontal sinus is not in this prosperous condition. More knowledge along this line is needed sadly. All that we know is this: The serum poured out in acute inflammation of the sinus may not absorb but become infected by the ordinary pus producing bacteria. The pus infects the mucous membrane so that in certain places the mucous membrane becomes thicker and in other places not only thickens but becomes polypoid. If the duct is sufficiently plugged, the pus seeks an outlet by way of the brow or by way of the orbit. Cultures of the pus secured at operation from my cases were either sterile or full of unrecognizable detritus. In three of my cases the report read: "No tubercle bacilli, no bacilli of influenza, the meningococcus not present." In a case of one of my colleagues the report came back, "A pure culture of the pneumococcus." I feel that someday the tubercle bacillus will be found to play a part here as elsewhere in the body. Tuberculosis and syphilis are the two great systemic diseases which claim every region of the body. One of the things longest known and best known about the etiology of sinus disease is that syphilis causes it in many cases. It is a striking fact that disease of the bony walls of the sinus is rarely found. I know of but two instances. A sequestrum is practically never found unless trauma was the starting point of the suppuration. Recent work goes to show that the periosteum is not involved any oftener than any of the other layers of the mucous membrane.

The other layers of the mucous membrane may be extensively changed so that the sinus is filled with polypi and yet the periosteum show but little if any alteration. This would seem to rule out periostitis as a cause except in cases of syphilis and to confine the seat of the disease to the mucous membrane, and make the probable cause some infection of the mucous membrane.

Symptoms.—The chief symptom is brow pain over the affected sinus. The pain may be neuralgic, but generally it is of a dull, heavy, throbbing character. At first it may be intermittent but later it becomes practically constant. Usually there is pus in the nose, but it may be absent until catheterization of the sinus is successful. Along with the pain there are gastric symptoms

One case of mine had persistent gastralgia, another had for months morning nausea for some days before her period and was constantly uncertain as to whether or not she was pregnant. In severe cases dizziness is present. Trouble with the vision of the eye of the affected side often is a very early symptom and sends the patient to the oculist.

I have found that cases of chronic suppuration of the frontal sinus are divided into two distinct groups:

1. A group where the chief features are the eye symptoms.

2. A group where the prominent features are pain and nasal discharge. The first group of cases come first to the eye clinic; the second as a rule come first to the throat and nose clinic.

First group. The characteristic of this group is exophthalmos or ethmoid tumor or both. The exophthalmos is due to pus gaining the orbit by perforating the floor of the sinus and displacing the globe of the eye. The ethmoid tumor is due to pus coming into the orbit by perforating the lacrymal bone. Ethmoid tumor is seen as a rounded swelling just above the inner canthus of the eye. In half of the cases of the first group there is no pus in the nose. Pain is not prominent.

Second group. In the second group there may be edema of the inner half of the upper eyelid but no ethmoid tumor or exophthalmos; instead pus and polypi are usually present in the nose and there is very marked pain.

Diagnosis. Where there is ethmoid tumor or exophthalmos if the x-ray plates do not locate the disease in the frontal sinus only exploratory operation will rule out the various new growths of the orbit, or affections of the tear sac. Pus in the nose would point to the frontal sinus or to the ethmoid region or antrum. Where there is brow pain and pus in the nose with tenderness under the upper inner angle of the orbit and edema of the upper lid or of the brow plus gastric disturbance or perhaps dizziness the diagnosis is practically certain. It can be made positive by the x-ray or by getting into the sinus from the middle meatus and withdrawing pus through the catheter or along the catheter. Pain giving by suppuration in the antrum is occasionally located over the brow. The pain given by inflammation of the frontal sinus is occasionally in the occipital region as well as in the frontal.

Treatment. Only a very few cases of chronic suppuration in the frontal sinus can be cured by passing a catheter from the nose into the sinus and irrigating with astrigent or anti-septic solutions. This method is tedious in the extreme and unreliable. To attempt to enlarge the duct of the sinus from below and to insert a tube to be retained in the duct is dangerous, because you are working in the dark. All methods like these two leave out of account the extensive disease of the mucous membrane of the sinus. No wash can irrigate the sinus thoroughly if it is half full of polypi or is divided into recesses by septa. An operation to have any chance of success must

thoroughly eradicate the mucous membrane and the polypi and remove all the septa. An opening into the sinus should be made large enough to accomplish this. This means in a small sinus that the whole front wall must be removed, and in a large sinus the greater part of the front wall or occasionally the whole of it. When this fundamental step has been taken the methods of finishing the operation open to the operator are as follows: First, he can enlarge the opening of the sinus into the nose; second, he can let the duct alone, except to clean it of diseased mucous membrane and polypi, and pack the cavity of the sinus through the brow incision until it heals by granulations, and is obliterated; in the third place, after the frontal sinus has been opened well above the orbital margin and the diseased mucous membrane, the polypi and the septa removed, the operator can make an opening along the side of the nose and resect the ascending process of the superior maxilla, thus exposing the ethmoid labyrinth from the front. By working from the ethmoid region upward and from within the sinus downward, the internal part of the floor of the sinus can be removed and a larger opening made into the nose than it is possible to make in any other way. If there is extensive disease of the ethmoid region, the tear sac is pushed aside and part of the inner wall of the orbit taken out so that the whole ethmoid region can be curetted. Not only the ethmoid region can be thoroughly dealt with in this way, but this is the most direct route to the sphenoidal sinus.

No one operation is suitable for all cases. It requires judgment to fit the operation to the case. The ideal operation is to open the sinus through an incision in the eye brow which is hidden by the eye brow later, to open well up on the forehead and to enlarge the opening sufficiently to clean out the mucous membrane and polypi and septa and then to make a large opening down into the nose. This method will occasionally succeed. The trouble with it, however, is that the duct tends to close and give a return of all the symptoms. If an attempt is made to keep the duct open by a tube passed through it into the nose just as soon as the tube is taken out the granulations caused by the irritation of the tube shut off the duct again. Temporary packing of the duct with gauze is even worse. Unless the anatomical structure of the sinus allows the making of a sufficiently large enough opening into the nose so that granulations will not bridge across the duct and close it, the operation just described will do nothing more than relieve the surgical indications for the moment. Even if the major surgical symptoms do not return, the discharge into the nose may continue. From the standpoint of the specialist no case of sinus disease is classed as cured if there is any considerable amount of pus in the nose. As this operation leaves no deformity, and does not interfere with other procedures if they become necessary, it is often the operation of first choice. By this operation I had the satisfaction of curing a physician who wished

of all things to avoid a scar and did not care if he had to wash out his sinus himself at intervals. When he last reported, some six months ago, there was no discharge. By this method also I operated on both sinuses of a boy of seventeen. The sinuses were very large. By a little intranasal work the openings which were made into the nose were easily kept open. The boy reports for washing of the sinuses periodically. The discharge is decreasing, the boy is comfortable. The deformity which would have been caused by the granulating method of treating these sinuses would make the boy an object of comment among his companions.

THE METHOD OF OBLITERATING THE SINUS BY GRANULATIONS.

The bone cavity left after a mastoid operation is allowed to heal from the bottom by granulations. When healing is complete the cavity is obliterated and in proportion to the original size of the cavity there is pitting or sinking of the scar. The great advantage of this method when applied to the frontal as well as to the mastoid is that the cavity operated upon is obliterated; the disadvantage is the sinking of the scar. A sunken scar back of the ear is noticed but little; a similar scar is very conspicuous on the brow. A sunken scar, however, is often a moderate price to pay for a cure of chronic suppuration of the frontal sinus. The injection of paraffin will better the scar to a certain extent. The granulating method is simple. It is done as follows:

Enough of the front wall of the sinuses is removed to allow the mucous membrane to be thoroughly cleaned from every part of the sinus. Great care is taken on this point. The mucous membrane is removed from the duct of the sinus but the duct is not enlarged as the object is to obliterate it. After the sinus is cleaned a part of the incision is left open and the sinus packed with gauze. Some men report sinus obliterated in this way in six weeks. In my experience the time has been between eight weeks and four months. This prolonged packing is tedious. Great care is necessary that parts of the sinus do not catch across and form pockets instead of closing steadily from the bottom. If this occurs the pain returns. In a large sinus the sinking of the scar often produces marked deformity. This method leaves behind it the satisfactory feeling that the sinus is obliterated and out of the way forever.

The third method of treating chronic suppuration of the frontal sinus is the most radical. It is a strong rival of the granulating method. It is a combination of two operations requiring one skin incision and two bone incisions. A wide strip of bone is left along the rim of the orbit and at the root of the nasal bone. This bridge makes it possible to take off the whole of the anterior wall of a large sinus and yet have very little if any deformity afterwards. The skin incision runs through the middle of the whole

length of the eyebrow and then down the middle of the side of the nasal bone. The first bone incision is in the brow well above the root of the nasal bone, so that a good bridge of bone is left after the second bone incision is finished. The second bone incision is made at the outer border of the nasal bone. Through this the ascending process of the superior maxilla is resected. Through these two bone incisions the inner angle of the floor of the frontal sinus can be thoroughly removed. In the seven cases which I have done in the last year, I have proved to my own satisfaction that in a small sinus there is absolutely no deformity and in a large sinus very little, — less deformity in the large sinuses than after the granulating method. By the Killian method, as this third method is called, not only the inner angle of the floor of the sinus is taken away, making as large an opening into the nose as the sinus will possibly allow, but the ethmoid cells are opened from the front and can be cleaned out more thoroughly than by any other route.

This operation requires more skill than the other operations because the pulley of the superior oblique must be avoided and the lachrymal sac must be turned from its bed without injury and the bridge at the root of the nose be preserved at all costs. Three fourths of the incision is in the eyebrow and so is hidden by it. All that is visible is a half-inch linear scar along the outer border of the nasal bone. It is a long operation to do, but the healing is short. The whole incision is closed and firmly healed in a week. It is a great relief after the tediousness of the granulating method. As the whole ethmoid region can be cleared out and the inner part of the floor of the sinus taken away so that the sinus is left as the dome of the nasal fossa, it would seem as if operative procedures could go but little if any further. So far I have gotten better results with this method than with any other. The last case but one where I used this method contrasts the method of Killian and the granulating method very strongly. About a year ago, I attempted to obliterate a large left frontal sinus and packed it at intervals, which were never longer than three days, for eleven months. A sinus running well back over orbit in the deep orbital prolongation of the sinus persisted until the patient was thoroughly tired. I was equally so. About a month ago I reoperated this case by the Killian method. Healing was complete in a week, there has been no drawback, and there is practically no pus in the nose. The relief of ending this dragging case was very great.

In the cases of chronic suppuration which have exophthalmos or ethmoid tumor, nature attempts to do this operation for herself. In two such cases I found the inner angle of the floor of the sinus necrosed away as well as the greater part of the anterior half of the inner wall of the orbit. All that was left for me to do was to clear out the ethmoid cells and to leave a bridge at the root of the nasal bone.

SUMMARY.

The x-ray plate is the only means of telling whether the frontal sinus remains in the orbit as an undeveloped ethmoid cell or whether it comes on to the brow. The x-ray in very many cases will show whether the sinus contains pus. Acute inflammation of the frontal sinus responds readily to treatment. In any except the most trivial of the acute cases the removal of the anterior end of the middle turbinate produces more benefit than any other form of treatment. In chronic suppuration of the frontal sinus syphilis should be ruled out at the start. With the exception of syphilis and trauma, very little is known of the etiology of chronic suppuration of the frontal sinus. The mucous membrane is the seat of the disease as the bony walls of the sinus are rarely involved. The prognosis is increasing invalidism from pain, from gastric disturbances and dizziness and inability to use the eye. Occasionally in neglected cases the pus will necrose its way into the cranial cavity, but as a rule it breaks into the orbit or into the nose. Thus, suppuration of the frontal sinus is not as dangerous as suppuration of the mastoid. But curiously enough when the meninges are exposed to pus in the region of the frontal the liability of fatal infection is much greater than when the same thing happens in the mastoid.

The three chief symptoms of chronic suppuration of the frontal sinus are interference with sight, pus in the nose, and chronic frontal headache. The pain may, however, be in the occipital region. Treating suppuration of the frontal sinus by catheter through the nose into the sinus is only palliative, seldom curative. The rational method of treatment is to open the sinus through an incision in the eyebrow and to see what the conditions are within it. Then remove all the mucous membrane, polypi and septa, and make as large an opening into the nose as possible and maintain this by intranasal work. This method will cure in a certain number of cases. If it does not cure it does not interfere with other procedures. It will always give relief to stormy symptoms. The granulating method is long but more successful than the method just described. The granulating method would seem to be best suited to sinuses of moderate size. In these it gives little or no deformity. The same thing is true, however, of Killian's method. This does away with a small sinus as completely as the granulating method; but in another way, it turns the sinus into a widely open recess of the nose. A granulated sinus can reinfect and then everything has to be done all over again. If trouble follows the Killian operation there is a good prospect of dealing with it through the nose. In all cases where there is exophthalmos or orbital tumor it is wasting time to use any operation except that of Killian because nature has partly done this operation for you. In all cases where there is a very large sinus with many septa and marked evidence of ethmoiditis the combined ethmoid and frontal operation or the operation of Killian is the operation of choice.

It is useless to expect a cure of suppuration in the antrum when there is disease of the frontal sinus above which is dropping pus into the antrum. Many uncured cases of antral disease are due to this cause. The x-ray plate is very valuable in clearing up these cases.

THE TESTIMONY OF THE FATHERS.

BY A. E. F. ROCKWELL, M.D., WORCESTER, MASS.

THE machinery of life has become so complicated and the rumble of it so fills the air that vital fundamental issues are many times obscured. We are deceived on the one hand as to the precise nature of the basic principles involved, and distracted from their proper application on the other. So deeply concerned are we with the superficial questions which impede our progress through the world that the real problems are neglected. I have seen a bear so worried by thorns in a thicket that the continued pursuit of his quarry no further interested him. There is nothing so difficult of suppression or so rapidly contagious as the right. Any effort to stifle its expression or limit its sphere of action but reacts upon the forces which seek to compass its undoing.

If we will but carefully scrutinize and intelligently interpret history, we may easily find ample argument and precedent for almost any righteous act. Arguments and precedents founded upon fundamental principles are not poorly conceived make-shift remedies for the various ills, real or fancied, which we intermittently believe beset every department of human activity. The fathers saw more clearly because their training was more simple and direct; they judged more correctly because life was less complex, and, therefore, the causes for distraction fewer. And we need not always penetrate very far the shades of the past to mold aright our views and draw sound conclusions. If, then, we undertake to approach temperately and inspect with sagacity some of the problems which through earlier misdirected effort have returned to us for re-solution, let us review a few expressions of opinion from gentlemen eminent in their profession, and distinguished for their sense of justice, catholicity and mental grasp of basic facts.

I quote, therefore, in this connection largely from "An Ethical Symposium," G. P. Putnam's Sons, 1883, to which Alfred C. Post, William S. Ely, S. Oakley Vanderpoel, Lewis S. Pilcher, Thomas Hun, William C. Wey, John Ordronaux, Daniel B. St. John Roosa, Cornelius R. Agnew, Abraham Jacobi and H. R. Hopkins were illustrious contributors.

Twenty-four years ago William S. Ely, M.D., wrote: "There is no difference between physicians but such as results from their personal talents, medical acquirements or their experience. . . . The pursuit of truth, justice and humanity are alone enjoined and each individual is to determine whither that pursuit shall lead him.

"Between those who believe in the creation of the world by cataclysms and those who believe in orderly evolution there is as wide a difference as between sugar pills and castor oil. Yet I never heard of one body of scientific men refusing to sit down and compare views of creation with the other."

At the same period Lewis S. Pilcher, M.D., wrote: "Any remarks upon the nobility of the profession of medicine would be trite; it claims for itself, and the willing tribute of others accords to it, the pre-eminence among the callings that men give themselves to, for the devotion to humanity, the high courage in the face of danger, the self sacrifice for the relief of others, the public spirit, the liberality of views and the general culture which the duties, the studies and the influences of the profession tend to develop, and which its members as a class display.

"A physician is not a member of a guild or corporation, the rules of which he must comply with in order to retain his membership therein and to enjoy its benefits, but a member of a liberal profession, the rules of which are the unwritten law of humanity and the special requirements of which must vary much according to the peculiarities of his environment."

Thomas Hun, M.D., expressed himself almost a quarter of a century ago with reference to this subject as follows:

"Dr. Austin Flint, Sr., who seems to have studied carefully the whole question and who has published in the *New York Medical Journal* an admirable commentary on the code of medical ethics, says in the April number, 1883, page 372: 'The objectionable point of the code is that which makes a practice based on an exclusive dogma' the ground of a refusal to meet practitioners in consultation. This is not a valid objection. Any physician has a right either to originate or adopt an exclusive dogma, however irrational or absurd it may be."

On page 373: "Opinions held by members of the regular profession, however at variance with those generally entertained, and however absurd, may fairly give rise to criticism and ridicule, but they cannot be made occasions for professional discipline.

"It is pleasant to find one's views coinciding with those of one who has carefully considered the whole subject, and who has brought to its study distinguished ability and high personal and professional character. When we remember that Dr. Flint is a prominent leader of a party in the profession, to most of whom these liberal and just views must be extremely distasteful, we cannot but admire his candor and fairness. The views he has presented are eminently sound and commend themselves to the judgment of those who understand the conditions which underlie all scientific progress, to wit: the largest toleration and freedom of discussion. Under their influence new truths are brought out and examined and errors eliminated, for error is most dangerous when driven into obscurity. No man or body of men can lay claim to absolute truth;

the wisest are no more than seekers after truth. There can be in medicine no heresy because there is no orthodoxy.

"If the principle I have, in accordance with the views of Dr. Flint, endeavored to establish in the beginning of this paper, namely, that those who have received a medical education are entitled to recognition by the profession, irrespective of their doctrines and systems, is sound, then this exclusion of the educated homeopaths, because their practice is based on an exclusive dogma, is illogical. Toleration, if it means anything, means toleration of error, and I do not see how to draw the line which shall limit this principle. To me homeopathy is so false in its statements and assertions, so unsound in its reasoning and extravagantly absurd in the therapeutic agencies on which it relies, as to put a great strain on my power of toleration; yet, even in an extreme case like this, it is unwise to violate by any act of exclusion this great principle lying at the foundation of scientific discussion and of search after truth.

"But there is, according to Dr. Flint, still a disqualifying cause which should exclude homeopaths from consultation, and this is the assumption of a name and organization distinct from and opposed to the regular profession."

"There is undoubtedly force in this objection, but if we look back at the history of the rise and growth of homeopathy in this country the objection will be weakened, if not invalidated. Surely the doctor is old enough to remember the persistent efforts made in the beginning by the homeopaths, when as yet they had no organization, to be admitted into our county medical societies, or in the case of members of the societies who adopted homeopathy to resist expulsion. The numerous suits unsuccessfully brought before the courts to compel the societies to admit or retain them sufficiently attest that if they now have a distinct organization the fault is not on their side. We thrust them out-of-doors, and now it comes with a bad grace from us to give as a reason for refusing fellowship with them that they are not in our house. Here the regular profession lost its great opportunity. If, instead of rejecting those among the applicants who had received a medical education, we had taken them into our ranks notwithstanding their adoption of an exclusive dogma and unsound therapeutic doctrines, we should have avoided for ourselves much embarrassment and mortification, and the career of homeopathy in this country would have been very different. It is plain that this objection now made by Dr. Flint to their recognition was not at that time a valid reason for their exclusion, for it was created by that very exclusion. They were excluded on the charge of 'having their practice on an exclusive dogma' which we now, in accordance with Dr. Flint, maintain to be not valid, and consequently their exclusion was a blunder of the regular profession. This blunder drove them into a separate organization, and this now constitutes a great objection to their recognition, and, as I understand Dr.

Flint, the only objection, provided they have received a medical education. Shall we, then, by persisting in the blunder which has driven them into a separate organization, which is itself, as Dr. Flint has pointed out, the only valid objection to their recognition, perpetuate this schism, or shall we, by retracting our false step, try to heal it? Let us proclaim that every man who has completed his medical education goes out with full right and duty to adopt such views as seem to him true, and such practice as seems to him prudent and useful, and that those who entertain different views and adopt different practice have no right to condemn or oppose him except by fair argument. The time for sober thought will come, and the principles and measures involved in this discussion must ultimately be decided by intelligent reflection, and not by the clamor of a noisy crowd assuming to be the guardians of medical interests and honor. To arrive at a decision which will be wise and satisfactory we need no suppression of discussion, no securing of pledges, no virtual expulsion of minorities, nor other devices borrowed from impure sources, but a free interchange of opinions without passion or prejudice, and with one end in view,—the dignity and usefulness of our profession."

We find Abraham Jacobi, M.D., writing about this time as follows: "When I said that the changes which have taken place in homeopathy consisted of dropping one article of faith after another, I mean to express no reproach. I was simply stating the fact that no two decennia of homeopathy look alike. From one such period to another the homeopathic literature becomes less credulous—less apologetic, more medical. The art of diagnosis stands highest in the estimation of homeopaths. The class of men who nowadays are best known in the ranks of the homeopaths are those who are more distant from Hahnemannism than any of the rest. Their talents and studies have been too many to be imprisoned within a sect. How many of them would have been glad to renounce their sectarian name if they had been permitted to do so, cannot be told at present. If there will be no more battle cries of 'Crucify!' there will be many more men who formerly had to be called homeopaths, and called themselves so by habit and coercion, who will be satisfied with the honorable name of physician."

"All of these men who proclaim their independence of Hahnemannian doctrines, and discard even the name of homeopathy, are still classed as homeopaths. By whom? By us. They have been so. They may have been. They claim they are no longer. We claim they are. What a ridiculous position for us, not for them. All they want is to be let alone in their progress toward medical science. We tell them they are outside, and there is no redemption for them. It is we who insist upon the persistence of their sectarian orthodoxy and who are doing the same we see the public doing constantly. We have enlisted the sympathy of the press and public

in their favor and improved their chances of recognition by proclaiming loudly our objections to it. Thus we have both injured the professional dignity and influence, and harmed the public. In order to destroy homeopathy and spoil the public's taste for it, we have commenced at the wrong end. Instead of improving ourselves we have excommunicated those who threw systematic medicine overboard; and nowadays when we meet men who in a genial and gentlemanly manner proclaim their readiness to join us, we refuse to let them do it in their own way, and insist upon their professing loudly that they have always walked in darkness and lived in perversity."

It was William C. Wey, M.D., who said, "The circumstances of the profession, however, have undergone a marvelous change. The thoughts of medical men and of the people have been subject to modification through the shifting events of increasing years, and the laws and the opinions which make laws have been revolutionized by the demands of the day and the hour, and the period has arrived, after much expectation, for a revision of the rules applied to medicine which our fathers so guardedly established."

Theodore W. Dwight, LL.D., on the faculty of Columbia College Law School, gave the following opinion in April, 1882: "The State Medical Society [of New York] exercises a right conferred on it by the statutes of the state. . . . It profits by the exclusion of unqualified persons from practice. When the state authorizes practitioners of other schools to practice medicine, does not courtesy to state authority dictate recognition of their fitness for association? How can the State Medical Society consistently demand public recognition by reason of state legislation, and yet deny it to others who have precisely the same authority?"

Charles A. L. Reed, A.M., M.D., in his presidential address before the fifty-second annual meeting of the American Medical Association, June 4-7, 1901, uttered the following significant words: "I proclaim, events proclaim, the existence of a new school of medicine. It is as distinct from the schools of fifty years ago as is the Christian dispensation from its pagan antecedents. It is the product of convergent influences of diverse antecedent origin. It acknowledges no distinctive title, it heralds no shibboleth. It is a school of human tolerance, of personal independence, of scientific honesty. It is the slave of neither prejudice nor preconception and abandons the accepted truth of yesterday if it only be the demonstrated error of to-day. . . . It makes no proclamation of completeness, no pretension to sufficiency. It recognizes that truth is undergoing progressive revelation, not ending to-day, but continuing through the ages. It greets as a friend him who thinks, though he thinks error, for, thinking, he may think truth, and thereby add to the common fund. It heeds all things, examines all things, judges all things."

Clinical Department.

A SECOND ECTOPIC PREGNANCY IN SAME PATIENT WITHIN PERIOD OF FOURTEEN MONTHS.

BY BRADFORD ALLEN, M.D., NASHUA, N. H.

PATIENT, Mrs. C. S., aged twenty-six. On Dec. 7, 1904, Dr. Maurice H. Richardson removed the left Fallopian tube with ovary and part of the broad ligament, for tubal pregnancy of about two months' duration.

On Feb. 13, 1906, Mrs. S. came to my office, her reason being that she was sure, from her feelings, that her condition was the same as in 1904, that is, insisted she had extra-uterine pregnancy on the other (right) side. She had menstruated regularly every twenty-four days for the past six months, the last menstruation; occurred on Jan. 25; had flowed a little nearly every day since Feb. 9, blood being darker than usual. Occasionally there were neuralgic pains over the right ovary. Examination showed the uterus normal in length and by the vagina slight tenderness in region of the right ovary. She came to the office several times. On Feb. 22 she attended the "Old Liners" ball and fainted, immediately had nausea and vomiting and had general tenderness over the whole abdomen. Temperature was normal and I considered the attack as acute indigestion aggravated by the heated hall and dancing. She was out driving the next day.

I was called to see her every two or three days after Feb. 2. The symptoms being severe pains over the right ovarian region, lasting a few hours; then she would be up and about. Only once was temperature above normal, 100° for one day.

There was an enlargement about the size of a hen's egg, detected by vaginal examination. Diagnosis: Tubal pregnancy or salpingitis. Entered the hospital March 8, temperature 99.2°, pulse 120. On March 10 at 9 A.M., the temperature was 101° and the pulse was increased to 128, and while the nurse was scrubbing the abdomen fluid could be readily made out in the abdomen by the swishing sound.

Assisted by Dr. A. W. Shea I made an abdominal incision about $\frac{3}{4}$ inch to the right of median line and of former incision. Peritoneum and omentum adherent under and about the old cicatrix.

No adhesions with the intestines. Pelvic cavity filled with dark coagulated blood. The uterus and broad ligament were firmly bound down by adhesions. As soon as the uterus could be brought up in sight the right Fallopian tube and broad ligament were found to be greatly thickened, and apparently a large ruptured cyst near the fimbriated extremity of the Fallopian tube.

Clamps were at once applied so as to include these organs with the ovary, one near the uterine extremity of the broad ligament, the second near the pelvic wall; ligatures were applied and the included parts cut away.

Under this portion of the broad ligament was found a firm, hard mass about the size of a large hen's egg, adherent to the broad ligament in front and the pelvic wall behind. Several ligatures were applied where necessary. Pelvic cavity cleared of blood clots and washed out with saline solution. Patient made a rapid recovery and on the nineteenth day was removed to her home.

The case is of especial interest from the fact of being the second ectopic pregnancy occurring in the same person within a period of fourteen months.

An examination made by Dr. Wm. F. Whitney of the ligament, tube, and clots verified the diagnosis.

Medical Progress.

PROGRESS IN GASTRO-INTESTINAL DISEASES.

BY ELLIOTT P. JOWLIN, M.D., BOSTON.

MEDICAL TREATMENT OF GASTRIC ULCER.

THE medical treatment of gastric ulcer has undergone as little criticism during the last two decades as almost any disease. The Leube-Ziemssen plan of rest to the ulcer, with the following gradual increase in diet, has been universally followed. The duration of the restriction of all food by the mouth has varied from a few days to a few weeks, but the general principles of rest to the body and the stomach have universally prevailed. It therefore came somewhat as a shock to medical opinion when Lenzhartz, of Hamburg, at the German Congress for Internal Medicine in 1902, sharply criticised the above plan. He raised the question whether it was of advantage to subject debilitated and anemic patients to still further loss of strength and vitality, and suggested that by so doing the conditions for the healing of the ulcer were made still more unfavorable. Instead of the accepted mode of treatment he advocated a more liberal diet. He began with 200 cc. milk and one to three eggs, within twenty-four hours of the hemorrhage, and added to this one egg and 100 cc. milk daily, until eight eggs were eaten and 1,000 cc. milk drunk. Sugar was given at the start and the amount raised from 20 gm. to 50 gm. at the end of one week. Meat was then allowed in amounts of 35 gm. to 70 gm., and at the end of two weeks rice, zwieback, raw ham and butter. In this way the whole system was treated and not merely the local condition. His detailed schedule¹ is as follows:

| Days after last hemorrhage | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 |
|----------------------------|-----|-----|-----|-----|-----|-----|-------|-------|-------|-------|-------|-------|-------|-------|
| Eggs, gm. | 2 | 3 | 1 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 |
| Sugar, gm. | | | 20 | 20 | 30 | 30 | 40 | 40 | 50 | 50 | 50 | 50 | 50 | 50 |
| Milk, cc. | 200 | 300 | 400 | 500 | 600 | 700 | 800 | 900 | 1,000 | 1,000 | 1,000 | 1,000 | 1,000 | 1,000 |
| Raw meat, gm. | | | | | | 35 | 70 | 70 | 70 | 70 | 70 | 70 | 70 | 70 |
| Milk rice, gm. | | | | | | | 100 | 100 | 200 | 200 | 300 | 300 | 300 | 300 |
| Zwieback, gm. | | | | | | | | 20 | 10 | 10 | 60 | 60 | 80 | 100 |
| Raw ham, gm. | | | | | | | | | 50 | 50 | 50 | 50 | 50 | 50 |
| Butter, gm. | | | | | | | | | 20 | 10 | 10 | 10 | 10 | 10 |
| Calories | | 280 | 420 | 637 | 777 | 955 | 1,135 | 1,388 | 1,721 | 2,138 | 2,478 | 2,941 | 3,411 | 3,873 |

The suggestion of Lenzhartz received neither approval nor attention, and except for the various articles published from his clinic nothing appeared in confirmation of his views. Recently Wirsing, Minkowski and Senator have taken the subject up, and to a greater or lesser extent have admitted the soundness of his reasoning and acknowledged good results from the use of his method.

Wagner, the assistant of Lenzhartz,² says Lenzhartz began this new plan of treatment with chlorotic girls who had gastric ulcer, but had suffered no hemorrhage. These were fed with nutritious albuminous food from the start. Very little milk was given on account of its bulk, and because these patients often have dilatation of the heart with edema. This first series of cases did well and left the hospital early. Gradually more severe cases were treated in the same manner, and it was found that the pain due to the hyperacidity was thereby alleviated and the condition of the blood improved. By this means the two factors (hyperacidity and anemia) which help in the production of the ulcer of the stomach were controlled. It has been experimentally proven by Quincke-Daetwyler and v. Silberman that artificially produced ulcers in dogs heal much more slowly in the anemic than in the non-anemic animals. Such considerations should certainly make a physician ponder long before he deliberately produces a further loss of weight and strength in his patient. The danger of secondary troubles is not small, and these exhausted individuals are good subjects for tuberculosis. Kliemberger³ has studied the loss which patients undergo under these old methods, and finds that body weight, blood pressure and pulse sink uniformly, but less rapidly, the poorer the conditions at the start. Blood pressure fell 30 mm. mercury, but the hemoglobin and number of red corpuscles remained about constant. The loss of weight per day is about three quarters of a pound; thus the average for eight of his patients each for fifteen and one-half days on rectal feeding was eleven and one-half pounds. Two to three enemata daily were given besides salt solution. Each enema consisted of 200 to 400 cc. milk, two to three eggs, a dessert-spoonful of plasmon and a teaspoonful of salt.

Wagner does not depart from established lines in the remainder of his treatment. An ice bag he considers valuable because it prevents distention, favors contraction and diminishes the

surface of the ulcer. Rest in bed for four weeks is a *non negotium*. Bismuth is employed in 1 to 2 gm. doses, and Blood's salts and arsenic are regularly given. Morphine is never used.

In a recent article by Lenzhartz⁴ are questions whether long abstinence from solid or after nutrition desirable even after a severe

⁵Med. Woch., 1904, No. 1, p. 12.

rhage. Such treatment runs counter to recognized teachings, if the hemorrhage occurs elsewhere in the body.

Wirsing in the following year⁶ reported the results of treatment, partly under the old and partly under the new system, of 320 cases of ulcer of the stomach. The article is of especial interest, because it gives the condition subsequent to discharge. The patients were treated by the well recognized methods during the years 1901-1903 inclusive. The condition of 108 was learned in 1905. Sixty-four of these (59.3%) were found to be well, but 44 (40.8%) remained ill. These figures are of especial interest because 78.7% of these patients had been discharged as cured within an average period of three years. They closely resemble the Massachusetts General Hospital statistics for 1888-1898, compiled by Greenough and Joslin,⁷ who showed that while 80% of the patients were considered cured or relieved at the time of discharge, later information revealed relief to have persisted in but 40%. The two sets of statistics for the condition at discharge were practically the same, and doubtless the later results would have more closely approximated had the German after-period of three years been as long as the American. It shows great advance in medical progress to obtain such figures instead of reading of Leube's 2.0% mortality. But it must be remembered that in turn gastric ulcer statistics are of little value because the worst cases are treated to a considerable extent by the surgeons.

Between February and September, 1904, Wirsing treated 42 gastric ulcer patients according to Lenhart's teaching. These individuals took the diet well, gained an average of three kilos and hemoglobin showed an increase of 31.8%. In only one instance was there a subsequent hemorrhage. On later inquiry only one half were discovered to be well, which is a smaller per cent than Wirsing found when the old method was followed. Strangely enough, at first sight, the severest cases were the ones who did the best, whether treated by old or new methods. Apparently this is because their condition is most obvious and they are kept longer in bed. Wirsing recommends the Lenhart method in the severest cases, the Leube method in those of a milder character.

Minkowski⁸ has also followed to a modified degree the Lenhart plan in thirty cases, and expresses himself as pleased with the result. In only one instance was there a secondary hemorrhage. He does not feed the patient the same day as the hemorrhage, because he considers the 300-400 calories which Lenhart prescribes as of little importance. The patient might get as much as this from the blood which is poured out into his own digestive tract. He approved of the Lenhart treatment after two or three days because the form in which the albumin is given does not stimulate the secretion of gastric juice. The diet is soluble and finely divided and occupies

little bulk. He advocates cream and butter and specifies the avoidance of salt.

Senator⁹ has very recently described his treatment of ulcer of the stomach in an excellent article. His postulates are:

1. The diet should not overburden the stomach by quantity or weight.
2. It should be soothing, and not apt to cause hemorrhage, but rather prevent it.
3. It should diminish the secretion of hydrochloric acid.
4. It should be easily digested, and yet sufficiently nutritious.

He believes these requisites were attained by a diet which consists of albumin, gelatin, fat and sugar. The gelatine is readily digested, and has been recently shown to favor the coagulation of the blood, and consequently is hemostatic. Fat and sugar are both nutritious, and alike have the quality of diminishing the flow of hydrochloric acid; moreover, the fat is soothing, and for this quality alone has often been used for analogous processes in the throat and esophagus.

Senator therefore prescribes in the fresh cases of hemorrhage a solution of pure white gelatin, 15 or 20 gm. to 150 or 200 cc. water, which has been flavored with lemon juice. A dessert-spoonful of this mixture is given every one or two hours, or even as often as every quarter of an hour. Fresh butter and cream are given in small quantities though the butter may amount to 30 gm. a day, and the cream to at least 250 cc. The butter may be given frozen in pill form, and the cream can be kept on ice and beaten up with sugar. By this means even 900 to 1,000 calories are procured, which are twice the quantity suggested by Lenhart. He then increases the milk and gives it earlier than by former custom and progresses to shaved meat. Gradually the gelatin is withdrawn. Jellies of all forms are allowed. Should it be desired the butter may be replaced with olive oil, plain or frozen, or in the form of an emulsion. He has not used rectal feeding in recent years.

Shattuck¹⁰ has shortened his customary period of rectal feeding in ulcer of the stomach from two weeks to three or four days and Cutler¹¹ thinks one or two days, or at the most three days, sufficient. Neither of these writers, however, appears to have been cognizant of Lenhart's observations.

HEMORRHAGE IN GASTRIC ULCER.

The diagnosis of gastric ulcer has always attained increased weight if hemorrhage has occurred by the mouth or rectum, but its absence has never ruled out ulcer. The more accurate tests for blood in the stools have greatly facilitated the detection of hemorrhage and thus contributed much to the knowledge of ulcer. But the test has further made treatment more precise, because by it the progress of the healing of the ulcer can be watched. The test is repeated here,

though mention has been made of it on two other occasions by the JOURNAL.

Rub up in a mortar 10 cc. of liquid feces or one half that quantity, if formed, with 2 cc. of glacial acetic acid; add 15 cc. of ether and transfer to a test tube. Insert a cork and mix for five minutes by gently turning the tube up and down. Violent shaking often produces an emulsion which later makes the decantation of the ether difficult. After the ether has separated, decant. Add to the ethereal solution ten drops of a freshly prepared tincture of guaiac, made by shaking a few granules of guaiac in half a test tube of alcohol, and add thirty drops of hydrogen peroxide. A blue color indicates the presence of blood. A single positive or negative test is of little value. The only fault to find with it is that it is too delicate. Blood which enters the gastro-intestinal tract from the mouth, throat or lung may, of course, give the reaction, and similarly, blood which is produced by the irritation of the stomach tube may lead to confusion. The introduction of blood in the form of fish, meat or their extracts can be easily avoided by excluding these articles from the diet for three days before making the test.

Ewald¹² has recently pointed out the advantages and disadvantages of the test. "It must be said at the very start that the diagnosis by means of the demonstration of occult blood is not lightened but made more difficult, even though this may sound paradoxical. It gives us the idea that something diseased exists where we have not expected, or have thought that it no longer existed." Its chief value comes from its presence in the stools of patients with gastric ulcer. But even here it is only found during the active or recurrent stages of the ulcer. This also holds true of cancer, though Boas is right when he claims that the stools of cancer patients generally show its constant presence.

Occult blood is valuable in diagnosis and treatment of ulcer, because it obviates the necessity for using a stomach tube. It is again valuable in differentiating ulcer from a neurosis. Its value in treatment is shown by the fact that Ewald has had patients who have had no symptoms of ulcer for a week, and yet have shown blood regularly in the stools. The indication would be to keep such patients abstemious, and to continue a careful diet.

It has been suggested that the constant presence of blood in an ulcer suggests the change of the ulcer to a cancer, but this is not invariable, nor does the constant presence of blood with patients on a milk diet mean cancer. Occasionally occult blood is a preliminary symptom of hemorrhage. On the other hand it may be useful in ruling out the probability of the occurrence of hemorrhage when such is anticipated.

Steele¹³ agrees in general with the conclusions above set forth, but also calls attention to the value of the blood test in determining the uselessness of further medical treatment. Blood in other gastro-intestinal infections is interesting

but not definite. For instance, Ewald recently had an undoubted case of cancer of the sigmoid flexure, and again and again failed to find blood in the stools. The diagnosis was confirmed by operation. In another case repeated positive tests caused alarm, but further observation showed that the hemorrhage must have been due to a polyp too high up for recognition. One must further consider gastro-intestinal hemorrhages in cirrhosis of the liver, and also in septic processes. The presence of blood in other doubtful cases may, under circumstances, lead to erroneous diagnosis by diverting attention from the real seat of trouble.

It must be remembered in differential diagnosis that the blood in pulmonary hemorrhages is not always bright red and foamy, and in gastric diseases dark and tarry. If the blood collects in an acid free stomach and is then quickly expelled, it looks bright red; and conversely in hemorrhages from the lungs, if the blood has remained some time in a cavity or dilated bronchus, it may be dark and without foam. Thin, slightly changed blood in the stools does not always mean that it comes from the lower intestine. It may have its source from the small intestine, or even the stomach when the hemorrhages are abundant and the peristalsis active.

Ewald has had little success from the use of styptisin, syptol and stagnin. Adrenalin, gelatin and calcium chloride have not been of essential value. He has, however, washed the stomach with ice water with apparent advantage in cases of severe hemorrhage. To lessen the discomfort the throat is sprayed with a weak solution of cocaine, and occasionally morphine is given. Pains are taken to insert the tube but a short distance into the stomach until the ice water has been poured in. Then it can be inserted without harm. He strongly recommends the use of lavage with ice water before resorting to operative interference.

Reports of Societies.

THE AMERICAN THERAPEUTIC SOCIETY.

SEVENTH ANNUAL MEETING, HELD AT THE ACADEMY OF MEDICINE, NEW YORK, MAY 3, 4 AND 5.

THURSDAY, MAY 3.

PRESIDENTIAL ADDRESS, GALLSTONE DISEASE.

THE PRESIDENT, DR. CARL BECK, New York, selected for the subject of his address, "Gallstone Disease." During the last few years, he said, the place formerly held by heated debates on the subject of appendicitis has been usurped by more or less antagonistic discussions concerning gallstones and their cure. It seemed unfortunate to him that prominent men in the profession were making the attempt to draw analogies between appendicitis and cholelithiasis, for appendix and gall bladder, in the anatomical, physiological and clinical sense, were two entirely different organs. There was a very striking contrast in the fact that cholelithiasis is, in the first place, dependent

¹² Berl. klin. Woch., 1900, No. 9 and 10, p. 254.

¹³ N. Y. Med. Jour., 1900, Jan. 20.

upon the presence of a foreign body and is marked by the very different forms of reaction on a mucous membrane *sui generis*. The essential part, then, was the stone.

If we summed up the main etiological factors we found that in general the gall bladder was the shop for the manufacture of gallstones; not merely a receptacle, as in the case of the urinary bladder. Such conditions as cause a stagnation of bile were especially liable to favor the formation of stones, but that the stagnation itself was not of importance was evident from the fact that concrement formation usually failed when such stagnation-producing conditions as closure of the ductus choledochus by chronic inflammation, by cicatricial contraction, or by tumefaction, were present. While he would admit that the bacterium plays a leading part in the formation of stones, he would dispute the contention of Naunym that the bacterium alone is the exciting agent. There must be a third agent, which, acting in unison with the other two factors, favored formation; but this had not as yet been disclosed. It seemed to him that tissue changes must be prominent in this action, and that this point ought to be determined in the laboratory. Especially did the matter of hereditary predisposition speak for such an assumption. It was the special distinction of Naunym to have established the differentiation between a regular and an irregular cholelithiasis. He classified the first amongst those processes which do not complicate themselves with noteworthy signs of inflammation, while he regarded the irregular cholelithiasis as a condition which manifests itself by the additional appearance of inflammatory signs. The recognition of these two distinct forms, Dr. Beck thought, presents the key for the understanding of the indications. In other words, it decides the question as to whether medical or surgical therapy is to be employed. Having referred to the medical and dietetic treatment of cholelithiasis, he went on to say that if the attacks always recurred with renewed violence and if inflammatory symptoms of serious nature made their appearance, surgical interference was called for. He then took up some points of technique in the operations performed upon the gall bladder. In conclusion he stated that while some surgeons now recommend ectomy as the normal procedure in cholelithiasis, he himself was unable to see the reasons for such a radical measure in the majority of operative cases. When cystostomy is performed the inflammatory process in the mucous membrane of the gall bladder quickly heals while drainage is carried on. We also have the advantage that stones which pass from the hepatic ducts can still be extracted. Furthermore, ectomy carries with it greater danger to the life of the patient. In a large number of gallstone operations done by him in hospital and private practice Dr. Beck has only exceptionally found it necessary to extirpate the bladder.

DR. CLARENCE J. BLAKE, Boston, read a paper on the THERAPEUTIC EFFECT OF SOUND WAVES OR MECHANOTHERAPEUTICS OF THE EAR.

(To be published in the JOURNAL.)

DR. F. M. POTTENGER, Monrovia, Cal., read a paper on

THE UNDERLYING PRINCIPLES OF TUBERCULIN THERAPY.

He said that in spite of the mass of experimental and clinical evidence to its value, which had now been accumulating for fifteen years, there seemed to be a very hazy idea as to what tuberculin is, how it acts and what it is expected to do. In the elucidation

of his subject he discussed, first, nature's method of cure in specific diseases; second, conditions which militate against tuberculosis curing itself, and, third, the manner in which specific inoculations of tuberculin aid in the cure of tuberculosis. Nature's method of cure consisted in the production by the organism of defensive bodies in response to stimulation from toxins engendered by the specific microbe causing the disease. In tuberculosis, owing to the character of both the bacillus and the tubercle, this specific toxin failed to gain access to the blood in proper quantities, and at the proper intervals, to be effective. In this connection it was to be remembered that too great stimulation is harmful and will defeat nature's purpose, just the same as a failure of stimulation. That the blood was deficient in protective substances was shown by the measurement of its opsonic power. This, as a rule, was below the normal standard. That the opsonic index in patients suffering from tuberculosis can be raised by the injection of tuberculin had been established by Wright, Bullock, Lawson and others. Their observations were in harmony with the observations of Koch, Moeller and others as regards the increase of the agglutinating power of the blood after the administration of tuberculin. This increase in the agglutinating and opsonic power of the blood meant that the natural defenses of the organism had been increased. The opsonic power was that power of the blood serum which prepared the bacilli for destruction by the leucocytes.

In a series of cases tabulated by Lawson and Stewart the leucocytes of patients treated by ordinary sanatorium methods were able to destroy only 75% of the number of tubercle bacilli that a normal person's blood should destroy; while the leucocytes of the same patients, after treatment by tuberculin, were able to destroy 19% more than the leucocytes of a normal individual. The value of this increase of the natural defenses of the organism was evident. The one reason why tuberculosis killed was because of its tendency to spread to new tissues, either adjacent or distant, and it had long been claimed by those familiar with tuberculin therapy that the disease shows much less tendency to spread in those cases treated with tuberculin than in those treated by ordinary methods. In the light of these new discoveries in immunity and immunizing treatment this was easily explained. This immunizing action of tuberculin was not, however, its only method of aiding in bringing about a cure. When properly administered it furnished, by promoting the formation of fibroid tissue, a stimulation which hastened the healing of tuberculous areas. While tuberculin thus had theoretically a firm foundation on which to stand, its clinical workings confirmed the theory. Tuberculin was undoubtedly of great value in chronic nonfebrile cases of tuberculosis, but it was in early cases that the most brilliant results were to be expected. Among 1,200 first-stage cases the data of which were collected by Dr. Pottenger, there were 20.2% more apparent cures with tuberculin than without. Five hundred and eighty-nine of the cases were given tuberculin and 611 were treated in sanatoria with ordinary open-air treatment. Another test of the value of tuberculin was the permanency of results; it being generally accepted that cases treated by it show less tendency to relapse. Another clinical proof of the value of tuberculin was its action upon local visible tuberculosis, such as is found in the larynx. No remedy offered so much hope in tubercular laryngitis as tuberculin, and with patience and perseverance a cure could be obtained in a large percentage of cases. Recent reports from Wright

and Bullock showed that tuberculin could be used to advantage also in other forms of tuberculous, such as ulcerations of the subcutaneous tissue and bone, invasion of the lymph glands and infections of the genito-urinary system. With the mass of evidence before us, he said, in conclusion, we must admit that tuberculin therapy is in accord with the modern ideas of immunity; that theoretically tuberculin is capable of increasing the natural defenses of the organism, when given in the proper doses at proper intervals, and that clinical experience warrants a more general use of it in combating tubercular infection.

Dr. H. T. OSBORNE, New Haven, read a paper on

THE THERAPEUTIC VALUE OF ERGOT.

He had never known any of the medicinal preparations of ergot to cause the condition of ergotism which was formerly observed to result from the use of rye infected with the *claviceps purpurea*. He regarded the fluid extract as much the most efficient preparation, and advocated its hypodermic injection. Dr. Osborne would employ ergot in a considerably larger number of conditions than is commonly done. He was convinced that it intensifies the action of morphine and he had found it of great service in diabetes insipidus and cerebro-spinal meningitis.

Dr. R. W. WILCOX, New York, read a paper on

THE MEDICAL TREATMENT OF GALLSTONE DISEASE.

He said that notwithstanding the now very voluminous surgical literature upon gallstones, a careful consideration of the subject led him to regard surgery as adapted only to stones of gall bladder origin, and then only under conditions demanding mechanical relief—obviously a very small part of the subject of gallstone disease. The treatment of gallstone disease was practically entirely medical, while that of gallstones themselves were generally surgical. If this distinction were kept clearly in mind, more would be expected of the internist, and fewer disappointments laid at the door of the surgeon. The recognition of the microbial origin of gallstones dated only back to 1886. Since then it had been shown that both the colon bacillus and the typhoid bacillus might be causative factors. That other infections were directly responsible had been his experience, for low grade cholecystitis had been observed after acute infectious pneumonia, acute rheumatic polyarthritides and chronic tuberculosis. The treatment of microbial causes of gallstones was the treatment of the infection itself, and the limitation of the opportunities for entrance of the infectious agent. In passing in review the mechanical causes, he said that chronic venous congestion of the portal system was the great underlying cause of the gallstone disease.

In the treatment of cholelithiasis the important features were the regulation of congestions and inflammations in the portal system and dependent organs and local antiseptics. The Spa treatment was one which appealed to many. Within recent years practically as good results could be obtained at home by the use of a proper regime. Having referred to diet, exercise and the prohibition of alcohol, Dr. Wilcox expressed his preference for salicylic acid as a cholegogue, because it was also a biliary and intestinal antiseptic. The use of bile acids and their salts was better than the administration of bile itself, and sodium glycolate was the most satisfactory of the preparations. Both bile as a whole and its salts were, however, uncertain in action. Like salicylic acid, the acid sodium oleate was exerted by the epithelium of the bile ducts to assist in dissolution.

Four to eight pills of the following combination,

given in a full glass of water once or twice daily, had proved efficient in his hands in some thirty-five instances of gallstone disease: 14 gr. each of salicylic acid and acid sodium oleate; 1 gr. of phenolphthalein; 4 gr. of menthol. The phenolphthalein was a safe and prompt laxative, while its antiseptic effect was prolonged throughout the alimentary tract. The elimination of gallstones of the hepatic variety was generally rapid. Here amyl valerianate, 15 minims in capsule, two hours before breakfast and after supper, was of service in the prevention of pain. After detailing two illustrative cases he said: The conclusion we should reach is that gallstone disease is not purely a disease due to a foreign body, but is primarily an hepatic disorder. The removal of these stones has but little to do with the cure of the patient, for when the end-result, the removal of the gallstones, has been accomplished by surgery the patient is but at the commencement of his treatment to remove the cause of the disease, which is entirely within the province of the physician. It is the congestions and inflammations in the domain of the portal system that require treatment, and the infectious catarrhs of the bile ducts and gall bladder and faulty bile formation in the liver that need correction, and these are purely medical problems.

(To be continued.)

Recent Literature.

Recent Advances in Physiology and Biochemistry.

By BENJAMIN MOORE, J. J. R. MACLEOD, LEONARD HILL and M. S. PEMBERTON. Pp. 740. New York and London: Longmans, Green, & Co. 1906

This volume marks a new enterprise in the literature of physiology and biochemistry; it stands between the elaborate reviews of work in special fields which fill the "Ergebnisse," and the rather meager statements found even in the best textbooks. The attempt of the writers, all of whom are experienced teachers and investigators, has been to bring before the physician who is interested in the fundamentals of medicine a review of the most important recent work having practical bearings. Such subjects as diabetes, uric acid metabolism, hemolysis and immunity, mountain sickness and carbon sickness with oxygen as a therapeutic agent, the metabolism of fat and the treatment of obesity, metabolism as influenced by temperature, by relative dryness of the atmosphere, by work, diet, baths, clothing, etc., the causation of dyspnea and of Cheyne-Stokes respiration, the influence of thyroid and suprarenal glands on metabolism, the action of digestive ferments, catalysts and chemical extracts, the colloidal structure of protoplasm and the influence of electrolytes in solution, the formation and absorption of lymph, the urinary secretion, these and other subjects suggest the wide range of topics that are treated. Each article is followed by a bibliography which will lead the reader on to the complete literature of the matter treated. An excellent index makes the many important points of the articles readily available.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JUNE 7, 1906.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

THE ORGANIZATION OF THE MEDICAL PROFESSION IN AMERICA.

THE organization of the medical profession in America will doubtless be a very gradual process accompanied by many vicissitudes and changes of policy. This is natural and inevitable in a country of such size wherein the interests of different sections, although centered in the general good, must naturally preserve a certain degree of autonomy. Progress up to this time has been altogether satisfactory. The state societies have developed according to the several needs of the regions they represented, and the national society has striven to unify these diversified elements. The result has been the beginning of an organization which has in it much promise of good. It must, however, also be remembered that this country is so large and the increase of population is so great about certain centers that the completest individuality must exist if the good of the whole is to be best subserved. It is altogether possible that the future will see the state societies welding themselves into larger units in certain limited sections of the country. It is, for example, becoming evident that the East, the Middle West, the West and the South might each develop a representative medical organization which would go beyond the limits of the individual state societies but would still be less cumbersome than the American Medical Association at large bids fair to become. If the American Medical Association increases at its present rate, and there can be little doubt that this will be the case, it is clear that the mere mechanical difficulties of a great general meeting will

become prohibitive. It is still possible to bring together four or five thousand physicians with results of great value. The problem will become a very different one when perhaps fifteen thousand are assembled for a common object. A natural consequence of this situation would be the closer organization of certain affiliated state societies based on geographical lines. There is at least in this suggestion the possibility of a solution of the mere problem of numbers. Some time ago Dr. Edward R. Campbell, of Bellows Falls, Vt., in an address suggested the possibility that the New England States might join in the formation of a New England Medical Association, which could hold its meetings at stated times in one or another of the cities of the six New England States. By so doing the individual state societies would no doubt be benefited through the stimulus of contact with men from other states, and the physicians of this region of the country would be brought into closer relations than is possible through the medium of a single state society.

In other words, what we shall in the future need is a central organization represented from every part of the country, together with individual organizations of states or groups of states which will develop along their own lines according to the peculiar problems presented by the part of the country in which they happen to be located. It is, perhaps, useless to speculate as to what course events will take, but it is clear that the ultimate organization of medicine in America demands both the perfecting of the central association and the individualistic development of the various organizations which form its component parts. The problem in its details is evidently a difficult one and will demand wise judgment and foresight in no small degree if the good of the whole and the good of all its parts is to be most completely attained.

THE MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

THE actual success of a great medical meeting cannot be absolutely determined during the days it is in progress. As we go to press, the fifty-seventh annual meeting of the American Medical Association is occupying the attention of a representative body of physicians from every part of the United States and not a few from Canada and abroad. It is, however, doubtless safe to assert that the meeting will be productive of much good to the cause of medical science. The efforts which the committee of arrangements

has made, through the issuance of a guide book and various smaller pamphlets of directions, in addition to the official program, should have made the task of our visitors easy in solving the proverbial intricacies of Boston streets and localities.

In one sense it is regrettable that so much has been offered by the association this year since it is quite impossible for any member, even in one department of medicine, to attend all the meetings and demonstrations that are given. On the other hand, the principle of the elective system is evidently coming into vogue in these great medical meetings as elsewhere. A man must choose what he particularly wishes to see or study rather than follow the general line of least resistance. The plan of inaugurating a clinical exhibit in various parts of the city exemplifies admirably this idea, and we have no doubt that the facilities offered for special study by this means have been fully appreciated by the visiting members of the association. Although the meetings are still in progress, it is already perfectly evident that the elaborate organization of the committee of arrangements has more than justified itself in the ease and facility with which the members have been able to find their way through the maze of material offered them. In general, we are not premature in saying that extensive as its plan has proved to be the meeting has been a success, and we hope has offered something new to every member. It is unwise to forecast the future, but it is nevertheless of interest to speculate as to the changes which will take place in medicine and in its manner of presentation before the next meeting of the association in this city.

THE ORIGIN OF THE BLOOD PLATES.

We publish in this number an article of great significance to scientific medicine. Dr. J. H. Wright presents the results of a careful investigation on the origin and nature of the blood plates in a communication which cannot fail to excite the interest of students of the blood in particular and of medical men in general. It is unnecessary with the article before our readers to discuss Dr. Wright's methods of procedure in reaching the important conclusions which his paper presents. It is, however, interesting to observe that these conclusions are based upon the results of a special staining method. Not the least of Dr. Wright's contributions to medicine has been his readaptation of old methods, and the discovery of new, to

special histological problems. The present investigation is another example of the necessity of originality of technique and the capacity to apply such originality to individual problems.

MEDICAL NOTES.

A PENSION FOR MME. CURIE. — It is announced that the French Government is to give Mme. Curie a pension of 12,000 francs in addition to a university chair.

OFFICERS OF AMERICAN DERMATOLOGICAL ASSOCIATION. — At the Thirtieth Annual Meeting of the American Dermatological Association, held in Cleveland, Ohio, May 31 and June 1 and 2, 1906, the following officers were elected for the ensuing year: President, Dr. Arthur Van Harlingen, of Philadelphia; vice-president, Dr. William A. Pusey, of Chicago; Secretary and Treasurer, Dr. Grover W. Wende, of Buffalo.

OFFICERS OF THE AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS. — At the recently held meeting of the Association of Pathologists and Bacteriologists the following officers were elected for the coming year: Dr. William H. Welch, of the Johns Hopkins University, president; Dr. A. S. Warthin, University of Michigan, vice-president; Dr. H. C. Ernst, Harvard Medical School, secretary, and Dr. H. W. Williams, of the University of Buffalo, treasurer.

HONORARY DEGREE TO BARON TAKAKI. — Baron Takaki has been the recipient of an honorary degree from Durham University. It is stated that the Baron was further honored by being drawn from the railroad station to the hall, where the degree was conferred, by the students. Baron Takaki was formerly Director General of the Japanese navy, and before coming to this country as a guest of the American Medical Association had given three lectures at St. Thomas's Hospital in London. He was a student at this hospital in 1874 and there distinguished himself by receiving the treasurer's gold medal and the Cheselden medal for surgery.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.

For the week ending at noon, June 6, 1906 there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 64, scarlatina 35, typhoid fever 8, measles 81, tuberculosis 51, smallpox 0.

The death-rate of the reported deaths for the week ending June 6, 1906, was 20.68.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, June 2, 1906, was 240, against 200 the corresponding week of last year, showing an increase of 40 deaths and making the death-rate for the week 21.03. Of this number 132 were males and 108 were females; 234 were white and 6 colored; 162 were born in the United States, 70 in foreign countries and 8 unknown; 57 were of American parentage, 163 of foreign parentage and 20 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 38 cases and 2 deaths; scarlatina, 29 cases and 1 death; typhoid fever, 6 cases and no deaths; measles, 75 cases and 1 death; tuberculosis, 46 cases and 21 deaths; smallpox, no cases and no deaths. The deaths from pneumonia were 44, whooping cough 2, heart disease 22, bronchitis 5 and marasmus 2. There were 13 deaths from violent causes. The number of children who died under one year was 51; the number under five years 75. The number of persons who died over sixty years of age was 60. The deaths in public institutions were 72.

There were 3 cases and 1 death reported from cerebrospinal meningitis during the week.

MEETING OF THE HOUSE OF DELEGATES, AMERICAN MEDICAL ASSOCIATION. — The annual meeting on June 5 of the House of Delegates of the American Medical Association was more largely attended than any hitherto held.

LYNN HOSPITAL. — This hospital has been in existence twenty-five years, its charter having been granted the latter part of the year 1880. Since its inception it has grown to be a hospital of much importance. During the year 1904 the number of patients admitted was 1,441, whereas during the year 1905 the number admitted was 1,721, an increase of 280. The average number of patients in the hospital per day was 75.

PREVENTION AND CONTROL OF TUBERCULOSIS. — A meeting will be held, June 12, at two o'clock, in the large lecture room of the Administration Building of the new Harvard Medical School on Longwood Avenue, of all committees appointed by the district societies of the Massachusetts Medical Society, to consider the best measures for the prevention and control of tuberculosis. This meeting is held the day before the general

sessions of the Massachusetts Medical Society and it should be largely attended. The committee having the matter in charge is made up of Dr. Alfred Worcester, Dr. H. Lincoln Chase and Dr. Henry Jackson.

FORMAL OPENING OF THE AMERICAN MEDICAL ASSOCIATION MEETING. — The formal opening of the meeting of the American Medical Association was held on the morning of June 6. The speakers on this occasion were President Eliot of Harvard University, who eulogized the medical profession; Dr. A. T. Cabot, president of the Massachusetts Medical Society; Gov. Curtis Guild, of Massachusetts and Mayor Fitzgerald, of Boston. The mayor spoke particularly of the great services medicine was rendering to the people and alluded particularly to our hospitals, not omitting the hospital for tuberculosis which he has from the first strongly advocated. Dr. William J. Mayo, at the end of these exercises, was formally installed as president of the association for this year.

LOVING CUPS FOR DR. H. L. BURRELL AND DR. R. B. GREENOUGH. — As a recognition of the efforts which Dr. H. L. Burrell as chairman and Dr. R. B. Greenough as secretary of the general committee of arrangements of the American Medical Association have made, loving cups were presented them at a dinner given by President Mayo and Dr. Ochsner. The dinner was in honor of the foreign guests of the association and was given on the evening of June 4. Among those present were: Baron Takaki; Dr. Frederick Trendelenburg, Leipzig; Dr. Simon W. Tunstall, Vancouver; Dr. Murray MacLaren, St. John, N. B.; Dr. James Bell, Montreal; Dr. Francis J. Shepard, Montreal; Dr. H. H. Chown, Winnipeg; Prof. Alfons von Rosthorn, Heidelberg; Prof. Alfred Dührssen, Berlin; Dr. James F. W. Ross, Toronto; Dr. Wesley A. Mills, McGill University, Montreal; Dr. Max von Frey, Würzburg; Prof. Max Joseph, Berlin; Professor Krehl, professor of the medical clinic, Strassburg; Dr. Richard A. Reeve, Toronto, president British Medical Association.

NEW YORK.

BEQUEST TO ARMY MEDICAL AND SURGICAL LIBRARY. — In the will of Edward A. Crane, of New York, who died recently, there is bequeathed to the Army Medical and Surgical Library at Washington a copy of the very rare work, Clowes on "Gunshot Wounds," which was published in 1596.

A QUESTION OF FEES.—In engaging beforehand to attend an accouchement case for a stipulated sum it is just as well that in the agreement made some provision for additional compensation in case of complications should be understood. Some months ago a grocer living in Ozone Park, Borough of Queens, secured the services of a physician for the confinement of his wife, for which he agreed to pay a fee of \$18. When, possibly owing to the fact that the air of Ozone Park is especially conducive to fecundity, the baby came to be born, there were three of him, and, having brought the triplets successfully into the world, the doctor, properly setting an increased value on his services, sent in a bill for \$50. The grocer refused to pay this, on the ground that the agreement made called for only \$18, and the case went to court. It was tried in the Jamaica Municipal Court on May 31, and decided against the physician. In view, however, of the fact that the delivery of the triplets required the services of two other medical men, and that certain medicines and appliances were furnished by the plaintiff, judgment was rendered for \$30.

MORTALITY RECORD. The condensed quarterly report of the bureau of records of the City Health Department for the quarter ending March 31, 1906, shows that the number of deaths during this quarter was 19,915, representing a death-rate of 19.16, per 1,000 of the population, as against an average of 19,269 deaths for the corresponding quarters of the preceding five years, producing (with the smaller population) a death-rate of 20.65, a decrease of 1.49 points. The first quarter of the year is seen, therefore, to have been a very healthy one. The greatest decrease in the mortality from any one disease was in that from lobar pneumonia, and the low mortality from influenza was associated with a correspondingly low rate not only in the latter affection, but also in organic heart diseases, Bright's disease, tuberculous diseases and old age. The record would have been still more favorable but for the mortality from measles, which was far above the average and which was attended by a proportionate increase in the deaths from bronchopneumonia. Comparing the number of deaths from the principal causes with those of the preceding quinquennial averages of the corresponding quarters, corrected to correspond with the increase of population, the following decreases are found: Typhoid fever, 42; malarial fevers, 11; smallpox, 17; scarlet fever, 185; influenza, 239; pulmonary tuber-

culosis, 115; other tuberculous diseases, 46; apoplexy, 34; organic heart disease, 64; acute bronchitis, 112; lobar pneumonia, 656; Bright's disease and nephritis, 136; old age, 102; suicides, 9. Those showing increases were measles, 301; whooping-cough, 44; diphtheria and croup, 48; cancer, 14; bronchopneumonia, 400; accidental deaths, 44; homicides, 24. The number of deaths under five years of age increased 111 (a result to be attributed to the increase in measles and bronchopneumonia); those from ages five to sixty-five years decreased 1,005, and at ages sixty-five and over, 327.

CITY AND SUBURBAN HOMES COMPANY.—The annual meeting of the City and Suburban Homes Company was held on May 28, when the President, Dr. Elgin R. L. Gould, who was city chamberlain under the administration of Mayor Low, and the other directors were unanimously re-elected for three years. The statements made by President Gould, in his annual report, as to the business of the company were extremely encouraging to those who have held that investment in model tenement houses may be made to yield a satisfactory return for capital, while performing a substantial and greatly needed public service. Previous to 1900 the dividends paid on the stock of the corporation were 3% and 3½%, and since then they have been 4%. The directors have now decided to put the stock on a 1½% basis. The present assets of the company are \$4,175,000, without taking into account the increase in ground values, and it is believed that as soon as investments approach the sum of \$6,000,000 it will without difficulty be able to pay 5%, to which its charter limits dividends. The company has provided model tenement accommodation for 1,115 families in Manhattan and 162 houses at Homewood, in Brooklyn. After referring to the fact that its collections have been made with no appreciable loss from bad debts, Dr. Gould said, "These figures furnish an irrefutable answer to the absurd, but oft repeated assertion, that wage earners and their families do not appreciate the best class of living accommodations." It might be worth while to add, he went on to say, that in addition to ordinary purchases of capital stock in the company, there is a field for investment in such stock that should appeal to those who have large sums of money to invest for special purposes in philanthropic work. The principal performs a useful public end in extending improved housing in New York, and the

income goes for the benefit of the endowment fund. A two-fold purpose is thus accomplished by the one gift.

Obituaries.

CHARLES WARRENNE ALLEN, M.D.

DR. CHARLES WARRENNE ALLEN, of New York, died at Gibraltar on May 31, from typhoid fever. He had been attending the International Medical Congress at Lisbon, and was on his way home, by way of Naples, when he was taken ill. He was persuaded to leave the steamer at Gibraltar. Dr. Allen was born in Flemington, N. J., Dec. 4, 1854, and was graduated from the College of Physicians and Surgeons, New York, in 1878. After post-graduate courses in Paris and Vienna he devoted himself to the treatment of diseases of the skin in New York, and became a recognized authority in this specialty. From the first he took a great interest in radiology, and he made a number of valuable contributions to the scientific study of the subject. He was the author of "Radiotherapy, Photography, Radium and High Frequency Currents" and "The Practitioner's Handy Book of Medical Progress," and wrote a number of chapters in the "Twentieth Century Practice of Medicine." At the time of his death he was Professor of Dermatology in the New York Post-Graduate Medical School, consulting dermatologist to the Randall's Island hospitals and consulting genito-urinary surgeon to the City Hospital, on Blackwell's Island. Dr. Allen's last public appearance in New York, shortly before he sailed for Europe, was in March, when at the Medical Association of the Greater City of New York he took part in a symposium on the Present Status of Radiology in Diagnosis and Treatment. It is a curious coincidence that Dr. Allen's death occurred on the same day as that of Dr. Louis A. Weigel, of Rochester, who, like Dr. Allen, was one of the principal speakers on the last previous occasion when this topic was discussed before the association.

LEWIS A. WEIGEL, M.D.

DR. LEWIS A. WEIGEL, of Rochester, one of the best known surgeons in the state of New York, died on May 31, at the age of fifty-two years. His case appears to be one to be added to the list of those in which prolonged exposure to the x-rays has caused cancer in a previously healthy individual. Dr. Weigel was for many years an enthusiastic worker in radio-therapy, and one of the highest authorities on the subject. The disease from which he died first manifested itself in the hands, and early in 1904, Dr. Welch of the Johns Hopkins Hospital from the examination of specimens submitted to him, pronounced it of malignant character. His case excited much interest, and after a consultation partici-

pated in by a number of eminent surgeons and physicians, the right hand was amputated at the wrist, and the greater portion of the left hand also removed. Temporary improvement in his condition resulted, but in a short time the disease manifested itself in other parts, and subsequently other operations became imperative. Part of the right shoulder was removed, and then it became necessary to excise a growth of considerable size involving the right breast and adjacent muscular tissue. The last operation was performed in February of this year. Dr. Weigel knew that his condition was hopeless, and awaited the end with philosophical resignation, his chief consolation being that he had done something towards the advance of medical science.

HALL CURTIS, M.D.

In the death of Dr. Hall Curtis, at the age of seventy-one, which took place June 1, at his summer home in Beverly Farms, Boston loses one of its earlier generation of practitioners. Crippled by chronic disease Dr. Curtis for many years has not actively practiced his profession, but until ill health forced him into private life he held high rank in his profession over a long period of years. He was graduated from Harvard College in 1854 and later took his degree at the Harvard Medical School. During the Civil War he served as surgeon of the Twenty-fourth Massachusetts Regiment. He leaves a widow, a son and a daughter.

Disseclanp.

GOVERNMENTAL MEAT INSPECTION.

THE *Medical Record* makes the following pertinent suggestions regarding the inspection of meat: "Whatever may be the feelings with which those interested in the livestock and meat packing industries regard the Beveridge Meat Inspection bill, which was passed by the Senate on May 25, there is no doubt that the people of the country at large will be greatly relieved when its provisions are put into force. While no layman can realize to the full the disgusting possibilities and actual perils to health that attend meat packing done in a slovenly or dishonest way, or even meat packing carried on under conditions in which any solitary precaution that ingenuity can devise is neglected to the slightest degree, the nauseating details said to attend the preparation of this class of foodstuffs have lately been so forcibly presented to the public through various literary channels that the psychological moment for reform seems truly at hand. If the conditions in the great packing houses are as bad as they have been painted, no legislation intended for their improvement can be too drastic, while if the packers are innocent of wrongdoing they have nothing to fear from

the proposal to make the inspections more rigid. It is, unfortunately, not very probable that the secrets of the packing house have been exaggerated in the telling, and we can but hope that the entire matter will now be put on so firm a basis of governmental supervision that even the pathologically trained imagination of the physician need conjure up no unpleasant specters of diseased animals, filthy surroundings, or unclean workmen, when he partakes of such flesh food as his nature may incline him to use."

NATIONAL VOLUNTEER EMERGENCY-SERVICE MEDICAL CORPS.

The calamity upon the Pacific coast has become not only heartrending but absolutely stupefying in its unprecedented and stupendous proportions. Moved by a common impulse, the whole country is hastening to alleviate the distressed.

There are occasions of disaster and epidemics, of all too frequent occurrence, when all men recognize the tremendous part played by the medical profession in the relief of suffering and the saving of life, but even we, the members of that profession, have as a rule no adequate and abiding realization of the part. This is probably due to the fact that while our aid is always rendered promptly and heartily, it is done on the spur of the moment and without the advantage of special preparation for the emergency. In other words, it is because of lack of organization, and this lack detracts materially from the effectiveness of the best intended efforts.

This need of readiness for the purpose of rendering medical and sanitary aid and relief in emergencies, including catastrophes, pestilence and war, is met with by the National Volunteer Emergency-Service Medical Corps, which is modeled on a distinct military basis, provided with officers varying from surgeon-major-general, sanitary engineers to nurses and trumpeters, and with material appliances from transports and temporary shelters to cooking utensils. Such a corps especially trained, disciplined and fully equipped would be ready for any and every immediate emergency service, whether casualty, epidemic, war or civic function where there is a large aggregation of people liable to accidents or overcome by heat.

With such hospital and ambulance corps, a detail, company, platoon or battalion permanently established and located in every city and town, ready to render relief whenever and wherever required and fully prepared to be called into requisition at a moment's notice to assist state and local health boards in the enforcement or execution of sanitary measures for public welfare and safety; or in the field, at the call of civic or military authorities to render aid to victims of calamities, as exigencies may require, would inspire the confidence of the people and assure the safety and prosperity of the community.

This organization is not antagonistic to any Red Cross society, with whose operations it does not in any way desire to interfere, its intended scope, being technical and professional, as far wider reaching and efficient, being a strictly medico-sanitary body after the model of the Medical Department of the United States Army and Medical Staff Corps of England. It is confidently expected that its services will be instantly forthcoming when required, as are those of a fire brigade — all things necessary in time of disaster being immediately forthcoming and ready from the

simplicity with which its vast military machinery can be put in motion.

This corps stands in the same relation to the community in protecting the life and health of the people as does the National Guard and State Militia in guarding the property of the citizen, with this essential difference, that it is self-supporting and without entailing either upon national or state government the expense of equipment or maintenance.

The ravages of catastrophes, epidemics and famine are far more destructive to the welfare of a nation than any war ever was or can be, particularly in these days of our activity in the additional channels of infection, — our colonial possessions, — the Philippines, Cuba, Panama.

Let us hope that the Knights Hospitaler of old will live again in this brotherhood of scientific aid and relief as befitting this progressive twentieth century, and perils by land, and perils by sea, railway crashes, floods, conflagrations, earthquakes, volcanic eruptions, tornadoes, pestilence, famine and all other disasters will be shorn of half their horrors. From no other class of men is this blessing so likely to come as from the medical profession.

J. ADELPHI GOTTLIEB, M.A., M.D., LL.D.,
Surge-Maj.-Gen., *Commandant*,
Brig.-Gen. PERCIVAL KUTNER,
Paymaster-General,
Prof. NICHOLAS SENN, M.D., Ph.D., LL.D.,
President Advisory Medical Council.

Physicians, pharmacists, nurses and medical students are invited to become members, as it is desired to have representatives in every city and town.

Corps,
Temporary Office, 225 West 106th St.,
New York City, U. S. A.

BRITISH MEDICAL ASSOCIATION.

As a supplement to the issue of the *British Medical Journal* for May 24 the general program of the meeting is given, which this year is held in Toronto, Canada, from Aug. 21 to 25. Sir James Barr is to deliver the address in medicine and Sir Victor Horsley the address in surgery. Under the heading "Hints for Travelers" the following suggestions are made, which might also be of use for those from the States who propose to visit Canada during the sessions.

For the Atlantic voyage a warm suit, warm underclothing, an overcoat and wraps will be required, and they may prove useful also on the lakes or on the mountains, but the British traveler is likely to find Canada in August warm (the average temperature for Toronto in August is said to be 66° F.) and the United States something more than warm. As there will be dinners and evening reception, as well as afternoon parties, dress appropriate to these occasions must be taken, but the high silk hat of European export is well best of place. There is a difficulty about getting boots cleaned in Canada, at Toronto during the meeting a "shoe shine colony" will be established in the grounds for the convenience of members, but it will be well to take a box of shoe polish for use in other places.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING MAY 30, 1906.

BLUE, RUPERT, passed assistant surgeon. Relieved from special temporary duty in San Francisco, Cal., and directed to proceed to Washington, reporting at Bureau. May 29, 1906.

AMESSE, J. W., passed assistant surgeon. Directed to proceed to Stapleton, N. Y., for special temporary duty, upon completion of which to rejoin station at Ellis Island, N. Y., May 24, 1906.

LOYD, B. J., passed assistant surgeon. Leave of absence granted Passed Assistant Surgeon Lloyd, for fifteen days from May 1, 1906, revoked. May 25, 1906.

LOYD, B. J., passed assistant surgeon. Relieved from duty at Guayaquil, Ecuador, and directed to proceed to Fort Stanton, N. Mex., for duty and assignment to quarters. April 30, 1906. Above order revoked May 26, 1906.

EBERT, H. G., assistant surgeon. Relieved from duty at Seattle, Wash., and assigned to duty on the U. S. Revenue Cutter "Perry." May 24, 1906.

PETTYJOHN, JOSEPH, assistant surgeon. Assigned to duty on the U. S. Revenue Cutter "Thetis." May 24, 1906.

FROST, W. H., assistant surgeon. Relieved from duty at Baltimore, Md., and assigned to duty on the U. S. Practice Ship "Chase." May 23, 1906.

KENNEDY, S. R. M., acting assistant surgeon. Granted leave of absence for four days from May 27, 1906. May 24, 1906.

RICE, W. E., acting assistant surgeon. Granted leave of absence for five days from June 2, 1906. May 25, 1906.

WATKINS, M. H., pharmacist. Relieved from temporary duty in San Francisco, Cal., and directed to rejoin station in Chicago. May 24, 1906.

CHANGES IN THE MEDICAL CORPS U. S. NAVY FOR THE WEEK ENDING JUNE 2, 1906.

J. H. IDEN, passed assistant surgeon. Detached from the Naval Hospital, Newport, R. I., and ordered to the "Columbia."

E. M. BROWN, passed assistant surgeon. Detached from the Naval Hospital, New York, N. Y., and ordered to duty in the department of government and sanitation, Ancon, Panama.

M. H. SIMONS, medical director. Detached from duty in command of the Naval Hospital, Mare Island, Cal., and ordered to duty in command of the Naval Hospital, Philadelphia, Pa.

R. C. PERSONS, medical director. Detached from duty in command of the Naval Hospital, Norfolk, Va., and ordered to duty in command of the Naval Hospital, Mare Island, Cal.

C. P. KINDLEBERGER, surgeon. Detached from the "Independence" and ordered to the Asiatic Station.

A. FARENHOLT, surgeon. Ordered to the "Independence."

A. E. LEE, assistant surgeon. Appointed assistant surgeon, with rank of lieutenant (junior grade), from May 9, 1906.

H. L. DOLLARD, acting assistant surgeon. Appointed acting assistant surgeon from May 26, 1906.

SOCIETY NOTICES.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.—The annual meeting of the Society will be held on Tuesday, June 12, at 1 o'clock P.M., at Sprague Hall of the Boston Medical Library, 8 The Fenway. Business: Election of officers. The following papers will be read: "Criminal Abortion; Perforation of the uterus with passage of the fetus into the abdominal cavity, and prolapse of the intestine; Death; Disembowelment," Dr. Francis A. Harris, Prof. William T. Whitney, "Air Embolism," Dr. Frank Holyoke, "The Chinaman Murder," Dr. H. M. Dudley. The annual lunch will precede the meeting. FRED E. JONES, Recording Secretary.

QUINCY, MASS.

AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION.—The annual meeting of the American Medico-Psychological Association will be held in Boston, at the Hotel Vendome, June 12-15. Physicians of Boston and vicinity are cordially invited to attend the meetings.

GEORGE T. TUTTLE, M.D.,

Chairman of Committee of Arrangements.

Address.

THE MEDICAL PROFESSION AND THE ISSUES WHICH CONFRONT IT.

BY WILLIAM J. MAYO, A.M., M.D., HON. FRANK EDEN, ROCHESTER, MINN.

PRESIDENT'S ADDRESS AT THE FIFTY-SEVENTH ANNUAL SESSION OF THE AMERICAN MEDICAL ASSOCIATION AT BOSTON, JUNE 5-8, 1906.

THE American Medical Association begins its fifty-seventh annual session under the most auspicious circumstances. After an interval of forty-one years it again meets in Boston, the guest of this great commonwealth which has ably upheld the highest medical traditions since the founding of New England.

Another cause of febrile stimulation: The sectional differences in New York have been overcome and the Empire State, for the first time in twenty-five years, presents a unified delegation.

The House of Delegates of the American Medical Association (which technically is the American Medical Association) represents directly about 55,000 and indirectly the 120,000 regular practitioners of medicine in the United States. The official organ, *The Journal*, reaches each week over 43,000 subscribers, and, under the able editorship of Dr. George H. Simmons, has become the leading professional magazine in the world.

The medical profession is to be congratulated on these evidences of a useful organization, but much remains to be done. In his individual capacity the medical man has not been found wanting. Go where you will in civilized lands, you will find the physician self-sacrificing, patient and charitable, upholding the honor and dignity of his noble calling. Collectively, medical men do not have the influence which we might expect and without which great movements for the welfare of humanity cannot be carried on. A lack of unity has prevented a realization of our hopes, and if we are to gain and maintain the pre-eminent position to which we are entitled we must unite for the common good.

The present organization of the American Medical Association is but a beginning; we must further the interests of this body unselfishly, not for ourselves alone, but that we may better fulfill our sacred obligations to mankind. The people must be educated up to a point where they can understand the broad humanitarianism of modern medicine. Society appreciates the saving of a sick person's life by the skilled physician, but fails to see the priceless gifts to the human race made by preventive medicine and sanitary science. It views every thing in detail and misses the perspective. We have failed to secure the support of the mass of the people to much-needed sanitary reforms, because we have appealed to them as one individual to another without the weight of an authoritative organization.

That the people are ignorant of medical affairs is due to bad education rather than prejudice.

They are more than two decades behind advanced medical thought; it is our duty to keep them better informed. The theory of medicine did not contain the essential principles of a science until within the last quarter of a century. Originally a part of priestcraft, the profession had its beginnings in a time of mysticism and superstition. Anatomy, gross pathology and chemistry were among the early foundation stones which made progress possible. Clinical treatment was based on a very few specific remedies and a considerable number of drugs of proved value in the cure or alleviation of disease. But, lacking a sound theory of causation, the results were not much better in the average self-limited malady than those claimed by the various "systems" based on the giving of inert or useless remedies which, like the incantation of the Indian medicine man, kept the patient and friends interested until cure came about through natural processes. The public found that the large majority of sick persons got well under any, all or no treatment, and, not rightly understanding the reason, have never been able to comprehend why one method or form of treatment, as long as it apparently yielded about the same average of results, was not as good as another.

The germ theory promulgated by Pasteur and given surgical significance by Lister, strengthened our foundation by adding to it the long-sought-for causation of the majority of diseases, and this, with the aid of experimental research, has led the practice of medicine out of the wilderness and established it as one of the exact sciences.

New and fundamental truths have followed each other so rapidly that we have scarcely been able to digest them and much less can we expect the public to have kept pace. The layman's view is that of twenty-five years ago. He accepts with avidity new dogmas and "paths" based on theories miserably foolish in the light of modern investigation and we have allowed him to become fixed in these beliefs. We have permitted the public to be educated by "patent medicine" advertisements and the voluble charlatanism of the commercially interested. In return we are classed with these schemers, and efforts for the general good are believed to be selfishly inspired.

The Utopianism of our profession is too idealistic for ready comprehension in this commercial age. The time has come for the public to be taken into our confidence. If we wish better results we must enlighten the people for with them lies the final word.

THE PROFESSION AND THE PEOPLE

General sanitary matters of the greatest importance are becoming understood through medical influences. The public has been and is being educated in regard to the great white plague, tuberculosis, and statistics are beginning to show the effect of this diffusion of knowledge. In Massachusetts and some other states a committee has been appointed in each district to

promulgate measures for the relief and control of tuberculosis. This should be imitated in every state in the Union.

We can already see the good which has resulted from the teaching of the habits of mosquitoes, the short distances they travel from their breeding places, and especially the necessity for the quarantine of patients afflicted with yellow fever and malaria, not directly to protect mankind, but to prevent infection of the little pests who act as carriers of the contagious micro-organisms.

Society must be taught the early symptoms of cancer, the greatest foe of humanity, that its manifestations may be recognized while in the curable period. A propaganda of this kind, inaugurated by the profession of Germany, has borne fruit.

The typhoid fever crime of cities through polluted water-supply is not the least of the many branches of popular education. There is no reason why a man who has become infected with typhoid from a city's neglect should not sue for damages as he would for personal injury sustained from falling through a defective sidewalk. Unavoidable sickness is bad enough, but when we stop to consider that the life of the individual is worth \$5,000 to the state, and that those who recover undergo great disability and expense, the continuance of unsanitary conditions is criminal. The experience of Vienna, which was converted from a typhoid center to one of freedom from such outbreaks by bringing in a pure water supply, has now been repeated over and over again in every civilized land. Yet hundreds of deaths from this preventable source yearly attest that the lesson has not yet been learned.

How can the work of education be best continued? The answer, as shown by our very efficient chairman of the Committee on Organization, Dr. J. N. McCormack, is through the local society. Occasional meetings to which the public shall be invited must be devoted to questions of general interest, and the proceedings published in the local newspapers. The county society must become the unit, and the allied professions of pharmacy and dentistry urged to attend and take part in the deliberations.

To the *Ladies' Home Journal* and *Collier's Weekly* the public owe the successful crusade against poisonous substances and intoxicating beverages which are sold under the guise of "patent medicines," patent only in the sense that the name is copyrighted; the constituents can be changed at any time and in any way.

Do you think that our American mothers will continue to give "Kopp's Baby Friend" and "Mother Winslow's Soothing Syrup" to their babes when they find that these mixtures contain opium and that instead of securing rest the little ones are narcotized and that many deaths are directly attributable to this cause?

Will the American people continue to use bromo seltzer and similar dangerous preparations to an extent which causes them to exhibit blueness of the skin surfaces from poisonous coal-tar products, or become victims of drug

habits from cocaine catarrh cures, when they discover the harmful and dangerous character of these agents?

Will our prominent people, statesmen, politicians, ministers and ladies of note continue to allow their photographs over signed testimonials to be published, telling their fellow-citizens how much better they have felt after taking Peruna, Warner's Safe Cure and the various nervines and tonics, when they find that most of these preparations depend on alcohol for the stimulating effects which they describe? The success of most "patent medicines" depends on the fact that they contain drugs and stimulants which create a craving and must be repeated. Once get the public conscience awakened and we will have a demand that every "patent medicine," before being sold, shall have its exact component parts printed on its label, and its claims to cure verified by scientific investigation. The action of the Postoffice Department in denying the use of the mail service to some of the worst offenders against common decency is to be commended.

PUBLIC HEALTH LEGISLATION.

One of the few misfortunes of the individual freedom afforded by a republican form of government is that it enables the most ignorant man, through prejudice, to interfere with and delay needed legislation, with the result that, by the time the law can be passed, the immediate object to be obtained has often disappeared.

In Germany compulsory vaccination has practically caused smallpox to disappear from the army and country, a person properly protected being immune. In the state of Minnesota inability to enforce vaccination in the late smallpox epidemic permitted, from a few sources, 27,876 persons to become infected with this disorder; all due to a small but vociferous band of anti-vaccination agitators.

Contagious disease in any place is not a matter of local or state interest alone, as the ease and freedom of transportation render local control impracticable and properly place it in the hands of the general government.

The keenness with which the American people are watching the affairs at Panama argues well for the future. The communication of Dr. Charles A. L. Reed awakened public interest. His portrayal of red tape and obstruction to sanitation in the Canal Zone has resulted in obtaining for that most able army medical officer, Colonel Gorgas, power to carry out the necessary reforms and has made the Canal Zone the most sanitary place in Latin America.

Compare our record in the Spanish-American War with that of the Japanese in the war with Russia. We had 14 deaths from disease to 1 from wounds, and more than 95% due to disregard of the simplest problems in sanitation—therefore, unnecessary and avoidable. In the Japanese army there were 4 deaths from wounds to 1 from disease, a difference of 56 to 1. This was not due to the fact that the Japanese had superior knowledge, but that their medical

officers were thoroughly organized and in sanitary matters were supreme. The knowledge which they used was obtained in western institutions and was the product of the Occidental, not the Oriental, civilization.

The army and navy medical departments have worked intelligently against overwhelming odds. Their individual members have international reputations honestly achieved. Their schools for the special training of their men are in the highest degree efficient and deserving of every praise; but the departments have been so small as to be unable to act even as nuclei about which in time of war competent forces could be gathered, and the militia of our country enter into conflict fearfully handicapped. The indications, however, are that these matters will now be rectified, and if so it will guarantee to the patriotic American that should he again be called on to serve his country his enemies would be in front and that he will not be destroyed by his own side through neglect of sanitary laws.

The United States Public Health and Marine-Hospital Service has been and is doing splendid work in sanitation. Its skilled investigators have revolutionized quarantine measures and have placed preventive medicine on a solid basis. Their powers should be extended so that such unnecessary outbreaks as occurred in New Orleans shall not be repeated. They should be given control of national quarantine in all its phases.

MEDICAL EDUCATION, STATE LICENSURE AND RECIPROCIITY

What is needed is a higher standard of requirements and more and better supervision of professional schools. The Council on Medical Education is working hard and is now in a position not only to show what should be done, but to initiate needed reforms. No more important work has ever been taken up by the profession. At the present time medical education is uncontrolled and each state has its own standard of requirements. We cannot rid ourselves of dogmas and "pathys" until we can secure a universal primary law as to the minimum amount of knowledge on fundamental branches. To accomplish this the American Medical Association must co-operate with and encourage medical colleges to do better work. The profession owes it to itself to investigate in some manner what the schools are actually doing and to make it known whether or not they fulfill their obligations to the student. No well-conducted college could object to such reasonable supervision.

Another question of great importance is that of reciprocity in medical license. The conditions now are well-nigh intolerable and restrain the individual freedom guaranteed by the Constitution. The boundaries between states are imaginary lines; yet a physician on one side of a border cannot relieve human suffering on the opposite side without becoming amenable to the law or subjecting himself to vexatious examinations which he has already successfully passed

in his own state. This must be met and speedily by agreement between examining boards as to the minimum of requirements. After all, this is but a part of the educational problem. If we could solve this, licensing boards could at once adopt more uniform examinations and reciprocity.

RELATIONS TO INSURANCE COMPANIES, CORPORATIONS, ETC.

We come now to consider some abuses from which the physician suffers. It is a matter of professional pride that, in the general condemnation of the life insurance companies, although every other part of the control has been shown to be corrupt, no breath of scandal has touched the medical department. Yet the local examiner has the most cause of all to be dissatisfied. The New York Life, some years ago, cut the fee for examination 40%, apparently not as a matter of economy, for at that time the most corrupt practices existed, but rather to enable the agent more easily to pass "new business" at any cost. This action has lately been imitated by the Equitable and some others and has resulted in forcing the resignation of many of their best examiners. The general officers have taken great credit on themselves for voluntarily reducing their salaries 20%. It is a rank injustice that the one body of men who have emerged clean from the insurance scandals should suffer the most for the crimes of others. A thorough medical examination to prevent fraud by the admission of unsafe risks is essential. With few exceptions the line companies pay a fair fee and less should not be accepted. The casualty companies, such as the Maryland, are the worst offenders, and some concerted action should be taken to compel them to mend their evil ways.

Lodge practice is another scheme by which officers of an association draw salaries ostensibly to give medical services at a figure below the possible point at which a professional man can live and continue his education. The people are badly served, as competent physicians cannot be secured to do the work, and the whole scheme is properly condemned by the various medical associations all over the country.

Public service corporations abuse hospital privileges in a way that is no more nor less than an open scandal. In Pittsburg the steel companies pay \$100 a day for the care of their injured men at the hospitals, and for the class of patients under discussion this cannot be provided for less than \$1.00 per day. The companies pay the surgeons at the hospitals absolutely nothing for their service to its injured, which amounts to thousands of dollars a year. The same condition exists with many of the large railroad and street car companies and other public corporations.

Hospital abuse by patients who are able to pay, through the neglect and indifference of the trustees is prevalent and thereby the profession is robbed of just returns for labor and the funds of charitable persons misused to an extent which

is almost beyond belief. All hospitals should have competent individuals whose business it is to see that no one secures free treatment who is able to pay.

Some great hospitals go still further and receive any patient, rich or poor, allow him to have a suite of rooms and bath and several nurses if he can pay for the same; but will not allow him, even if he is willing to do so, to pay the surgeon who operates on or the medical man who takes care of him. If the patient is disposed to be more just than the trustees of the hospital, he can do so only by giving a gratuity at Christmas, as would be done with a servant. Such indignity should be resented by every right-feeling man.

It is a misfortune that the large majority of hospitals have not physicians among their directors. Hospital management is often extravagant and wasteful, due to official influence in furnishing comfortable berths for incompetent relatives or unfortunate friends in some salaried executive position.

Fortunately the list of grievances is not large, and I believe that they can be harmoniously adjusted if taken up with the proper authorities in a conciliatory spirit. Our first object must be to see that no poor person shall be subjected to the slightest inconvenience or annoyance and that every worthy charity shall have our united support; but we must look to it that the charitable practitioner's time, knowledge and skill shall not be misused.

THE PRACTICE OF MEDICINE AS A BUSINESS.

It is a hard matter to adjust the financial side of the practice of medicine; that doctors are poor collectors and bad investors is a notorious fact and makes them the easy prey of the various investment "gold bricks." A physician owes it to himself, to his family, to his profession, and especially to the community at large, to manage his finances well. Otherwise he cannot pursue his studies and give to the sick his best efforts, which they have a right to expect and demand. No sensible man enters on a medical career with a view of making money. I have never known a physician who has become rich solely from this source, and it is better so, for beyond that reasonable competence which leaves him free to pursue his life work the care of money interferes with the highest aims of the true physician, and few who have been burdened with wealth have reached their ideal in a calling which makes no distinction between the rich and the poor.

One of the demoralizing tendencies in this commercial age is the money standard of success. Physicians are not called or chosen; accident or environment brings about their choice of profession. While professional life broadens the mental horizon and increases sympathy, it cannot change man's nature, and men who are unfair in business affairs are to be found in our midst.

The one crying evil, which fortunately is not widespread, is the giving of commissions—in other words, the selling of the confidence which the patient has in his practitioner—to some

specialist who will divide the fee in return for reference of the case. The one secretly takes money from the patient without his consent, and the other, in order to complete the bargain, charges more than he should. This is equally harmful to the one who receives and to the one who gives. Such matters cannot be kept secret, and I have personal knowledge of men of good attainments and remunerative practice who have been ruined through losing the confidence of their communities by this pernicious traffic. Some attempts have been made to justify it, but the very fact that it is secret shows that both parties are ashamed to have it known and is an acknowledgment of its moral obliquity.

Our relations with the allied profession of pharmacy are not on as ethical a footing as they were twenty years ago. Then the druggist was the faithful friend of the physician. To-day, in putting up from 50% to 60% of the prescriptions sent to him, the educated pharmacist cannot use his skill as a chemist, but simply acts as a distributor of copyrighted preparations which the physician calls for a few times only to take up with something new and leave the shelves of the druggist filled with the unused remnants.

Many physicians compound their own prescriptions, to the detriment of the pharmacist. The proprietary medicine people have managed this very cleverly; to the medical profession they are continuously calling out that the druggist is "substituting"; with one hand they have given the physician remedies to dispense himself, and with the other furnished the druggist with "patent medicines" with which to compete with the physician, and these two natural allies have drifted apart. The average pharmacist cannot live on physicians' prescriptions alone, but he should be treated justly, and both physician and druggist would profit by mutual concessions to the great benefit of the public.

The higher grade of pharmaceutical houses already see the danger to honest pharmacy in the forced promotion of "ethical" and fake nostrums under catchy names, and it is to be hoped in the future will confine themselves to the open compounding of legitimate preparations; and these and these only should be found on the advertising pages of reputable medical journals.

MEDICAL PROGRESS.

Graduation from a college is merely a commencement of a life study of medicine. Therefore, young men without special training under competent teachers should not be encouraged in wanton assaults on major surgical diseases unless justified by necessity. The future will demand schools for advanced training for those who desire to do special work.

The recent graduate in medicine should begin in his county society by contributions to the newer methods which will be interesting to the older men. This should be his kindergarten; from there he will carry his papers to the district meetings; and at the end of five years he will be competent to bring useful material to the

state society and later to the sections of the American Medical Association.

In the practice of medicine the student days are never over. There is so much to be learned that a long and industrious life leaves one with the feeling that he is but a beginner. The most important habit a young physician can form is the "daily study habit." Let him put in even one hour a day with the reading of journals and books of reference and much can be accomplished. He should keep an account of the time, and if something interferes for a day he should charge himself up with it. A two weeks' vacation means fourteen hours to be made up. Most men can do more, and no man has a right to do less, no matter how busy he may be. The leaders in our profession make a daily average of five or six times this amount of study the year round, in addition to the demands of an active practice.

The practitioner must make frequent trips away for the purpose of observation. In no other way can he avoid the rut of self-satisfied content, which checks advancement and limits usefulness. No amount of diligence as a student can take the place of personal contact with men in the same line of work.

What are the rewards of so laborious a life? They cannot be measured, because there is no standard of comparison. To realize that one has devoted himself to the most holy of all callings, that without thought of reward he has alleviated the sufferings of the sick and added to the length and usefulness of human life, is a source of satisfaction which money cannot buy. I know many a man grown gray in the profession with little of a tangible nature to show as a result of his work, but who is not only contented with his lot, but proud to have served in the ranks, and who looks back on a life of privation and hardship for the benefit of humanity as a privilege which he is thankful has been vouchsafed him.

Let us continue to strive as individuals for the honor and dignity of our profession. In this we but follow out the aims and ideals of those who have gone before and prepared the way. But the great movements of the future cannot be brought about by individual action. They must be initiated and controlled by united effort, and in no other way can the epoch making truths of preventive medicine be made to bear fruit. Unity is the spirit of the times; it marks the difference between the old and the new.

The vital need of the medical profession is a harmonious organization—an organization that will encourage right thinking and good usage among ourselves, help to secure needed medical reforms, compel redress of grievances and promote and encourage the highest interests of its individual members, and in this lies the future usefulness of our profession as a whole.

THE HYPEREMIA TREATMENT OF CONGESTED AND INFLAMED TISSUES.*

BY R. H. BRADFORD, M.D., BOSTON.

ANYONE whose attention has been called to the recent literature of the subject will have noticed the frequent reference made in German medical journals to the hyperemia treatment of chronic inflammatory conditions, and even to some of the more acute forms of tissue inflammation. The reported cases are presented as demonstrating the efficacy of a new method of treatment which is claimed to be of value in a variety of disorders.

When a method is credibly reported to be generally and successfully applied in so great a range of affections as ulceration of the cornea, cervical endometritis, gonorrhea, tuberculous joints, furunculosis and eczema, it deserves more attention than has been accorded to it in American literature.

In this country attention has for some time been directed toward the hot air treatment of swollen joints, which, with some elaboration and expense in outlay, has been used for the last few years; but the general medical profession has been more inclined to regard this as a manner of treatment to be classed with hydrotherapeutics and massage, rather than to consider that it contains a new principle of therapeutics. In Germany, however, the hyperemia treatment appears to be regarded as almost a new medical dispensation. The principles of the treatment which have been recently ably presented and advocated by Professor Bier of Bonn, though not absolutely new, are not, however, to be regarded as a revival of the old method of counter-irritation by blisters, by setons or the cautery, but are based upon a more rational hypothesis consisting of an attempt to combat certain stages of inflammation by increasing the amount of blood in the tissues.

In the earlier days counter-irritation was employed by surgical theorists for the purpose of drawing the peculant humour from the tissues. With the decadence of the humoral pathology a system of treatment directed toward combating congestion by the application of cold and compression, inducing anemia, became almost universal. Bier claims that under certain conditions the true antiphlogistic is not induced by anemia, but on the contrary, by increasing rather than diminishing the amount of blood in the affected parts. Where degenerative changes are taking place, these are assisted or checked by an increased amount of blood in the tissues. It is manifest that this hyperemia treatment is not applicable to all stages of inflammation, but this may be equally true in regard to the treatment by anemia.

Taking it for granted that the theoretical reason for supporting the hyperemia treatment

TRAINED NURSES FOR THE PHILADELPHIA PUBLIC SCHOOLS.—The Board of Education has advocated the employment of a number of trained nurses for work in the public schools. *N. Y. Medical Journal*.

* Read at meeting of the Boston Medical Library, April 11, 1906.

may be sound, the question of its application and practicability is of importance. The most simple method of producing thorough hyperemia is the application of dry heat. The usual methods of the application of moist heat do not permit evaporation nor excrete perspiration, and although they furnish means affording relief, as has been shown by poultices, hot cloths, the application of Denver mud, etc., yet where the perspiration is prompted rather than checked, a greater amount of heat can be employed with benefit; this constitutes the Bier method of active hyperemia, which consists in surrounding the affected parts by a chamber of hot, dry air.

This method has been much elaborated, but as used in the Bonn clinic it is to be seen in its simplest as well as most efficient form. It is evident that where the heat is prevented from radiating rapidly, the tissues can be treated by the application of a much lower heat. It is therefore essential that the chamber surrounding the joint should be made of a material which does not permit rapid radiation. It is also advisable that the arrangement employed should be portable and cheap, and that the heat should be under careful regulation. It is for this reason that a light wooden box is preferable to the heavy and expensive appliances which have been furnished by many instrument makers. Electricity has been utilized as a means of furnishing a heat without the danger of inflammability, but electrical heat is not as easily regulated as that given from a Bunsen burner.

The advantages of the method of active hyperemia have been shown in many well-recorded cases, but in certain instances no benefit has been derived from its application, and it is for these that the method of passive hyperemia has been recommended.

By passive hyperemia is meant increasing the amount of blood in the tissues without increasing the arterial flow. This is accomplished by constricting the limb above the point affected, and can be done most simply by placing an ordinary elastic bandage around the limb, and retaining this moderate constriction for a sufficiently long time to congest the tissues.

Practical experience has shown that better results are obtained where this constriction is applied for a comparatively long time as a moderate amount of pressure than where constriction to a great degree is applied for a short time. It is not desirable that the limb should be made cold, or that the limb should lose its reddish color.

This method should not be applied except under the direct eye of the surgeon, and the degree and duration of constriction are matters of judgment in each individual case. Where the hip and shoulder joints are involved, constriction can be applied by placing an elastic band in the groin and in the axilla, and retaining it by cross straps around the trunk. Congestion of the tissues of the head is brought about by a moderate amount of constriction applied to the neck.

A still further application of this congestive method is afforded by the method of suction hyperemia, which is perhaps suggested by the old method of vacuum treatment, or perhaps earlier by the method of cupping. As applied at present, the limb is placed in a glass cylinder with the open portions furnished with flexible rubber cylinders which are bound upon the limb, preventing the entrance of air. Suction is applied to the contained air by means of an

ordinary pump, and in this way not only is a slight amount of constriction furnished to the limb by the pressure of the rubber fabric preventing the increase of air, but congestion is increased by the attenuated air chamber surrounding the part. Where portions of the body are to be treated which cannot be incased in the cylinders, cupping glasses of various shapes can be applied.

Anyone who has had experience with this suction method can testify that it appears to be of advantage in ways which are not furnished by the application of heat. Patients will express a sense of relief from its application. The perspiration is increased during the application of suction, and benefit in the flexibility of the joints and in the circulation of the tissues follows.

The three varieties of application of the hyperemia treatment are considered as applicable to different conditions. The suction hyperemia is especially applicable to brawny and septicly congested tissues, as is seen in cellulitis, phlegmons, etc. The constriction hyperemia is applicable to the less virulent infections, as those of tuberculosis, and especially of benefit in blennorrhagic joints, while the active hyperemia is more applicable to what may be termed the less active forms of inflammation as in arthritis nodosa.

In reviewing the evidence which has been presented in the literature, the critic naturally queries as to what the method of treatment by hyperemia actually accomplishes. How much may be regarded as fact, and how much as fancy. Is there an underlying scientific truth which can be utilized, and are the supporting clinical facts carefully reported, and are these methods in reality of more value than a varied application of the cupping glass and blood-letting of our predecessors?

To anyone who has tried the methods it is clear, however, that the hyperemia method of

treatment in its various forms of application furnishes to the surgeon important means of increasing the flow of blood to the skin, and to the deeper tissues. With it we can stimulate the circulation more easily than by previous methods but it is not yet proved whether heat can act in any other way than a stimulation to the circulation. It has been suggested that sluggishness of the lymph circulation may be overcome by suction, and it is even possible that by the application of slow heat for a length of time cell

disappeared from the tissues as if washed away by the congestion induced. He thinks that it is probable that the bacteria and other toxins have also been influenced in the same way. But it is evident that much more thorough investigations than have yet been undertaken are needed before the method has been brought to a sound scientific basis.

Improvements in the methods of application of active hyperemia and dry heat are needed. It is desirable to furnish the cheapest, most

activity may be promoted or in other words, that the chemistry of the living tissues may be changed by a process which may be called a cooking by a slow fire.

It is not improbable that the action of the lymphatics may be altered by suction, but in order to determine these facts further physiological investigations are of importance. Some investigations, which have been made at the clinical laboratory of the Children's Hospital by Drs. Low and Z. Adams, were undertaken with a view of determining more carefully the changes made in the tissues by the methods under consideration, and although these results have not yet been published, I am permitted by the kindness of these gentlemen to report that there can be no doubt of the dilatation of the smaller vessels produced by suction, heat and constriction.

Hofman in the *Monatsschrift, Wechselkraft*, Sept. 26, 1905, claims that the lymphatics have

portable, efficient appliances for this purpose. Experiments in regard to this matter are now being conducted at the Children's Hospital under the direction of Dr. Z. Adams which has succeeded in constructing a box, where practically no radiant heat is given.

If the hyperemia treatment is of value, it is, of course, probable that the methods at present employed may be improved upon. Active hyperemia, that is to say, the method of active hyperemia, is not a new thing, and has been often employed, and it is also possible to deliberately stop it, as in the case of a cold, by fresh air, and to the extent of attracted air.

The former of these has been attempted by Dr. John A. Lee of Boston, and the latter one of them with hyperemia has been done by Dr. Monks of the Boston City Hospital.

It is probable also that a combination of these methods of treatment with the other therapeutic methods, such as massage with the rubber, may be bene-

ficial if judiciously used. The hyperemia treatment is naturally aided by massage, vibration and electrical irritation.

In brief, it may be said that the hyperemia treatment of congested tissues is not only one which deserves careful investigation, but may be regarded as undoubtedly deserving an assured position in the treatment of certain affections which are not readily amenable to the methods previously used.

SANITARY AND MORAL PROPHYLAXIS.*

BY PRINCE A. MORROW, A.M., M.D., NEW YORK.

I wish to express my appreciation of the honor of being invited to appear before this society and my sense of great personal gratification that the subject appointed for this evening's discussion is one in which I have long been interested.

Preventive medicine presents no more pressing problem at the present day than the prophylaxis of a class of diseases which have such important relations to the public health, the welfare of the family and the interests of society.

The advances made in our knowledge of the pathology of venereal diseases within recent years have singularly amplified our conception of their danger to the public health, and especially their significance as a social danger from their morbid irradiations into family and social life.

Venereal diseases from their nature and mode of communication are the most essentially human of all diseases; they enter into the most intimate and sacred of human relations; they contaminate the very sources of life itself; they are the only diseases transmitted in full virulence to the offspring — destroying the productivity and sapping the vitality and vigor of the race.

The prophylaxis of these diseases has long been recognized as the most difficult and delicate of all the problems of social hygiene. Certainly its satisfactory solution would represent the greatest possible benefit that preventive medicine could render humanity.

We may first inquire does sanitary and moral prophylaxis offer such solution? Can this problem be worked out along the lines indicated in this scheme of prevention? Upon this point, it will be admitted that there is a pronounced skepticism on the part of many members of the medical profession. A similar skepticism was manifest a few years ago in regard to the prevention of many infectious diseases which have since been brought under control. The present era of preventive medicine has been marked by a singular aggressiveness on the part of sanitary science in attacking communicable diseases which had hitherto defied control. Perhaps its most notable achievement is the successful crusade now being waged against the "great white plague," but before the "great black plague" it has paused irresolute, baffled and beaten back. It sees no clear way in which this pestilence, entrenched in the stronghold of pri-

vacy, wearing the defensive armor of shame and secrecy and protected by social sentiment as well as by professional ethics, may be reached by the strong hand of official repression. Notification, the first and most essential condition of sanitary control, does not appear practicable; here the medical secret dominates the situation.

The problem of prevention is rendered especially difficult by the exceedingly complicated character of its factors. Many of these factors are purely social and lie entirely without the sphere of sanitary control; it is evident that medical measures must be supplemented and reinforced by influences and agencies which can more effectively intervene in the correction of the causes of these diseases and the conditions under which they are spread; especially must they be adapted to their peculiar nature and communicative mode.

One distinctive peculiarity of venereal diseases is that they are commonly contracted and communicated by the voluntary acts of individuals, but we cannot draw a sharp line of distinction between *voluntary* infections and *ignorant* infections. No man voluntarily exposes himself to tuberculosis, but thousands of individuals expose themselves and infect others through ignorance; and it was to correct this ignorance that a campaign of education was inaugurated in the warfare against tuberculosis. The same is true of venereal infections; the vast majority of young men expose themselves ignorantly; men carry disease and death into their families through ignorance. It is the duty of the medical profession to enlighten them — to let them know to what they expose themselves, and especially to let them know that the introduction of these diseases into marriage has, upon their dependents and future generations, all the consequences of crime. There are, however, peculiar difficulties in the way of this prophylactic education which will be presently referred to.

Experience in dealing with tuberculosis and other communicable diseases has shown that the primary and most essential condition of success is the creation of public sentiment by awakening the perceptions of the general public to an appreciation of the nature and extent of their dangers. The public must comprehend the value as well as its need of prophylaxis. Publicity, which has proven to be the mightiest of all modern agencies in the correction of political, public and commercial evils, is a no less potent factor in the correction of social ills.

It is especially needful that the light of publicity should be turned upon a class of diseases which infect unseen the social body, which aptly typify "the pestilence that walketh in darkness," and whose ravages, especially the havoc wrought in the home and family, have always been covered up and concealed.

This can be most effectively done along the lines indicated in this evening's program, by exposing the grave dangers to health from venereal infection, the economic and social

* Read before the Philadelphia County Medical Society, March 28, 1906.

interests involved — and especially the dangers to the family, by appealing to that humanitarian instinct which prompts protection to the innocent and helpless members of society.

Such knowledge carries with it responsibility — a responsibility on the part of the medical profession which should find expression in an organized effort to educate the community, and when this knowledge is shared with the people, it will create a resulting responsibility on the part of an enlightened public to aid and co-operate in this prophylactic work. I may be permitted to hope that the outcome of this evening's discussion will be the formation of a society of sanitary and moral prophylaxis in this city, and I feel that I cannot more profitably employ the remainder of the time allotted me than in recounting the experimental work done by a similar society organized in New York some twelve months ago.

I speak of this work as experimental because it constituted an innovation, an exploration into a field hitherto neglected. It was evident that this work could not be undertaken from the hygienic side alone, — moral as well as socio-economic conditions are involved. The evil is composite in its causes and to be successfully combatted the co-operative efforts of different social groups is required. The society was, therefore, to be composite in character, embracing in its membership medical men, representatives of the clergy, the law, public educators, sociologists and public-spirited citizens interested in the social welfare.

It appeared that there were several lines of effort along which this prophylactic work might be profitably directed, — educational and moral prophylaxis, prophylaxis by treatment and social prophylaxis.

Since the foundation of all effective work must be the education of the public, it was decided to begin this work along educational lines.

First of all it was necessary to study the situation, to take our bearings, so to speak, before this unexplored forest of public ignorance. It was decided that the meetings for the first year should be a sort of continued educational symposium. A definite program was marked out in advance which has been strictly adhered to, taking up first the education of the youth of the country in sexual physiology and hygiene, studying the nature and scope of this instruction, the age at which it should be given, whether it should be progressive according to the age of the individual, through what agencies it should be given, — through parents, physicians or teachers; whether our educational centers, high schools and colleges, should be utilized for this purpose; whether the teaching of sexual physiology should be incorporated in textbooks of hygiene, etc.

Next was taken up the education of the young men and the young women of the working classes, — whether this should be individual or collective, through conferences, lectures, pamphlets, tracts, etc., and other means of enlightenment.

Next was considered the education of men of

the army and navy service; and finally that of the great body of the general public.

Returning now to a consideration of the practical application of this educational scheme, while it was easy enough to supply the requisite medical knowledge and even determine the nature and scope of the instruction to be given there was no provision in the organization of our educational system for its reception. It was necessary to have the co-operation of the teaching fraternity, who command the opportunities, and their advice as to the best ways and means of imparting this instruction. Recognizing that physicians are not specialists in pedagogy, we invited popular educators and practical pedagogists who were qualified by long experience and study to point out specific methods for carrying out this educational work.

In making provision for the education of the young men of the working classes it was obvious that a modification of methods was necessary. We were able to secure the benefit of the advice of instructors of physical training departments, the heads of settlements and workers with young men in various other social groups. The question of the education of young women of the working classes was submitted to women physicians for discussion.

In the matter of educating men of the army and navy service the co-operation of the national government was solicited. The society was assured through the Secretary of War of the thorough sympathy of his department with this work and its co-operation in every way possible.

As an earnest of this assurance, the assistant surgeon general of the Army and the medical director of the Navy were especially detailed to present papers and discuss methods. The figures and illustrative charts presented at our last meeting showed that venereal diseases overshadowed all other diseases as a cause of admission to the hospital, disability and discharge from the army, constituting by far the largest factor in impairment of the efficiency of the service.

The next phase of our study was how to enlighten the great body of the general public as to the extent and dangers of venereal diseases and their modes of contagion, direct and indirect. This was recognized as perhaps the most important and yet the most difficult part of our program. However valuable or even vital, we may recognize the education of the young in the laws of life and sex, this question must be submitted to the high tribunal of parental approval for decision. It cannot be doubted, however that when the issue is fairly presented to parents, whether the ignorant and dissolute shall continue to have the exclusive monopoly of the education of their sons in sexual matters or whether this education shall be committed to competent teachers, the decision will be in favor of sound, sanative and wholesome knowledge, rather than the false vicious and dangerous teaching they now receive.

The chief difficulty of popular enlightenment

comes from the fact that the ordinary channels of communication with the public are closed to this knowledge.

The newspaper press which is the most powerful of all agencies in the hygienic education of the public is absolutely barred to the mention, even, of venereal disease. Many newspapers which do not hesitate to speak freely of prostitution, which lay bare disgusting details of private intrigues in language which conveys a distinct conception of an immoral act, yet shrink from mentioning the pathologic consequence of that act as something unprintable. A newspaper in New York which may be taken as representing the very best type of journalism, some time ago devoted a long editorial to the diseases of immorality in the army,—the percentage of infections and the great damage to the efficiency of the service caused by these diseases; and yet this same newspaper would on no account make mention of the extent and dangers of these diseases in civil life. I might refer in this connection to the fact that certain types of newspapers are the most powerful of all agencies in the dissemination of venereal diseases by printing quack advertisements which hold out deceptive promises of cure,—of gonorrhea in from three to ten days, of syphilis in from thirty to sixty days, leaving their dupes not only to suffer from the consequences of improper treatment, but to go on sowing broadcast the seeds of disease which might have been sterilized by scientific treatment. Whether this be false ethics or not we must accept it as newspaper ethics.

Fortunately the entering wedge which may serve to open up communication with the public has been found in the "Charities and Commons" whose editor has the courage and public spirit to disregard traditional prejudice and print the papers and discussions of our society. If this publication goes into the homes of thousands of the best men and women in this country without offense, but with commendation for this work, there is no reason why larger and still larger public groups may not be reached by this and other publications.

One word in regard to the moral feature of this prophylaxis: Diderot long ago said that every question of hygiene is a question of morality. We must all realize that the training of the morals of the young is no less important than the training of their intellects. Many physicians do not believe in the practical wisdom of "mixing morals with medicine," but venereal diseases are inextricably mixed with immorality by both human and divine law. In the prevention of these diseases hygiene and morality go hand in hand. Viewing the individual not merely as an animal but as a human being, possessed of both a physical body and a moral nature, we must recognize as of the highest order the preventive value of that moral teaching which comes more properly within the province of the clergy.

Assuming that the educational feature of our

program is susceptible of practical application, the Utopian idea is not indulged that educational and moral agencies will prove an infallible corrective of incontinence. It is confidently believed, however, that a vast number of ignorant and reckless exposures will be prevented and we have sufficient faith in the inherent good in human nature to believe that an enlightened public sentiment and an aroused public conscience will no longer tolerate that crowning infamy of our social life,—the infection of innocent wives and children.

The educational feature does not, however, represent the entire scope of this society's work. In addition to the committee on education we have a committee on treatment, a committee on "the social evil" and a committee on legislation, which indicate the directions in which this society's work is to be expanded.

The only work thus far done by the committee on legislation is the drafting and introduction into the legislature of a bill to prevent "quack advertisements" in the newspapers.

The committee on "the social evil" has not yet materialized, owing to the intrinsic difficulty of securing the men best fitted to undertake this work.

This society has been criticised by some physicians for the adoption of a policy which excludes regimentation from its scheme of work. The failure of this system abroad in materially decreasing the spread of disease, apart from objections on moral grounds, and the hostility of public sentiment in this country, led to its rejection. It would seem a gross inconsistency for a society which holds that monogamy is the only sure basis of the social order, the normal productivity and progress of the race, to sanction the legal recognition of a class of women set apart for polygamous practices. A society that recommends continence as the surest preventive of venereal infection cannot consistently favor a legalized provision for incontinence. We cannot afford to lower the standard of morality. The supremacy of morals in private or public life can never be established unless we hold fast to those immutable principles of right based upon the "moral code," which is diametrically opposed to the "conventional code of morals."

"Physicians," declares Dr. Osler, "should be the apostles of continence." Whether or not the individual lives of its members conform to this standard, the medical profession in its corporate capacity, in societies and associations, should proclaim the doctrine, based upon sound physiology and experience, that continence is not prejudicial to health. The almost universal infection of the minds of young men with the converse of this doctrine—the so-called "Sexual Necessity"—is in my opinion, the most powerful determining cause of masculine immorality.

Now what has been accomplished by this year's work? The results may be summarized briefly—unfortunately, too briefly. Perhaps it is premature to expect material results, but

there are abundant evidences which would indicate that this innovation represents real progress. The mere agitation of this subject has been of immense service in awakening the perceptions of many serious-minded men and women throughout the country to the real, live importance of this work. The discussions in medical circles, the echoes of which have scarcely reached the public, have served to awaken interest, often in quarters least expected. Seeds wafted here and there, by chance merely, have found lodgment and have already borne fruit in inquiries, in commendation, in demands for more light. Numerous communications have been received from pedagogists, from instructors in physical training, from purity associations, etc., for literature which shall not only teach the teachers, but which may be placed in the hands of young men themselves. Many applications have been received from schools, societies and settlements and other institutions for lecturers who could give talks to young men on sexual subjects.

All these indications point to the conviction that the time is ripe, the opportunity propitious for launching a general campaign of popular education. Physicians are recognized as the logical leaders in this movement. Will the medical profession respond by sharing their knowledge with the public, through discreet literature, by talks and lectures to young men, and most effectively of all, by the formation of auxiliary societies of sanitary and moral prophylaxis which shall be centers for the diffusion of this knowledge?

Already, as signs of progress in this direction, it may be mentioned, that such societies are in process of formation in several cities and states. Another evidence of the awakened interest on the part of the medical profession in this important work may be cited in the fact that more papers have been read before medical societies upon syphilis and certain phases of gonorrhea infection, with special relation to their social dangers, within the last ten months than in the previous twenty years.

Finally I may say that one of the most favorable and cheering indications of progress is the contrast presented by this large, intelligent and, I trust, favorably disposed audience with the small group of half-hearted men who met together in New York twelve months ago, for the purpose of discussing the wisdom and expediency of forming the Society of Sanitary and Moral Prophylaxis. It required months of effort, of written appeals, of personal solicitation, to muster this small advance guard of a movement, which has since grown in numbers, influence and strength, and which is destined, as I believe, to do a great work in the interest of preventive medicine and for the good of humanity.

A BIOLOGICAL INSTITUTE FOR GERMAN EAST AFRICA.—The German Government is about to establish a biological institute in Dar-es-Salaam, East Africa, and has appointed Dr. Pütter, *privat-docent* of physiology in Göttingen, as director. — *Lancet*.

Clinical Department.

FRACTURE OF THE LOWER END OF THE FEMUR.*

BY GEORGE HILL FRANKS, M.D., BROOKLINE, MASS.

J. P. S., a veteran of the Civil War and bank president, aged sixty-four, is a man who weighs 225 to 230 pounds; has always been in the best of health and comes from a strong, vigorous and long-lived family; is inclined to be fat and rather soft, as for a great many years he has been much limited in the amount of exercise which he can take. At the battle of Gettysburg in 1862, he received a Minie ball in his left foot. Being left on the field he was captured by the Confederate troops and taken to Libby Prison where he was confined three months. During this time he had no surgical aid for his foot, which continually grew worse. After his exchange he was forced to submit to an amputation. This was done, by the surgeon's advice at a point eight inches below the knee. Since that time he has been obliged to use an artificial limb. During the rest of the war he served on recruiting duty and other honorable service, being mustered out at the close of the war with the rank of captain.

On Sept. 2, 1904, while taking a vacation in the White Mountains, rising in the night, to go to the window in order to see the view over the mountains by moonlight, and not having the support of his artificial limb, he fell and struck the outer side of the stump on the floor. The pain at the time of the blow was extreme. Fortunately there were two New York physicians of repute in the hotel at the time, so that his leg received immediate attention. He was told by them that he had a fracture of the thigh. On Sept. 6, he returned to Brookline, walking with the aid of canes and without any apparatus on the injured limb. That afternoon I first saw him, having been his family physician for many years. The result of my examination was to find the thigh from about the middle point, the knee, and the stump very much swollen. How much it was difficult to say owing to the atrophy of the limb from disuse. There was also considerable discoloration. The lower half of the femur and the knee-joint were surrounded by so much oedematous tissue that no landmarks could be felt. There was apparent shortening, but the amount could not be determined on account of the deformity and no crepitation could be distinguished. The patient was able to be up and walking on crutches, and had no pain, although there were marked spasms and contractions of the muscles, particularly on manipulation. He had no apparent shock from the fall. He was advised that under prevailing conditions the injury could not be determined without the assistance of an X-ray. The knee was done up in hot fomentations, and arrangements were made with Dr. Ernest Anory Codman, for taking a skiagraph of the leg.

On Sept. 9, for the first time the swelling of the knee had subsided sufficiently so that on manipulation a crepatus could be distinguished on the outer side of the knee but no further symptoms pointing to the exact location and direction of the fracture could be detected. On that afternoon Dr. Codman took a picture which I have the pleasure of exhibiting to you to night.

The lower end of the femur was broken off from the shaft and displaced backward; the fracture apparently extending into the knee-joint.

On the morning of Sept. 10, having secured a nurse, a fracture bed and other apparatus, the leg was put up with extension. On account of the extreme swelling and heat in the knee-joint, I did not consider it safe to

* Read before the Brookline Medical Club, Feb. 7, 1906.

attach the extension straps below the knee. This pulling was expected more to prevent the spasms and contractions of the muscles of the thigh than to draw the lower fragment down into place. A ham splint with a slight curve was applied to the limb to reduce the deformity with straight side and anterior splints.

patient not only to get thorough extension but also a nearly normal flexion of the joint as one of his greatest pleasures is playing upon the organ.

About a week after the movements were begun on manipulating the limb with the extreme force which I was compelled to use, something gave way with a

In this apparatus the leg was much more comfortable as the jerking of the muscles was obviated. The leg quite rapidly diminished in size and appeared to be held in good position.

On Sept. 16, Dr. F. B. Harrington was called in consultation as to the advisability of applying a plaster bandage. At that time the appearance of the knee had much improved although considerable heat and swelling were still present. Although the landmarks were still obscured it felt as if the lower fragment was much nearer to, if not in, its normal position. A plaster bandage reaching from the end of the stump as high as could be without going around the body, was applied by Dr. Harrington and myself. In this appliance the leg was very comfortable and the patient had more freedom of motion. From that time the leg shrank continuously as could be seen by the increasing looseness of the bandage.

On Sept. 28, twenty-six days after the injury, the patient got out of bed and sat in a chair, the bandage at this time being very loose and was held in position by a form of suspenders. On Oct. 7, five weeks after the accident, the plaster was cut longitudinally, care being taken not to break the plaster in removing from the leg. There was still a good deal of swelling in the entire limb and so much thickening around the knee-joint that not much could be made out concerning the position of the lower end of the femur. The motion of knee-joint was very slight. The union of the bone appeared to be quite firm. From that time daily passive movements were applied by me and the leg was massaged twice daily by the nurse. It was very important to the

crack which could be heard across the room. No evil result followed from this, however. The reduction of the swelling was quite slow and the thickening around the knee was still slower. The improvement in the motion of the joint can be best seen by examining the diagrams which were traced from the leg every few days.

On Oct. 10, the patient first got on crutches and walked into the next room and on the following day, the 11th, he walked down stairs to luncheon and dinner. On Oct. 14, he went out of doors in a wheel chair.

At this time the question of an artificial leg arose. It was impossible to get the stump into the socket of any leg which the patient had previously used. The knee-joint was so broad that it would not begin to fit between the steel braces which formed the joint of the artificial limb. The top of the socket of one of the legs was removed and a leather socket, which could be adjusted by a lacing in the back, was put in its place. The braces were then spread to admit the knee. As it was found that the patient could not straighten the leg by his own muscular efforts, a steel adjustment was attached to the socket which would throw the lower leg forward automatically. This leg was fitted on Nov. 2 and it was found that with the aid of this mechanism and of his crutches he was able to walk very well and on Nov. 9 he drove into Boston to his bank for the first time, not quite ten weeks from the day of the accident. On Nov. 15 he found that he could get along with one crutch and a cane and on Nov. 28 he went to his business office in that way. At this time

he could walk fairly well with two canes and on level ground with only one. About the middle of December he could walk around the room without any support. Shortly after that my attendance on him ceased although he still continued to have massage and passive movements of the leg by the nurse who came for that purpose. Although I have not examined the knee since that time I have seen the patient at intervals. The leg appears to be as useful as it was before the injury and although he carries a cane on the street he

Dr. C. S. Seudder's book on fractures treats more completely on this subject, and more satisfactorily than any other book at my disposal. He recommends that all apparatus should be removed and inspected in four weeks; union should be firm in from four to six weeks; at the end of eight weeks all apparatus should be removed; in the ninth week the patient should be up on crutches and in twelve weeks should walk without support.

never uses it in the house. The knee-joint is still markedly larger than it was before the accident as he cannot yet get it into any of the old legs.

Massage and rubbing, with passive movements, should be begun when the apparatus is permanently removed.

I do not intend this evening to enter into any lengthy discussion of the commoner forms of fracture of the thigh, but as I was able to find so little recorded regarding this particular form of fracture I think a few facts might be emphasized. From my researches it would appear that this is rather a rare injury because I could find no statistics concerning it. The diagnosis is generally rather easy, there being present some shortening, a mobility at the seat of fracture, a distinct crepitus, usually a displacement backwards of the lower fragment (caused by the contraction of the very powerful gastrocnemii) considerable oedema and more or less nervous shock. The history of a fall, usually landing violently on the feet, is the common occasion of this accident. If the knee-joint is involved, and sometimes when it is not—particularly if the limb is not at once treated, a severe exynovitis is liable to ensue which may cause an ankylosis or a supuration resulting fatally usually.

TREATMENT

The leg should be put up with extension on a curved ham splint or double inclined plane. This should be done under an anæsthetic which relieves the muscular tension so that the dislocation can be more readily reduced. Care should be taken that there should be no pressure on the popliteal vessels.

PROGNOSIS.

In some cases the results of treatment for this form of injury are very good, but in a number of cases there is shortening and stiffness of the knee-joint which sometimes impairs the use of the limb greatly.

Medical Progress.

PROGRESS IN GASTRO-INTESTINAL DISEASES.

BY HUGH F. JONES, M.D.

(Continued from No. 23, p. 667.)

PATHOLOGY OF GASTRIC ULCER

BLOOM¹⁹ contributes an interesting article on the pathogenesis of chronic gastric ulcer. It is generally recognized that three factors contribute to the etiology of gastric ulcer: *Situation*.—The gastric ulcer is almost always near the lesser curvature, and close to the pylorus; occasionally it is found in other regions of the pyloric part of the stomach and more rarely in the middle of the anterior and posterior gastric wall. It is almost never found in the fundus or along the greater curvature. *Acid gastric juice*.—In the second place the acid gastric juice bears a definite relation to the development and course of the ulcer, for

¹⁹ *West Med. Jour.*, 1905, No. 2, (Jan.), p. 131.

this form of ulcer is only found in those regions of the alimentary tract where acid gastric juice occurs. As a rule the secretion is more acid than normal. In ulcer of the esophagus the juice may be regurgitated from the stomach, or acid may be formed from the acid forming cells which exist in that region. *Trauma*. The third accepted cause is some injury to the gastric wall, which exposes the injured tissue to the gastric juice. The healthy gastric wall will not be attacked even if the gastric juice is very strong. As to the nature of the trauma, opinions differ. Many theories have been adduced, but the uniformly characteristic look and situation of the ulcer compel one to consider the same cause as acting in all cases.

It has been found that hemorrhagic infarcts of the mucous membrane may develop into ulcers. Emboli or thrombi and endarteritic processes in the small arteries may be shown as the cause of these. In quite a number of cases embolic abscesses in the mucous membrane appear to have led to the formation of ulcers, but the ulcers in nearly all the above cases were small, fresh superficial ulcers of the mucous membrane, which had little similarity to gastric ulcer. Experimental ulcers have also been produced in various ways but they all heal quickly. Lesions of the nervous system (section of the cord, sympathetics or pneumogastries) are the only sure method of producing ulcers, but such conditions so little resemble those met with in clinical experience that they have not been considered.

Ophuls¹² has confirmed some of these earlier experiments. He was able to produce chronic ulcers of the stomach with marked induration at the base and sharp edges in six of thirty rabbits in whom he cut both vagi below the diaphragm. These six cases were found in eighteen rabbits who were allowed to live for at least twenty-four days after operation. The gastric motility becomes poor, but it later regains its tone. For the present, he remarks, these experiments are simply an interesting observation.

Matthes¹⁶ observed on removing a piece of the gastric mucous membrane that the adjoining tissue contracted and covered the denuded space; if a larger piece was removed the edges only were covered. If the exposed muscularis mucosae were touched with acid gastric juice the contractions of the muscle were so extensive as to conceal even large ulcers. Matthes prevented this by sewing a glass ring on the outer wall of the greater curvature. He then opened the stomach and removed the mucous membrane from this region. After two days he fed the animals as usual, and at the same time maintained marked acidity of the stomach by introducing free hydrochloric acid. Four weeks later the examination of the stomach showed an ulcer in the ring.

Bloch examined five ulcers of the stomach microscopically. He found round-celled infiltration about the ulcer, and an increase of connective tissue, which extended into the muscular

wall, submucosa, muscularis mucosae and the surrounding mucous membrane. The walls and bases of the ulcer were uneven because the connective tissue and muscle were partially dissolved and necrotic. The base and walls of the ulcers were covered with many bacteria, but these were probably due to post-mortem changes because elsewhere in the stomach the bacteria were quite as abundant. Bacteria have been considered by some as an etiological factor in the form of ulcer and therefore, Bloch studied this question further. In two calves with perforated ulcers of the stomach bacteria were found only at the site of perforation, and here chiefly at the peritoneal surface. None were present in the ulcer.

Fresh ulcerations of the stomach are frequently found in infants who die with intestinal affections. These infants shortly before death vomit brown colored material containing blood. Bloch examined the stomach in two cases of this type. Hemorrhagic erosions were everywhere present, single or multiple, small or large. The hemorrhages can be seen especially in the interstitial tissue between the glands, and some coagula are as thick as the mucous membrane. The epithelium in some cases is lost over the hemorrhagic area, thus forming superficial ulcerations, but in others does not. The absence of epithelium from over the hemorrhagic areas is noticed chiefly in the region of the pylorus and lesser curvature, where the blood coagula extended to the muscularis mucosae. About this area the tissue was necrotic, and surrounded by round-celled infiltration. No bacteria were present in the tissue. All forms of transition were present between the hemorrhagic erosions and the larger ulcerations. The hemorrhages apparently entered the superficial epithelium, and so exposed the tissue to the digestive action of the gastric juice. The destruction of the superficial layer of mucus producing epithelium cells led to the ulcer rather than diminished circulation. Claude Bernard suggested that this layer of epithelium protected the tissue, and Matthes' experiment confirmed the earlier observation. It should be noted that the hemorrhages in the mucous membrane developed into deeper ulcerations only in the region of the lesser curvature and pylorus. Hemorrhages were as frequent in other portions of the stomach but no ulcers. Small hemorrhagic erosions appeared. It is true that the ulcers above described were not actually typical of peptic ulcer except in their localization. A cause for the development of the ulcers at the pylorus and lesser curvature cannot be explained by differences in the mucous membrane here from that in other portions of the stomach, for none exist. There is, however, an anatomical difference.

The stomach is usually described in its dilated state, the greater curvature then makes a long, sharp bow. The contracted stomach is very different. The arcs of the two curvatures are then quite similar, and the distance between the two is so slight as to give to the stomach the appearance of a sausage. The greater curvature is shortened most of all at the fundus. Measure-

¹² Jour. of Exp. Med., 1906, vol. VIII, p. 181.

¹⁶ Ziegler's Beiträge, 1893 Bd. 13.

ments show that the greater curvature in the dilated stomach is three to four times as long as the lesser, but in the contracted stomach it is barely twice as long, while the lesser curvature remains about the same in the dilated and contracted organs. Corresponding to the dimensions of the stomach is the change in the appearance of the mucous membrane. While in the distended it is almost everywhere smooth, in the contracted organ there are longitudinal and transverse folds which are highest and longest along the greater curvature, but less marked as the lesser curvature and pylorus are approached. Bloch confirmed these observations on fifty stomachs.

A study of the course of the muscle fibers of the stomach wall shows how these folds must occur. This is also obvious if one compares the fixed attachments of the lesser curvature between the cardiac orifice and the horizontal portion of the duodenum. Between these parts is the attachment of the lesser omentum, which consists of firm fibrous tissues through which large vessels pass to the hilus of the liver. The stomach also is held in position by the liver. Normal contractions of the stomach, therefore, can produce no essential shortening of the lesser curvature. The opposite holds for the lesser curvature. This swings completely free and can change its shape according to the degree of contraction.

The ulcers above described, as well as common gastric ulcer, are found chiefly near the pylorus and lesser curvature where the stomach is less able to contract, produces folds, and so protects the mucous membrane. Ulcers seldom appear along the greater curvature where the contractions of the muscular wall is unimpeded. These anatomical facts were simulated by Matthes's experiment by which he prevented local contraction of the gastric wall, and so artificially produced ulcerations.

Abscesses, necrosis or hemorrhage in the mucous membrane of the stomach will not cause an ulcer if the superficial epithelium remains intact. If this is lost ulceration occurs, and the acid gastric juice exercises its destructive action. A slight lesion may be covered up by the neighboring mucous membrane through the contraction of the muscularis mucosae. But if the lesion is large its course will vary according to its location in the stomach. Along the greater curvature the injured area may be protected, but on the lesser curvature or at the pylorus contraction of the gastric wall is limited, and the denuded area will be constantly exposed to the acid gastric juice. It is easy to explain why erosions may occur in any region of the stomach but ulcers only at the pylorus and along the lesser curvature. Ulcers in these latter regions may heal perhaps by the new formed connective tissue drawing the edges together, or, what is more likely, by the formation of new epithelium working in from the edges. In either instance a scar will be left if the ulceration has extended to the submucosa. It is easy to understand why the ulceration is most extensive in the mucous membrane, less so in the submucosa, and least of all in the muscle layer, thus

giving the characteristic "wedge shape and steps" of the gastric ulcer.

During digestion the stomach is in a uniformly contracted state. This contraction becomes more marked on the appearance of an ulcer. The central portion of the ulcer would be first attacked by the digestive juice because this would be the least protected by the surrounding tissue. With the lessening up of the contractions of the gastric wall the various layers of the stomach would slide over one another to a much freer extent on the greater than on the lesser curvature. These contractions will not properly take place unless the centripetal and centrifugal nerve supply of the muscular wall is intact. This explains why ulcers occur when any break in this arc occurs, for instance, in the sympathetics, vagi, spinal cord and medulla itself. As a result of such lesions hemorrhages or hyperemia occur with local destruction of tissue. This is exposed to the acid gastric juice because the contraction of the muscles can no longer protect it. The primary cause of the original lesion of the mucous membrane is seldom seen because the subsequent necrosis of tissue will have destroyed its identity.

INANITION IN DYSPEPTICS AND NERVOUS INVALIDS.

Matthieu and Roux discuss inanition which occurs in dyspeptics and nervous invalids.¹² The condition is most common in dyspeptics and neurasthenics, and since it is usually accompanied by loss of appetite or a perversion of the sense of hunger, no relief is obtained and the nervous symptoms become aggravated. In short, there is a vicious circle. Insomnia often plays a prominent rôle and esophageal spasm and uncontrollable vomiting may contribute to it. Finally, the effects of treatment with drugs given by various physicians may appear in the form of agastritis, until at length the patient is in a critical state. A severe gastric disease is considered a fatal prognosis may be given, and if the condition is not recognized death may really ensue.

The loss of weight may have been noticed in some cases but in others it has been so gradual as to be unobserved even by the friends. They recognize no other condition than the present one of malnutrition. In such patients the apparent volume of the liver is distinctly diminished. Its position may be lower or higher than normal. If other etiological factors can be excluded the small liver can be considered proof that the diet has for long been insufficient. With return of nutrition the liver increases in size.

People who lose strength and weight involuntarily are tormented by hunger and thirst. This is especially true if the starvation is at all general in the community, then one person aggravates the other's feelings, the same fact holds true for cases of stricture of the esophagus. With dyspeptics and neurasthenics the condition is other wise. This inanition is not so agreeable to them and their feeling of hunger is unrecognizable.

The loss of appetite may occur suddenly, but is more commonly of gradual onset. Nausea, distention and heaviness after food discourage eating, and one article after another is banished from the table. Often the nausea is accompanied by vomiting of mucus, similarly to that of patients with esophageal spasm. A feeling of fullness and weight appears behind the sternum, while the symptoms of anorexia may be most manifold. It is important to recognize this state or the treatment may continue the condition.

The tongue is white and not clean, the stomach splashes, and these signs may deceive the doctor. He should remember that they will disappear only with better nutrition. Chorsat has shown that in inanition the whole alimentary canal becomes smaller and emaciated just as the other tissues. The muscles of the stomach probably suffer likewise. It appears dilated even with a comparatively small quantity of fluid, and the doctor may fear to feed, though if he does the stomach will return to the normal, as the patient gains in strength. This may require months.

Hunger delirium occurs among people who are besieged or shipwrecked rather than in the cases of voluntary inanition. The progressive development of many a moral and physical sign of degeneration is observed.

Matthieu divides these patients with extreme inanition into three groups: (1) *Simple neurasthenia*. This is the most favorable form. The patient complains of discomfort after eating, continually narrows the volume of the diet in order to avoid this discomfort, and is perfectly satisfied with this peculiar mode of treatment. He gradually grows weaker, gets into a vicious circle, is despondent but resigned. He is capable of reasoning and understands how he must eat to regain strength. To successfully treat such patients one should explain to them that for the first two or three weeks they will have more or less digestive discomfort, but in spite of it must eat. (2) *Hysterical debility*. The patient is incapable of making the exertion which will bring him out of the condition into which he has fallen. Threats, requests and tears are without avail. He or she acts as if amused by these. Not until reduced to a living skeleton is an effort made to gain, and then it may be too late. The anorexia may have developed in various ways from indigestion,—pain, vomiting, esophageal spasm, sorrow, disappointed love, desire for attention, or desire to become thin. Anorexia rules, and there is total failure of the will to become well or to make an exertion for recovery. Common sense and threats are received with indifference or joking skepticism. Isolation and confinement in bed without any diversions are the best modes of treatment. (3) *Hereditary degeneration with fixed idea*. The patients have a poor heredity and imagine their stomach small, the intestines narrowed, the gastric juices insufficient, or themselves poisoned by fermentation or decomposition products. If not too long established their ideas can be conquered, but relapse is easy; if long established the condition develops into a

pure psychopathic state. On account of their fixed ideas they are really mentally unsound. One cannot drive their absurd ideas out of their heads. Prognosis is far less favorable.

CARBONIC ACID IN THE STOMACH.

Through careful examinations of dogs Loening¹⁸ was able to determine that the stomach absorbs to a large degree carbonic acid, which has been given with water. This absorption takes place very quickly in the first few minutes, so that over one half of the carbonic acid is absorbed in five minutes, and three quarters of it after ten to fifteen minutes. This rate of absorption then quickly decreases, so that after an hour but a small amount of the carbonic acid is left, which is absorbed either very slowly or not at all. The carbonic acid is also absorbed in large quantities from alcoholic drinks.

Seidelin¹⁹ reports examinations of the gastric contents of old people. In seventy elderly persons of fifty to seventy years of age, whom Seidelin examined, free hydrochloric acid was absent in the stomach juice in 28 (40%) while in numerous other cases the presence of hydrochloric acid was very slight, so that only with 6 persons, equal to 10%, the hydrochloric acid was within normal quantity. There were 35% of cases of achylia gastrica among the women, and 55% among the men. Arteriosclerosis seems to favor the lack of hydrochloric acid. As the result of his examinations Seidelin says that the secretion of the stomach juice can remain normal into old age, despite the signs of senility, but on the other hand, achylia gastrica appears in a comparatively large number of cases among elderly people. The significance of this fact is important in the diagnosis of cancer in elderly people.

Reports of Societies.

THE AMERICAN THERAPEUTIC SOCIETY.

SEVENTH ANNUAL MEETING HELD AT THE ACADEMY OF MEDICINE, NEW YORK, MAY 3, 4 AND 5.

(Concluded from No. 23, p. 659.)

THURSDAY, MAY 3. — Continued.

DR. T. E. SATTERTHWAIT, New York, read a paper ON THE DUTIES AND RESPONSIBILITIES OF THE PHYSICIAN IN BORDER-LINE DISEASES.

Up to this time, he said, the management of diseases on the border line between medicine and surgery had received very little attention from the textbooks of medicine. In fact, it was quite exceptional to find them considered, judicially, from the dual standpoint of the physician and the surgeon. In one of the most recent works on practice, for example, appendicitis was regarded as so pre-eminently a surgical affection that it was held to be proper for the physician, immediately on its recognition, to turn the patient over to the surgeon. Such an attitude, however, placed the

¹⁸ Zeits. für klin. Med., cited in Zentralbl. f. inn. Med., 1905, No. 23, p. 578.

¹⁹ Berl. klin. Woch., cited in Zentralbl. f. inn. Med., 1905, No. 23, p. 574.

physician in a false position, where he not only jeopardized the prospects of his patient, but rendered himself liable to adverse criticism. The same criticism might be directed against the medical practitioner when he was called upon for a professional opinion in the treatment of the twenty and more other diseases on the border line between medicine and surgery. In all these there were times when the physician might very properly ask himself, Is this an operative or nonoperative case? The affections referred to were abdominal and pelvic tumors, cirrhoses of the liver, pancreatic diseases, morbid collections in the kidney, chronic Bright's disease, cholelithiasis, intestinal hemorrhages, obstruction or traumatism, enlarged prostate, pleurisy or pericarditis with effusion, acute or chronic mastoid disease, diseases of the accessory sinuses, malignant tumors in general, epilepsy, hemorrhoids and even habitual constipation. The present relations between medicine and surgery made it obligatory on the part of the conscientious practitioner to keep himself informed as to the comparative advantages of all the methods in vogue, not only as applicable to any given case, but to the various phases of it; so that he might be ready at all times to give his patients the benefit of that treatment which offered the best prospect of relief. To this end he should be fully acquainted with all the latest improvements in the treatment of disease, whether they were medical, surgical, mechanical, hygienic, dietetic or even psychic; and particularly should he be able to form and give intelligent opinions as to the question of operative or non-operative measures in any of the affections mentioned. The physician would thus be prepared to enter the consulting room armed with definite data, from which to draw intelligent conclusions, perhaps, in the light of other facts elicited by the surgeon or brought to his notice by the patient or his friends. The average physician excelled the average surgeon in diagnostic ability, and surgeons were now disposed to admit that their increasing success was richly dependent on closer attention to diagnosis, including not only a more thorough study of their patients' histories and symptoms, but the use of aids the physician more especially recognized, such as pathological and laboratory findings and the newer methods of physical examination. If, therefore, the physician excelled the surgeon in diagnosis, what could conduce more to the successful issue of a case than that each should contribute his quantum of information and experience in these border-line diseases? Under certain circumstances a surgeon might urgently require both the counsel and the co-operation of the physician. If, for example, the chances of life were going to be slightly improved by an operation, but the surgeon hesitated, perhaps because his personal experience had been unfortunate in this particular line of affections, it would then become the imperative duty of the physician to urge the operation, as holding out the best prospects for success. Dr. Satterthwaite said that while he was perfectly willing to admit that the surgical operation in appendicitis had saved many lives which would have been lost under non-operative treatment, this was far from saying that all cases of the disease should go to the surgeon. He then discussed very fully the indications calling for operative interference and the circumstances in which this should be withheld. Having paid considerable attention also to pyelitis and pyelonephritis, he went on to say that in nearly all the border-line affections he had enumerated (the exceptions being possibly diseases of the pancreas and certainly pyothorax and certain suppurative diseases of the abdominal cavity, such as of the liver and spleen) non-operative treatment, and

certainly prophylaxis, on the part of the medical attendant, was of recognized utility. His contention in this paper, however, was this: In all the affections referred to he would have the physician fully informed as to the best methods of treatment, whether medical or surgical, the proper time to call for surgical advice, and the chances for the patient's recovery under surgical, as against medical, measures. More than this, he would have the physician qualify himself to make the diagnosis in all these cases, and be ready to sustain the surgeon should an operation be deemed advisable. Finally, he would urge that future textbooks of medicine contain not only the latest diagnostic data in these border-line diseases, but the most recent statistics of successful treatment, whether by medical, surgical or any other means.

In the discussion following the paper, Dr. F. H. Gerrish, Portland, Me., said that certain of the diseases which Dr. Satterthwaite had designated as border-line affections he, himself, would regard as purely surgical as soon as the diagnosis was arrived at.

FRIDAY, MAY 4.

DR. F. E. STEWART, East Orange, N. J., read a paper entitled:

WHY THE MEDICAL PROFESSION SHOULD SUPPORT THE PHARMACOPEIA.

Having given the history of the Pharmacopeia, he said the medical profession was a privileged class in the community, responsible to the state for the advancement of medical practice, including pharmacy and the maintenance of a pharmacopeia. Thus far, with the exception of a devoted few, the profession had taken very little interest either in pharmacy or the Pharmacopeia. It was time for a change of policy in this regard. Without a pharmacopeia progress in drug therapeutics was impossible. Common standards for determining the identity, purity and strength of medicines were necessary to maintain uniformity in them. Physicians should support the Pharmacopeia, for in no other way could pharmacy be redeemed from those who were attempting to convert the practice of pharmacy into a commercial business; in no other way could pharmacy be restored to medicine as a branch of medical science and practice. It was not a question of the retail druggist *versus* the manufacturer, as some would have us believe. The question was pharmacy and the Pharmacopeia *versus* a commercial business carried on under the name of pharmacy by those retail druggists and manufacturing houses alike who conducted their vocation in opposition to scientific and professional requirements and deluded the sick with misleading advertisements.

DR. L. KOLINSKI, Washington, D. C., read a paper on

THE EFFECT OF TREATMENT OF THE VOMITING OF PREGNANCY.

The pernicious vomiting of pregnancy, characterized by its intense symptoms and its fatality, he said, was as rare as the simple vomiting of that state was common. Having described the symptoms he stated that for precision of diagnosis and propriety of treatment the vomiting of pregnancy should be considered pernicious whenever weakness and wasting of the body had become sufficiently great to prevent the patient leaving her bed. He then gave the various treatments, based on different etiological hypotheses, which had been commended. The *distension of oophorum* was induced abortion or premature labor. A careful study of the phenomena presented in the condition had led Dr. Kolinski to discard the treatments hitherto in

vogue and to attempt the plan of a diet comprised of substances limited in number and of such physical structure that, by reason of their density and heaviness, their ejection from the stomach was well nigh impossible. Of proper foods, pork (ham or bacon) was first. A woman who had vomited incessantly for two or three weeks, who was too feeble to leave her bed, who had received varied and unsuccessful treatment, whose whole appearance was that of alarm, would find to her intense astonishment that the emesis did not occur after a breakfast of fried ham or bacon. She would then find that partaking of other solids improved her condition, and within a few days sleep and strength would have returned, so that she could be up and about again. In considering the factors producing this quiet he said it was apparent that the chief one was the stable tone given to the distressed viscus, much like ballast to a vessel in troubled waters. The co-operation of the patient, due to new confidence and the assurance that her malady could be cured, was also very helpful. The daily breakfast should consist of pork in some form, with corn bread and cocoa or chocolate. At other meals might be taken beefsteak, roast or corned beef, and such vegetables as rice, potatoes, spinach, cauliflower and turnips. Fish, game, fowl and cheese are also good articles of diet. Foods which induced vomiting were water, if taken freely, milk, tea, coffee, soups and fluids in general, eggs, custards, toast and fruit. The most unstable combination of a diet was toast, eggs and sweetened tea. Dr. Kolipinski had used this dietetic treatment with success in two cases of pernicious vomiting and also in instances of obstinate vomiting of the ordinary variety, and believed it worthy of trial by others.

DR. ROBERT REYBURN, Washington, D. C., read a paper on

THE MEDICAL TREATMENT OF CANCER.

As a preliminary to the question of treatment he expressed his opinions concerning the causes of cancer. He gave as the first and probably most powerful predisposing cause senility of the tissues and organs of the body. The real test of old age, he said, was not the number of years a person has lived, but the retrograde metamorphosis and degeneration which has taken place in the various parts of the body. Other predisposing causes were the habitual use of alcohol and the consumption of too much meat and other nitrogenized food. Two facts as to the causation of cancer seemed to be now generally admitted: (1) That it is probably always local in its early stages; (2) that its origin is due to some injury or local irritation of the part affected. Believing, as he did, that cancer is simply an error of cell development depending upon the retention of waste matter in the system, he said the treatment might be divided into two classes, the preventive and curative. To epitomize the treatment of cancer cases, it should be the effort of physicians to endeavor to bring their patients into the highest condition of personal health and excellence of hygiene. He thought it lamentable to see the apparent helplessness of most medical men when confronted with cases of cancer. Generally no attempt was made to treat these cases by medication, or to improve their hygiene, and the sole resource seemed to be the knife, the x-ray, or some form of electricity. Valuable as these agents were, it was his firm conviction that our success would be far greater if we would conjoin them with appropriate medical treatment. Each case must be studied individually and treated accordingly.

In the discussion DR. R. T. NORRIS, New York, said he would operate in all cases of cancer that were operable just as soon as the diagnosis was made, provided

such diagnosis were made early. Immediate operation was also strongly advocated by Drs. Gerrish, Satterthwaite, Lloyd, Leech and Janvrin.

DR. L. S. PILCHER, Brooklyn, N. Y., read a paper on

REMOVAL OF THE PROSTATE FOR THE CURE OF PROSTATIC DYSURIA.

Having summarized the conclusions which he had presented in two previous papers in which he had discussed the methods and results of prostatectomy for the relief of this condition, he stated that these conclusions had nowise been shaken by the experience of another year. In all the thirty cases previously reported, with one exception, the method of approach to the prostate had been through the perineum. In six cases operated since that report, only one had been perineal; in the remaining five the suprapubic transvesical route was employed. In the latter he had been well pleased with the control over the region of operation secured by the introduction of the gloved finger into the rectum, making counter-pressure against the prostate. Although his experience with it was limited, it had been sufficient to demonstrate to him that a very considerable advantage in the way of obtaining an intelligent direction of the work of enucleation could be secured by this method of conjoined rectal and intravesical manipulation, and he was now inclined to give a larger field for the suprapubic route than he had done in his earlier studies. In the majority of cases, however, he thought it probable that some method of attack from the perineum would continue to be method of choice. He was inclined to think that for the best fulfillment of all the operative indications, when the perineal route was adopted, it was desirable that a free exposure of the gland by a suitable perineal incision and retraction of overlying parts should be made. The gland, after it has been exposed, should be brought down as much as possible into the superficial operative field by the use of suitable tractors, and the removal of the obstructing masses should be carefully and systematically effected, under the guidance of the eye as much as possible. This was simply an application of that tenet of general surgery which demands the adequate exposure of an affected part as the first step of an attack upon it.

DR. HOWARD VAN RENSSELAER, Albany, N. Y., read a paper on

THE ETIOLOGY AND TREATMENT OF UREMIA.

Having reviewed some of the prevailing opinions as to the etiology and pathology of uremic states, he said he thought we were justified in assuming the following conditions to be present: That, probably by the action of bacteria in the intestine or liver, there is circulating in the blood a poisonous proteid, which is the actual exciting cause of uremia. That this proteid, by its irritant and destructive action on the kidney tissue, prevents not only itself from being changed or excreted, but prevents the elimination also of other excrementitious matters, such as urea, extractives and salts, and permits their accumulation in the blood. That these excrementitious matters are capable of producing part of the symptoms, such as vomiting, diarrhea, prostration, increased heart action, contraction of the pupils and, perhaps, muscular tremors. That the hyperosmosis produced by the increased amount of the crystalloid substances may perhaps modify the composition of the cellular structure in different parts of the body, sufficient to interfere with their functions and give rise to symptoms. If these premises were correct, he thought the treatment of uremia should be conducted along four general lines:

(1) *Removal of the Exciting Causes.*—Under this

he would place (a) Removal of the proteid by venesection. For an average sized adult a pint of blood, or even a little more, might be withdrawn, as early as possible during the uremic seizure. This method was also the quickest means of reducing the tension in the blood vessels. (b) Lessening the toxicity of the blood by dilution. This might be done in three ways. By the intravenous injection of a saline solution, by hypodermoclysis, or by drinking large quantities of pure water. This third method was the slowest, but it was the simplest and safest, and he believed it to be the best. (c) Removal of urea and extractives by dialysis. Here we should aid in removing these deleterious substances by stimulating the excretories in four ways: By drinking water, catharsis, diaphoresis and diuresis.

(2) *Prevention of the Reappearance of the Exciting Causes.*—If a poisonous proteid was produced by bacteria, it was obvious that we should keep the intestinal canal as clean as possible by catharsis, possibly aided by antiseptics, and be extremely cautious in the administration of food containing proteid.

(3) *Physiological Rest to the Diseased Tissues.*—Food, in the case of adults, should be withheld for at least twenty-four hours, when small quantities of peptonized milk or diluted gruels might be allowed. Cathartic and diaphoretic treatment also aided in giving the kidneys rest.

(4) *The Treatment of Individual Symptoms as they Arise.*—Convulsions might sometimes be controlled by chloroform or other anesthesia, or by morphine hypodermically. In those individuals whose pupils were dilated morphine seemed to act beneficially, while in those whose pupils were contracted, the reverse was true. Successful results had recently been reported from spinal puncture and the removal of sufficient cerebrospinal fluid to bring the intracranial pressure down to normal.

DR. SAMUEL LLOYD, New York, read a paper on

THE SURGICAL SIGNIFICANCE OF JAUNDICE.

He said that within the last few years jaundice had taken on a new significance, and that the great bulk of the information now at hand as to its cause was the result of surgical investigation. Having referred to the various classifications of jaundice, he mentioned one condition not included in Mayo Robinson's tabulation of the extra-hepatic variety which in his opinion was a direct result of the chronic catarrh of the gall ducts. This was an inspissation of the bile filling the common duct and sometimes the gall bladder, and even the hepatic ducts for a considerable distance into the liver itself, with a thick, pasty, dark bile. The bile was of about the consistency of soft putty, and offered a complete obstruction to the natural escape of the fluid. Medical treatment could be of little avail in removing this, while the results of operative treatment were so prompt, and offered so little danger, that it should be undertaken early. Two conditions had to be considered most carefully in the surgical treatment of jaundice; the changes in the blood and the condition of the kidneys. As regards the former, the change of most serious character was the marked decrease in coagulability; in fact, a pseudohemophilia, and it constituted one of the most dreaded conditions that surgery had to contend with in operations on the liver and bile ducts. The hemorrhages resulting from this condition did not, as a rule, occur immediately after the operation, but began from one to four days later. In all cases of prolonged jaundice marked and generally increasing anemia had also to be contended with; therefore, it was important that the percentage of hemoglobin should be determined at the same time that the coagulability of the blood was being investi-

gated. Operations of any kind undertaken with a hemoglobin percentage of less than thirty were exceedingly serious. Changes in the kidneys were important, both in determining the anesthetic to be employed and in influencing the prognosis. Naturally, when we had added to the toxemia of the jaundice the toxemia of nephritis, the patient was in a very bad condition to resist any surgical interference. It was not the surgeon's fault that the percentage of deaths in these cases was so high, but rather that of the medical practitioner, who delayed calling in the surgeon until such a serious condition had developed. Cases of jaundice which came to the operating table early, before they were suffering from general toxemia, did well, and usually recovered promptly. It was also to be remembered that in all probability the chronic irritation of gallstones may be the potent cause for the development of cancer of the gall bladder, gall ducts, duodenum, pylorus or pancreas. Many of the conditions referable to the stomach and treated as chronic gastric affections were also due to a spasm of the gall bladder and ducts, either with or without a chronic empyema. Exploratory incision would undoubtedly reveal the cause of many of these gastric troubles. It was of great importance, if possible, to determine prior to the operation whether the condition is due to removable obstruction or to malignancy. Enlarged liver was much more common in obstruction due to cancer than from gallstones, though it might be present in either. The conclusion of the paper was devoted to a brief consideration of the intrahepatic conditions.

The scientific sessions were brought to a close by a SYMPOSIUM ON THE RECENT ADVANCES IN SPECIAL THERAPEUTICS.

as follows: "Pediatrics," Dr. J. Madison Taylor; "Ophthalmology," Dr. W. B. Marple; "Gynecology," Dr. H. C. Gee; "Surgery," Dr. John B. Deaver; "Neurology," Dr. E. D. Fisher; "Obstetrics," Dr. L. H. Grandid; "Laryngology," Dr. C. H. Knight; "Electrotherapeutics," Dr. W. J. Morton; "Otology," Dr. Wendell C. Phillips.

The meeting on the third day, May 5, was devoted exclusively to the transaction of business.

Recent Literature.

Eye, Ear, Nose and Throat Nursing. By A. EDWARD DAVIS, A.M., M.D., and BEAMAN DORRASS, M.D. With 32 illustrations. Pp. 302. Philadelphia: L. V. Davis Company.

Although this book has been written for nurses it will certainly interest the practitioner and medical student. The question of antiseptics and asepsis, the preparation of solutions and dressings, have been carefully explained and the importance of preliminary training in some good general hospital before attempting the technicalities of special work has been emphasized. The authors in their endeavor to instruct nurses as to their duties in caring for operative cases and diseased conditions have succeeded in producing a volume containing a surprising amount of useful information, considering its small size, which will prove to be valuable as a textbook for training school and institution work and likewise a convenient means of ready reference in private nursing.

Practical Sanitary Science. A Handbook for the Public Health Laboratory. By DAVID SOMMERVILLE, B.A., M.D., Lecturer in Public Health, King's College, London. New York: William Wood & Co. Pp. x, 310. 1906.

The literary style of this handbook reminds the readers of a ride over a corduroy road; the substance excites conflicting sensations, — sadness to deep depression; gentle merriment to explosive hilarity; incredulous surprise to amazement; sympathy and admiration. Although intended for the laboratory, it is more suited to the hammock after a hard day's work. Time and space are too valuable for a critical analysis. It approaches far more than any other work of recent years that superlative known in the vernacular as "the limit."

Nose and Throat Surgery. Nasal Sinus Surgery with Operations on the Nose and Throat. By BEAMAN DOUGLASS, M.D., Professor of Diseases of the Nose and Throat in the New York Post-Graduate Medical School and Hospital. Illustrated with 68 full-page half-tone and colored plates. Philadelphia: F. A. Davis Company. 1906.

This is a book of 260 pages, describing concisely and clearly the important operations on the nose and throat, including also a review of the essential anatomy and a series of excellent half-tone plates from prepared anatomical specimens. Most of the book is devoted to the nasal accessory sinuses. For each of these sinuses in turn the anatomy and variations, the diagnosis of empyema, the different conservative methods of treatment and radical operations are described. The frontal sinus is first taken up, ending with a description of the different radical operations, of which the open method is classed as the ordinary operation and that of Kuhnt as the typical radical operation, although that of Killian is given in some detail. The ethmoid cells, the antrum and the sphenoidal sinuses are taken up in turn, and the anatomy, diagnosis of empyema and treatment well illustrated. The author omits to call attention to the value of the x-ray in discovering the size and shape of the frontal sinus before operating, and as a possible aid to diagnosis both here and in the antrum.

The next subject is deviation of the nasal septum, concerning the treatment of which there is so much difference of opinion that it would be impossible at the present day for any one in a short space to satisfy most of his readers. The author will probably be largely criticised for his comparative neglect of the submucous method of operating.

Cosmetic operations for the correction of deformities of the external nose are briefly described, including the injection of paraffin for the saddle-back bridge. To correct deviating nasal bones the author boldly goes through the skin, a method which has not previously received the attention it deserves but which must be carefully undertaken to avoid the danger of unsightly

scars. The same caution is even more necessary in recommending the insertion of foreign bodies under the skin for the purpose of building up a sunken nose. The removal of the turbinates and enlarged tonsils and adenoids receives careful attention. For the latter operation the author prefers a quick operation under nitrous oxide. In this community ether is the routine anesthetic, giving more time. The last chapter is devoted to tracheotomy and a brief description of laryngotomy.

There has been a need for a book of this kind. Methods of operating have developed rapidly during the past few years, and certain of these operations have not been adequately collected in our general textbooks. The book is well written, well arranged, clear and concise, perhaps too concise, as it omits references to fuller descriptions of the different operations, and does not always give sufficient detail to guide the operator without further assistance. But, on the whole, it fills the place which it was intended to fill very satisfactorily.

Atmokaussis und Zystokaussis die Behandlung mit Hochgespanntem Wasserdampf in der Gynaekologie. Von DR. LUDWIG PINCUS. Frauenarzt in Danzig. Zweite verbesserte Auflage mit 33 Textfiguren und Tafeln. Wiesbaden: J. F. Bergmann. 1906.

This is the second edition of Dr. Pincus's monograph on the treatment of the uterine cavity with steam under high pressure.

It is a volume of 371 large pages illustrated by thirty-three drawings in the text and five plates.

The author gives a most exhaustive historical review of the employment of hot water and steam to arrest hemorrhage and to cauterize, finding that the Greeks and Romans undoubtedly used this method. J. N. Rust, 1830, was the first to employ it systematically. Dzondi of Halle invented a machine in 1821 for generating steam for surgical uses, a rude model for the Pincus apparatus.

The different styles of development of the author's instruments are described and figured in great detail, followed by the scientific and theoretical considerations which were the foundation of his technique. Then came the gross and microscopic appearances of the uterine mucosa following steaming for varying lengths of time and at different temperatures.

The last half of the work is devoted to the clinical aspects of the application of steam. Here are to be found set forth with all the necessary minutiae, the steps of the technique and the indications and contra-indications for the use of steam cauterization. At the end of the book is an index of the literature, another of the authors and a third of the subjects cited.

To any one wishing to employ vaporization of the uterus and desiring to go to the fountain head of information on the subject the possession of this treatise is a necessity.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JUNE 14, 1906.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: \$4.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.00 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOYLSTON STREET, BOSTON, MASS.

REPORT OF THE MASSACHUSETTS STATE BOARD OF INSANITY.

The seventh annual report of the Massachusetts State Board of Insanity for the year ending Sept. 30, 1905, is in our hands. It will be remembered that the functions of this board are extensive inasmuch as the insane, the feeble-minded, the epileptic and the inebriate classes are all under its supervision. The entire number under care at the conclusion of the last year was 11,900, almost equally divided as to men and women. This was an increase for the year of 416. The larger part of these naturally are included under the general heading of the insane, and it is a rather startling fact that a simple calculation shows one insane person to every 206 persons of the general population. The removal of the insane from almshouses was entirely accomplished during the year, a total of 212 persons. It is gratifying, however, to note that the actual year's increase of the insane in public institutions fell far below that of any other recent year. The reason for this is somewhat difficult to analyze, but we are at least hopeful that preliminary care and quicker recognition of the onset of mental disease has done something to forestall graver consequences, demanding asylum treatment.

It is also satisfactory to record the fact that the relief from extreme overcrowding has been accomplished, and that complete correction of this evil is assured if the state continues to pursue the policy of meeting the constant demand for additional accommodation each year. The board recommends that provision be made during the coming year for 200 additional patients, which

at the present rate of increase, should adequately meet the demand.

The constant growth in efficiency of the school for the feeble-minded at Waltham has repeatedly called public attention to this institution. The extension of the work by the establishment of the Templeton colony and the very great benefit resulting to the patients therefrom has demonstrated that even the feeble-minded may be made of use and cease to be a mere burden to the state. Certain buildings are needed by this institution, the money for which should be forthcoming. In this connection it is important to observe that the provision for feeble-minded children in institutions adapted to their peculiar requirements is still inadequate in this state. In the neighborhood of one thousand applicants have been denied admission to the School for Feeble-Minded because of lack of room, with the result that these unfortunate children are housed at almshouses and even at insane hospitals, where naturally they cannot receive the care and instruction calculated to develop their imperfect faculties. This is evidently a serious matter. Such children must be cared for. They are peculiarly helpless and often inimical to the welfare of society, and every effort should be made to train them to the extent of their ability in order that they may at least become harmless and possibly useful members of the community. It has been amply demonstrated that much may be done for these children and it is none the less manifest that if nothing is done their future is not only pitiable in itself, but entails results which later force them upon the state, not infrequently among the criminal classes. The moral aspect of the question is also one of great importance and every legitimate means should be taken to prevent the reproduction of this irresponsible class. In view of these facts the board strongly recommends a progressive extension of accommodation for this class in existing institutions. It is also of the opinion, which the trustees of the Waltham School likewise hold, that the future of Waltham should be rather in the completion of its present facilities than in further extension of its capacity, which when the present buildings are completed will be 1,000 at Waltham and 250 at Templeton. It is therefore recommended that a new institution of a similar character be established preferably in the western part of the state. This undertaking should be begun at once to meet the growing demand.

Another class of the cognitum, which demands attention and for which the provision is even less

than that for the feeble-minded is epileptic children. It is suggested that the present hospital for epileptics be extended by the formation of a department for the care of children under fourteen years of age. It is, perhaps, difficult to distinguish in practice between the simple epileptic child and the epileptic associated with idiocy, but some effort toward a differentiation should be made, and to this end it is altogether desirable that provision for the young epileptic should be made at those institutions where the disease is particularly treated.

In general, this report of the State Board of Insanity is encouraging. It demonstrates the extreme interest which is being taken in the various defective classes and the excellent work which is being done by our various institutions. It is not to be questioned that Massachusetts will continue to maintain its pre-eminence as a progressive and far-seeing state in relation to the great social and economic problems relating to the care of its dependent classes.

MEETING OF THE MASSACHUSETTS MEDICAL SOCIETY.

OWING to the recent meeting of the American Medical Association in Boston, the program of the Massachusetts Medical Society, which met this week, has been somewhat curtailed. In view of the many scientific communications which the physicians of Massachusetts, in common with those from other parts of the country, have had the privilege of listening to during the past week, those who have had the arrangement of the meeting in charge have done wisely in limiting the papers to be read to one morning of the session and taking up but a single subject, namely, diseases of the bile passages, including the liver, gall bladder and pancreas. This proved a most interesting discussion and merely carried further the policy of the last few years in offering to the assembled physicians fewer scientific communications and more demonstrations.

As to the larger meeting of the American Medical Association, the new buildings of the Harvard Medical School proved a source of much interest to those physicians who had not hitherto had an opportunity of seeing them. On Tuesday a series of demonstrations was given at the new school buildings under the direction of Dr. W. T. Councilman, and in addition to these demonstrations an admirable exhibit of specimens, apparatus, drawings and photographs was shown in the Warren Museum in the Administration Build-

ing, and also in the Building of Anatomy. These exhibits and demonstrations were appreciated by the members of the society, not only in themselves, but as illustrative of certain of the best methods of modern medical teaching. The usual invitations to hospitals and institutions of interest to physicians were provided this year as heretofore.

The Shattuck Lecture of the year was delivered by Dr. Victor C. Vaughan, of Ann Arbor, Mich., on the subject, "A Contribution to the Chemistry of the Bacterial Cell and a Study of the Effects of Some of the Split Products on Animals." In this lecture Dr. Vaughan brought to the attention of his hearers certain new lines investigation is taking in the attempt to solve the underlying problems of metabolism, which no doubt will do much to shape medicine in the future. It is altogether advisable that such subjects, difficult as they may be of comprehension to the untrained mind, should be brought forward from time to time before an audience of practicing physicians in order that the rank and file may not be ignorant of certain of the most important modern methods of research. The annual discourse on "The General Practitioner and the Specialist" was this year delivered by Dr. John L. Hildreth, of Cambridge, and brought out much of practical importance to the physician and the public. Following the discourse the usual annual dinner was served, presided over by the president of the society, Dr. Arthur T. Cabot. Among the other speakers were President Eliot of Harvard University and the Hon. Henry N. Sheldon of the Massachusetts Bar.

MEDICAL NOTES.

OFFICERS OF THE AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION. — At the Ninth Annual Meeting of the American Gastro-Enterological Association, held at Boston, Mass., June 4 and 5, 1906, the following officers were elected for the ensuing year: President, Dr. H. W. Bettmann, of Cincinnati; first vice-president, Dr. Julius Friedenwald, of Baltimore; second vice-president, Dr. F. H. Murdoch, of Pittsburg; secretary and treasurer, Dr. Charles D. Aaron, of Detroit.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, June 13, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 38, scarlatina 19, typhoid fever 10, measles 76, tuberculosis 55, smallpox 0.

The death-rate of the reported deaths for the week ending June 13, 1906, was 18.00.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, June 9, 1906, was 224, against 188 the corresponding week of last year, showing an increase of 36 deaths and making the death-rate for the week 19.63. Of this number 122 were males and 102 were females; 219 were white and 5 colored; 143 were born in the United States, 74 in foreign countries and 7 unknown; 47 were of American parentage, 145 of foreign parentage and 32 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 53 cases and 3 deaths; scarlatina, 27 cases and 1 death; typhoid fever, 9 cases and 1 death; measles, 77 cases and 1 death; tuberculosis, 56 cases and 32 deaths; smallpox, no cases and no deaths. The deaths from pneumonia were 15, whooping cough 4, heart disease 19, bronchitis 4 and marasmus 7. There were 15 deaths from violent causes. The number of children who died under one year was 45; the number under five years 56. The number of persons who died over sixty years of age was 58. The deaths in public institutions were 83.

There were 2 cases and 3 deaths reported from cerebrospinal meningitis during the week.

AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION. — At the annual meeting of the American Medico-Psychological Association, being held at the Hotel Vendome, in Boston, this week, addresses of welcome on behalf of the state were given at the opening session by his Excellency Governor Curtis Guild, Jr.; Dr. Arthur T. Cabot, president of the Massachusetts Society; and Dr. Henry P. Walcott, chairman of the State Board of Health.

REPORT OF WORCESTER, MASS., BOARD OF HEALTH. — The annual report of the Worcester, Mass., Board of Health for the year 1905 gives certain statistics of interest. Seventy-five cases of scarlet fever were reported during the entire year, the smallest number since 1885, with but 4 deaths. The record for typhoid fever was 150 cases, with 26 deaths. It is interesting to note that the number of cases in excess of the previous year was 46, or precisely the number reported in the epidemic occurring in August, in a certain district of the city. A thorough investigation of this epidemic failed to disclose the initial case, but the source of the epidemic was established

as coming through milk delivered in that neighborhood. One hundred and thirty-two cases of diphtheria were reported with the rather large death-rate of nearly 10% due, it is supposed, to the prevalence of a particularly malignant type of the disease. Three hundred and thirty-eight cases of pulmonary and laryngeal tuberculosis were reported with 228 deaths. Of the 14 cases of cerebrospinal meningitis, 9 were fatal.

NEW YORK.

REQUEST TO ST. FRANCIS'S HOSPITAL. — Among other charitable bequests in the will of the late Peter Spies of New York, is one of \$1,000 to St. Francis's Hospital.

CENSUS OF THE BLIND. — Governor Higgins has appointed Dr. F. Park Lewis, of Buffalo, head of the commission to prepare a census of the blind in New York State which was created by the recent legislature.

COMMENCEMENT, NEW YORK UNIVERSITY. — The seventy-fourth annual commencement of the New York University was held at the Library and Auditorium building on University Heights, on June 6. In his address Chancellor MacCracken stated that in recent years the records of the university showed a marked falling off in the number of students of the three professions, medicine, law and divinity, and a corresponding increase in students taking up teaching as a profession. In the medical department (University and Bellevue Hospital Medical College) the Valentine Mott gold medal was awarded to August L. Beck, of New York, and the Lusk Memorial Science prize to Henry M. Lefkowitz, also of New York.

A REMARKABLE DISTANCE WALK. — On the remarkable pedestrian trip made by Edward Payson Weston, in which Mr. Weston, now sixty-seven years old, succeeded in walking from Philadelphia to New York, a distance of ninety-six miles, in twenty-three hours and thirty-one minutes, he was accompanied in an automobile by Drs. Robert Taylor and E. E. Smith, the one to care for his physical condition and the other to make scientific observations. The feat was undertaken in the interests of science to show the effects of such severe exertion on a man of the pedestrian's years, and to compare the results with the observations made by Prof. Austin Flint, on a similar trip, thirty-one years ago, when he was forty-six years old. It is notable that in his recent walk Mr. Weston beat his former time by twenty-five minutes.

CONFERENCE ON THE BEST LIGHT. — At a meeting of the Illuminating Engineering Society, held June 8, oculists and illuminating engineers met probably for the first time in this country in a discussion as to the kinds of light best for the eyesight. The discussion was opened with a paper by Dr. Louis Bell, of Boston, and the definite conclusion appeared to be accepted by all that brilliant electric lights in direct vision are harmful, and that in time it will be generally recognized that glare does not constitute beneficial illumination. Dr. Percy Fridenberg thought theatres, hotels, libraries and other public buildings were, as a rule, injudiciously lighted. There should be plenty of light, but the sources of it should be concealed as much as possible. Besides the important points of the intensity of the light and its placing, there was also the question of the heat from incandescents used at the desk. This had the same effect in producing dryness of the lids as the heat from a fire. Dr. N. J. Hepburn spoke in favor of subdued lights, and thought the yellow preferable to white light. Dr. William S. Dennett said there was no danger of getting too much light by artificial means. The main thing was to place the light properly and see that it was maintained steadily. The hall in which the meeting was held (the Edison Auditorium in West 27th Street) he thought was as beautifully lighted as any he had ever sat in. The lighting of the hall, it is stated, was done especially for the oculists. There were no lamps whatever about the speakers' platform, or in the line of vision of any one, a mellow radiance proceeding from overhead and filling the room with a very restful light.

Obituary.

MARY PUTNAM JACOBI, M.D.

THE death of Dr. Mary Putnam Jacobi occurred June 11 at her home in New York. She was sixty-three years old at the time of her death and had long been a sufferer from a chronic affection which for some years had entirely incapacitated her for active work. Dr. Jacobi was born in London, England, and was a daughter of Mr. George Palmer Putnam, the publisher.

She studied medicine at the Philadelphia Woman's Medical College and the New York College of Pharmacy, at a time when women in medicine were far less conspicuous than now. After completing her preliminary work in New York and Boston, she went to Paris and was graduated from l'École de Médecine to which she was the first woman to be admitted. Shortly after this she was married to the distinguished

Dr. Abraham Jacobi who survives her in the full activity of his powers. For the greater part of her life she practiced medicine in New York.

Dr. Jacobi was one of the most distinguished women physicians in this or in any country, and did much toward the progress of medicine in many lines of research. Not only was she a prolific writer on medical topics, much of which related to the nervous system, but she was also an ardent supporter of woman suffrage and a forceful writer on educational and allied topics. It will be remembered that a few years ago she was one of the speakers at the annual meeting of the Massachusetts Medical Society, and directed her remarks to a defence of vivisection. Although during the active period of her life she engaged in the practice of medicine, her interest in the more abstract and so-called scientific departments of her profession never flagged. She had a keen appreciation of the significance of the modern scientific movement in medicine and throughout her active life stood in the forefront of progress. In her death, quite irrespective of sex, the profession loses a distinguished member.

Miscellany.

THE INTERNATIONAL MEDICAL CONGRESS.

OUR contemporary, the *London Practitioner*, comments in the following somewhat pessimistic vein on the recent International Medical Congress: "Once again the International Medical Congress has come and gone, and once again it has passed like a ship in the night and left no mark on the sea of science. It was in some ways a fine pageant, and it is generally agreed that it was a pleasant picnic. It was abundantly evident that this was all most of the members wanted; the work was left to a few enthusiasts who took their pleasures sadly in telling each other what all knew beforehand they would say. The only sections in which even the appearance of scientific interest was kept up were those of medicine and hygiene, and in these, for the most part, the audience, if meet, was distinctly few."

"Usually the attitude of the audience towards the orator of the moment was that of Falstaff towards the 'old lord of the council,' who talked very wisely, but he regarded him not. Conversation was general, the president and officers setting the example. The object was to get through the business as speedily as possible. The hours of 'work' were nominally from 8.30 till 12; in reality the meetings did not begin till 9 or later, and were generally over by 11. In all the sections many whose names were down to read papers failed to put in an appearance; in some sections there was no one present but the officers; and one actually 'ceased upon the midnight with no pain' during the Congress, no meeting at all being held on the last day. It is not surprising, therefore, to learn that not a fraction of the communications on the program were read even by title.

"The Portuguese were in every way charming as hosts, and all who attended the Congress brought away with them the most pleasant recollection of the welcome they received from every one from the king and queen downwards. The Portuguese showed a delicate sense of courtesy in keeping their own language in the background. The German element was not so 'pushful' as it generally has been on previous occasions and showed a disposition to fraternize. The English, on the other hand, held themselves aloof in an isolation, which may in their eyes have been 'splendid,' but which to others seemed ungracious. As usual, this was due to want of organization.

"We have before had something to say as to the future of the International Medical Congress, and the recent gathering at Lisbon adds emphasis to the views we have put forward. The meetings are tending more and more to degenerate into international picnics, which, however pleasant in themselves and useful in bringing fellow workers acquainted with each other, do nothing whatever for the advancement of science. The original conception of the Congress was that it should be at once a center for the exchange of scientific discoveries and ideas, and a means of promulgating *urbi et orbi*, with the whole authority of the profession, the latest teachings of medical science in regard to matters concerning the suppression of disease, the maintenance of public health, and the action that should be taken by states and rulers to give practical effect to those teachings. To all who are really interested in the welfare of the human race it is painful to see how far the Congress has drifted from this intention. From the position of a Universal Council of Medicine it has fallen to that of a trade exhibition. For any higher purpose, indeed, the Congress has become useless. Men go to the meetings largely not to learn, for they know already, through the channels of information which are now almost embarrassingly numerous, all that their colleagues and rivals have to teach; but to show themselves, and to impress on the public mind the fact that any charitable suggestions as to their professional extinction are, as Mark Twain said of the rumor of his own death, 'greatly exaggerated.' This is the microbe that lurks in all congresses of whatever kind. Its effects can be resisted by a sound constitution, but this is just what the International Medical Congress no longer possesses. It has, in fact, only a very thin-spun thread of continuous life, and this may be at any time 'slit' by the 'blind fury with the abhorred shears'.

"At Lisbon the proposals for the establishment of a Permanent Committee, which should be the visible link of unity and continuity, and for the increase of the interval between meetings to five years instead of three, do not seem to have been seriously discussed. It was, indeed, resolved that at the next Congress, to be held at Buda-Pest, in 1909, no further invitation for a definite date should be received. But nothing has been done to place the organization of the Congress on a

really international basis, and at Buda-Pest, as at Lisbon, the meeting will be a social function that will rejoice the hearts of local hotel keepers, and science will wear motley to make a medical holiday."

Correspondence.

SOME TRUTHS AND SOME FICTIONS.

NEW YORK, MAY 30, 1906.

Mr. Editor, It has seemed to me for many a day, and with passage of time the conviction is stronger, that the practice of medicine would be more satisfactory from every point of view, if a few truths were insisted upon again and again until both patients and physicians were in thorough accord.

First among these truths is the fact that though the diagnosis is up to date, correct, the results of treatment may be different. At one time they may be entirely successful, again only partially so, or, indeed, wholly negative and the patient remains unimproved.

In ultimate analysis, so far as we know at present, this depends upon what is understood as personal peculiarity, individuality. It exists, probably, always. No two persons are alike absolutely in body or in mind; in organ or function. How can we expect, how should we believe, that in two only apparently similar cases we shall obtain similar effects from the use of a particular drug, or agent? If this be true, and I am confident it is, why not impress upon every one of our patients the fact that every good physician, even the very wisest and best, must invariably *grasp* somewhat, try to find out by faithful, intelligent and judicious trial, what is best to do in any given case.

While this truth should be accepted, it should also be affirmed the vast and most important difference between the search for truth of the level-headed, instructed and competent man and that of the ignorant, or honest enthusiast. Where shall we put the class of intentional frauds who prey continuously upon the immense number of gullibles and unreasoning? In the abyss. Alas! what can we do but virtually preach character and brains.

This letter is inspired, notably, by Dr. F. C. Shattuck's able address before the Boston Homeopathic Medical Society, March 1, 1906.

BARBARA ROBINSON, M.D.

SUBDELTOID BURSTS: A PATHOGNOMONIC SIGN FOR ITS RECOGNITION.

105 WISE 7TH STREET, NEW YORK, June 9, 1906.

Mr. Editor, I have read with pleasure and profit the scholarly article in your issue of May 31, upon Subdeltooid Bursts. Dr. Goldman has made a most careful study both anatomically and surgically. The disease is, as he says, by no means a rare one. And since there are hardly a half-dozen other affections for which the practitioner is liable to mistake this, perhaps the present note may not prove devoid of interest.

In my own surgical clinic, during the past eighteen years, as occasion arose from time to time, I have found the correct which comes to the surgeon is not made hard to the patient, from certainty of diagnosis, and of the following simple procedure.

Let the arm, as I had away from the side a few inches, and the elbow rest upon the doctor's shoulder. In the latter place, pressure, extreme abduction, the arm is expected will be so directed, with the protection of the pronator process, a direct or quite to be beyond reach of the point of pressure. The expected sore spot will suddenly have disappeared, whereas this position will not, should the tenderness on palpation persist, and the other causes of it in this region.

ROBERT H. M. DAWSON, M.D.

CHANGES IN THE MEDICAL CORPS U. S. NAVY
FOR THE WEEK ENDING JUNE 9, 1906.

J. M. MOORE, passed assistant surgeon. Detached from the Naval Medical School, Washington, D. C., June 15, and ordered to report for examination for promotion, and then to await orders.

F. M. SHOOK, assistant surgeon. Detached from the Naval Hospital, Mare Island, Cal., and ordered to the Navy Yard, Mare Island, Cal.

A. J. GEIGER, assistant surgeon. Detached from the Navy Yard, Mare Island, Cal., and ordered to Washington, D. C., June 15, for examination for promotion, and then to wait orders.

G. M. MEYERS, J. W. BACKUS, assistant surgeons. Detached from the Naval Medical School, Washington, D. C., June 15, and ordered to report for examination for promotion, and then to wait orders.

T. H. STREETS, medical director. Detached from command of the Naval Hospital, Naval Home, Philadelphia, Pa., and directed to wait orders.

G. PICKRELL, surgeon. Ordered to the "Franklin."

D. R. KEER, surgeon. Detached from the Naval Medical School, Washington, D. C., June 15, and ordered to the Naval Recruiting Station, Chicago, Ill.

L. L. VON WEDEKIN, surgeon. Detached from the Naval Recruiting Station, Chicago, Ill., and ordered to wait orders.

F. A. ANDERSON, passed assistant surgeon. Detached from the Naval Medical School, Washington, D. C., June 14, and ordered to the "Arkansas" temporarily, and thence home to wait orders.

U. R. WEBB, passed assistant surgeon. Detached from the Naval Medical School, Washington, D. C., June 15, and ordered to the Naval Hospital, Portsmouth, N. H.

H. SHAW, assistant surgeon. Detached from the Naval Medical School, Washington, D. C., June 15, and ordered to the Naval Hospital, Philadelphia, Pa.

R. H. MICHELS, assistant surgeon. Detached from the Naval Medical School, Washington, D. C., June 15, and ordered to the Naval Recruiting Station, Kansas City, Mo.

F. W. TYREE, acting assistant surgeon. Detached from the Naval Recruiting Station, Kansas City, Mo., and ordered home to wait orders pending expiration of term of appointment as acting assistant surgeon, July 1, 1906.

G. M. MAYERS, assistant surgeon. Detached from Naval Medical School, June 15, and ordered to Navy Yard, Washington, D. C.

F. E. CAMPBELL, assistant surgeon. Ordered to the "Constellation" and to additional duty at Naval Training Station, Newport, R. I.

G. H. MCCONNOR, assistant surgeon. Detached from the "Constellation" and ordered to the "Missouri."

C. E. RYDER, assistant surgeon. Detached from the "Missouri," and ordered home to wait orders.

J. B. DENNIS, surgeon. Detached from the Naval Proving Ground, Indian Head, Md., and ordered to command the Naval Hospital, Pungent Sound, Washington, with additional duty at the navy yard at that place.

F. M. MUNSON, assistant surgeon. Detached from the Naval Medical School, Washington, D. C., and ordered to the Naval Proving Ground, Indian Head, Md.

RECENT DEATHS.

DR. J. WESLEY RICHARDS, of New York, died on June 3, from pneumonia, at the age of thirty-seven years.

DR. JAMES G. LA ROE, of Greenpoint, Borough of Queens, New York, died on May 30, from cerebral apoplexy, at the age of fifty-nine years.

BOOKS AND PAMPHLETS RECEIVED.

A Case of Hysterical Anuria. By Edgar Garceau, M.D., and Joseph W. Courtney, M.D. Reprint.

Collected Studies on Immunity. By Prof. Paul Ehrlich and his Collaborators. Translated by Dr. Charles Bolduan. New York: John Wiley & Sons. London: Chapman & Hall, Ltd. 1906.

Notes on Surgery for Nurses. By Joseph Bell, M.D., F.R.C.S. Edin. New York: William Wood & Co. 1906.

Music and Poetry. Their Relation to the Medical Life. By A. W. Brayton, M.D.

Transactions of the American Pediatric Society. Vol. xvii. New York: E. B. Treat & Co. 1906.

Introduction to Materia Medica and Pharmacology, including the Elements of Medi-Pharmacy, Prescription Writing, Medical Latin, Toxicology and Methods of Local Treatment. By Oliver T. Osborne, M.A., M.D. Philadelphia and New York: Lea Brothers & Co. 1906.

Bulletin of the Ayer Clinical Laboratory of the Pennsylvania Hospital. No 3, June, 1906.

Catarrhal Deafness. (With report of 400 Chronic Cases.) By Dr. Sargent F. Suov. Reprint.

Twenty-eighth Annual Report of the Board of Health of the City of Lowell for the Year Nineteen Hundred and Five.

Proceedings of the American Medico-Psychological Association at the Sixty-first Annual Meeting, held in San Antonio, Texas, April 18-21, 1905.

The Urethrotomies and Kidney Capsulotomy in Diseases and Injuries of the Urinary Organs. By Reginald Harrison, F.R.C.S. London: John Bale, Sons & Danielsson, Ltd. 1906.

The Operative Treatment of Prolapse and Retroversion of the Uterus. By J. Inglis Parsons, M.D., M.R.C.P., M.R.C.S. Illustrated. London: John Bale, Sons & Danielsson, Ltd. 1906.

Operative Otolary. Surgical Pathology and Treatment of Diseases of the Ear. By Clarence John Blake, M.D., and Henry Ottridge Reik, M.D. Illustrated. New York and London: D. Appleton & Co. 1906.

Psycho-encephalonasthenia or Cerebrasthenia Simplex, and Psycho-encephalonasthenia or Cerebrasthenia Insaniens. By Charles H. Hughes, M.D. Reprint.

Railway Brain Strain of and Brain Strain Regulation of Railway Employees. By C. H. Hughes, M.D. Reprint.

State Charities Aid Association of New York. First Report of the Sub-Committee on After Care of the Insane. 1906.

A Practical Method of Abolishing the Cause of One Quarter of the Unnecessary Blindness in the United States. By F. P. Lewis, M.D. Reprint.

Commercialism, Professionalism and Their Mutual Relations. A Series of Editorial Articles. Reprint.

Twentieth Annual Report of the State Board of Health and Vital Statistics of the Commonwealth of Pennsylvania. Harrisburg, Pa. 1906.

Health's Manual of Minor Surgery and Bandaging. For the Use of House-Surgeons, Dressers and Junior Practitioners. Thirteenth edition. Revised by Bilton Pollard, F.R.C.S. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1906.

The Practical Medicine Series. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the general editorial charge of Gustavus F. Head, M.D. Vol. III. Series 1906. Chicago: The Year Book Publishers.

Address.

HOW PROGRESS COMES IN MEDICINE. *

BY FREDERICK C. BRATTUCK, M.D., BOSTON.

DURING the past year there has been no very conspicuous advance in medicine. Advance there has been, of course, but it has been all along the line rather than in any one direction. I propose, therefore, to-night to attempt roughly to sketch, as far as the limitations of time and my knowledge permit, some features of the progress of medicine in the past, its irregularity, apparent lack of logical sequence, dependence on the progress of science (knowledge) as a whole, the way in which advance along a very narrow line may lead to advance along the whole front.

We may for a moment compare the whole body of scientific workers to an army determined to enter into and possess the empire of ignorance, a country of vast extent and presenting every conceivable physical difficulty to advance and occupation. This is one obstacle. Another lies in the fact that the army has not — nor can it have — an organization comparable to that of the ordinary army with its commander-in-chief, chief of staff, corps and division and brigade commanders, although it has the corps and divisions. Each has its leaders, who owe their position solely to merit. Influence, dynastic, political, family — does not count. Promotion is from the ranks. The rise to high position may be very rapid; deposition is occasionally correspondingly so. Far more than in even Napoleon's army *la carrière est ouverte aux talents*. The freest criticism is permitted, nay, encouraged; government is largely by discussion based on observation and experiment. There are many scouts and skirmishers who are necessary to any advance, even of a division. There are also, alas, camp followers. As organized to-day we may distinguish six army corps, anatomy, physiology, chemistry, physics, pathology, clinical history.

Permit me now, dropping analogy, to call your attention to some of the lines of march which have been traversed, some of the territory won, some of the means by which it has been gained.

Gross anatomy was about as well known, of course, not so widely known three hundred years ago as it is to-day. Medicine had got about as far as it could until the knowledge of a heart, of blood, bright and dark, of blood vessels, was vivified by Harvey who without instruments of precision by experiments on living animals, by clear sight and straight thought, solved the mystery of the circulation of the blood. This step in physiology, in knowledge of function, threw a flood of light backward on structure and was indispensable to further progress. Harvey, a practicing physician, paved the way for Malpighi, anatomist, father of histology, who saw what Harvey had no means of seeing — the capillary circulation. He was contempor-

ary with Leeuwenhoek, the lens-maker, improver of the microscope, and then the microscopist making important contributions to the structure and function of the living organism. Here we see one of the first contributions of physics to medicine. It is remarkable that Leeuwenhoek could do what he did with the simple microscope. He had been in his grave more than a century before any essential advance was made in the compound microscope, gradually leading up to the instrument which has played such a vital part in the progress of modern medicine, and to which I shall again have occasion to allude.

Richat, indeed, performed his great work and founded the anatomy of the tissues without the aid of the microscope, so imperfect in his day that he thought it more likely to promote error than to discover truth. The ultimate anatomical component of the tissues and organs alike, the cell, though seen and described by Robert Hooke long before, was first seen in its developmental relations in plants by the botanist, Schleiden. Schwann extended this knowledge into animal life. Thus was founded the physiology of the cell. Fresh impetus was given to embryology, so deeply indebted to Caspar Friederich Wolff of the previous century, and the way was smoothed for Virchow and the pathology of the cell.

In the past hundred years the anatomy of the central nervous system has not been illuminated by anatomists. The microscope showed that the gray matter is composed mainly of cells, the white of fibers. No mere anatomical study could possibly have differentiated the function of gray and white matter, the anterior and posterior nerve-roots, the motor and sensory nerves running in a common cable. Charles Bell, the surgeon, by vivisection, made a great step in physiology and thus advanced anatomy. Marshall Hall, the physician, and Johannes Mueller, the physiologist, again made a further advance in explaining reflex action and its mechanism. Waller, the physiologist, teaches us the lesson of the degeneration of nerve fibers separated from their centers. Anatomy never could have taught us the great lesson of cerebral localization, nor could animal experimentation or physiology alone. The starting point came from the clinician who, through careful comparison of the experiments of disease on the human being during life and after death, pointed out the way for physiological experiment to follow. Critical clinical study first, pathological anatomy second, physiology third, anatomy fourth, structure and function, function and structure indissolubly bound together, advance in one must lead to advance in the other.

Time does not permit me to take up chemistry by itself. In other connections I shall allude to the help it has given to medicine and its progress. Chemistry looms large in the future and we must look to the biological chemist to solve or aid in the solution of some of the largest problems which confront us to-day.

Morgagni may be regarded as the founder of

* Oration on medicine at the fifty-seventh annual session of the American Medical Association at Boston, June 3-8, 1900.

pathological anatomy, John Hunter of its greater outgrowth — pathology. Pathological anatomy, however, remains sterile until wedded to clinical observation. Laennec is the high priest who officiated at this alliance. Borrowing percussion from Corvisart, who resurrected it from the grave of Auenbrugger, and, with the aid of physics, developing mediate auscultation, he compared the signs of thoracic disease in life in the ward with the changes wrought after death, and in ten years performed one of the most stupendous feats in medicine, putting the recognition of cardiac and pulmonary disease in the living at a level from which it had advanced little for sixty-odd years, when the physicist with his x-rays made a new advance. Not only so, but Laennec's conception of tuberculosis in the lungs was far more true than that to which a too exclusively anatomical point of view led Virchow, whose great authority again led astray Buhl, Niemeyer and a host of pathologists and clinicians. How Laennec's view of the unity of tuberculosis was confirmed and extended I shall touch on later. Louis follows close on Laennec and enforces the lesson of the value of method and accuracy in the study of disease. It is he who inspires his young American pupils to separate typhus and typhoid fever. Neither pathological anatomy nor clinical study alone sufficed; in conjunction they succeeded. The power to distinguish between the two diseases clinically has done much to bring about the practical extinction of the contagious typhus. In very recent times the clinical resemblance of typhoid fever, the estivo-autumnal form of malaria and of trichiniasis was in some cases so close as to render timely diagnosis difficult, to say the least. Laveran's discovery of the plasmodium, Widal's of the reaction bearing his name and Brown's of eosinophilia in trichiniasis go far to insure diagnosis, to aid treatment, to promote preventive medicine. Laveran directly aided diagnosis, but he also paved the way for Theobald Smith's brilliant demonstration of the cause of Texas cattle fever, of the rôle played by insects in the transmission of certain infections to man and animals. Thus the accusation of Manson of mosquitoes in general has ended in the conviction of some species as necessary links in the development, first, of malaria, next of yellow fever. The mysterious sleeping sickness of man and the tsetse fly disease of horses in Africa are found to rest on a similar pathology. The alarming spread of the sleeping sickness coincident with opening up the country and increased travel is noteworthy. In 1873 Obermeier discovered the spirillum of relapsing fever. In the African form of the disease, at least, it seems to have been recently conclusively proved that a tick plays the part of intermediate host. The life history of the *tenia* was worked out by close observation and experiment without much aid from the microscope, such is their size; but the analogous life history of these minute forms of life and their relation to disease must, perforce, await the modern microscope. These are some

of the latest triumphs in the application of bacteriology to medicine.

Bacteriology was brought into being by the conjunction of the perfected microscope; the chemist Pasteur who gave the death-blow to the doctrine of spontaneous generation; another chemist, Hoffman, who made his own fortune and then promoted the welfare of humanity by his discovery of the anilin dyes which enable us to see and distinguish organisms, many of which are otherwise invisible or unrecognizable; and the physician, Koch, whose solid media on plates so greatly facilitated the isolation and perpetuation of pure cultures of this and that organism. Cut out any one of these four links and we should not be where we are. Laennec's conception of the unity of tuberculosis of the lungs is confirmed, and it is proved that lupus and scrofula, which I have heard the great Hebra suggest to be manifestations of syphilis in the second or third generation, are tubercular in nature.

More than a century has elapsed since Edward Jenner, the provincial practitioner, conferred one of the greatest boons humanity has ever received by rendering it possible to practically annihilate the loathsome and deadly smallpox. The great pox remains a mystery — *pace* the *spirocheta pallida*. We anxiously await some discovery which will do for scarlet fever and measles what Jenner's discovery did for variola, what antitoxin has done for diphtheria. We are still in outer darkness as to the pathology of these eruptive infections, though the studies of Councilman and his pupils fill us with hope.

The demonstration by Fitz of the relation of the appendix to peritonitis and his work on the pancreas involve another combination; accurate pathologic knowledge, clinical observation, unusual critical acumen, and the experience of the past as collected and recorded in the library, a factor in the progress of medicine the importance of which is daily winning recognition. Would that we had with us to-day in the flesh James R. Chadwick, to whose enthusiasm, energy and devotion in building up the Boston Medical Library not this community alone, but the country at large is deeply indebted. His interest, counsel and duplicates were always at the service of infant medical libraries to many of which he was wet nurse.

Between Sir Humphry Davy, chemist, and Morton, dentist, the possibility of surgical anesthesia lay in an almost dreamless sleep for half a century. How sudden the awakening, how momentous its effects! Surgery ceases to be a last resort. Half its terrors are shorn away. Bacteriology shears away the other half, and to-day scarce an organ, cavity or part remains a sanctuary of disease. Anatomy, physiology, pathology, are all enriched by the surgeon's knife used for beneficent purposes on the living man,—literally vivisection. I specify alone tubercular peritonitis, supposed to be necessarily fatal until the surgeon, operating under the false diagnosis of ovarian cyst, proved that

it may be recovered from. Some cases of tubercular peritonitis need the knife; but many cases get well without any sort of operative intervention. For this advance, I repeat, we have to thank the surgical clinician.

The story of myxedema seems to be one of the most thrilling in medicine, and serves my present purpose in that it shows how the searchlight of clinical observation may illuminate dark places in physiology and pathology. The anatomist finds and describes the ductless glands. The physiologist is at a loss to explain their function. The thyroid is a riddle. Its endemic enlargement, often associated with faulty development alike bodily and mental, is noted, excites interest and speculation, but is another riddle. The great clinician, Gull, describes "A Peculiar Cretinoid State Supervening in Women in Adult Life." He puts forward no theory, but describes merely what he sees, a change coming over previously healthy grown women, producing a state similar to that of the cretin, and quite apart from endemic influence. He opens eyes which so easily overlook what is directly under them. Ord makes the first autopsy, and from the mucin reaction in the swollen tissues cuts the name down to one word, myxedema, still mainly descriptive. So also is Charcot's name, *cachexie pachydermique*. Clinical surgery now steps on the scene, and we see that the result of the extirpation of the thyroid for goiter, as reported by Kocher and Reverdin, is identical with myxedema. Thus the pathology of the condition is rendered clear, and for the first time we get a definite idea as to the function of the thyroid. The riddle is largely solved. Very soon myxedema becomes one of the most gratifying diseases to treat, and the remarkable fact appears that neither cooking nor gastric digestion notably impairs the efficacy of the gland. It is noteworthy that this great advance comes purely from clinicians, medical and surgical. The experiments of Schiff and Horsley on monkeys, although interesting and confirmatory, are not essential stones in the structure. The evidence is sufficiently complete without the aid of what is ordinarily termed the laboratory, and here it may be remarked that the tendency of the present day is too much toward the limitation of the term "scientific scheme" to that part of investigation carried on either apart from hospitals or by men not directly dealing with the sick. The work of the clinician may be every what as scientific as that of his laboratory brother. The purely laboratory man has the advantage that he can inaugurate, systematize and govern his experiments, most of which must be on animals. The clinician has the advantage that the experiments performed for him by disease are on human beings and are oftentimes of such a nature as cannot possibly be made artificially. On the other hand, the clinician is apt to find his time and strength so drawn on by individuals clamorous for relief that his highest work suffers. Does medicine afford a better illustration of the interdependence of workers in different fields than

lies in the story of myxedema? Great as was the specific discovery of the function of the thyroid, still greater was its direct outgrowth, the broad fact of internal secretion, the sole function of the ductless glands, perhaps also an important function of glandular structures pouring out a secretion through a constant and definite channel.

Before turning aside from the work of the clinician I should like to mention one other advance which has been made and several riddles which still confront us. In the index of Watson's Practice, a book not read to-day as much as it should be, American edition of 1872, neuritis is found only as optic neuritis. James Jackson had recognized paralysis due to alcohol. Buzzard popularizes the knowledge that the trouble is seated in the peripheral nerves in these cases, and that alcohol is only one of many toxic agents liable to cause this result. How easy it is to-day to recognize multiple neuritis, usually to determine its cause in any given case; but there were just as many cases of it fifty years ago as there are to-day. Jaundice was formerly a disease. It is now a symptom only. Rheumatism we now recognize as a tangled skein, the threads of which we are just beginning to unravel. We are dissatisfied with diabetes as a final diagnosis, and are groping for light which may enable us to differentiate the causes of sugar as we have those of bile in the blood and the tissues. We suspect an infection behind purpura. We speak of purpura simplex and purpura hemorrhagica. We know that there are many infections which, when intense, are liable to cause hemorrhage. Our ignorance is dense as to the part played in any case by individual peculiarity as well as to other features of many cases of purpura.

From the side of physics has come one of the most notable of recent advances. Roentgen rays are doing much for the clinician, medical as well as surgical. Are there η - and π -rays? How long must we wait for their discovery? What will be their practical application? Physics, again, has given us the ophthalmoscope and exposed a prolongation of the brain to direct vision. The aurist owes it much. It enables us to illuminate the interior of the bladder, larynx and trachea, and other cavities, to localize pathological processes, to watch their progress in the living body, intelligently to relieve and cure conditions which otherwise and formerly were necessarily left to that *vis nativa* which may be *medicatrix*, but is too often *lethalis*.

The debt of medicine to all these half truths which are too indiscriminately classed under the terms quackery or charlatanism is real and should be recognized. We believe homeopathy to rest on assumptions unfounded in fact untenable to-day. The most bigoted of us, however, for there is a bigotry of science as well as of religion, cannot deny that homeopathy has advanced medicine, leading to a clearer knowledge of the limitation of the therapeutic action of drugs, of their uses and abuses.

The power of suggestion, the influence of mind

over body, whether exercised through hypnotism, mind cure, faith cure, Christian science, what you will, throws a flood of light on physiology and pathology, stimulates the study of experimental psychology, illuminates the influence of the nervous system on the circulation and thus on nutrition. An eminent orthopedist recently classed the natural bone setters, so-called, as forerunners of science, at a time when ignorance as to the action of trauma and disease on joints was profound. They, relying on common sense and observation alone, achieved results which science, timid from knowledge of its ignorance, failed to achieve. There is always a germ of truth in every form of irregular (unscientific) healing — a fact which it behooves us to recognize and be ready to apply.

The services of a laywoman, Lady Mary Wortley Montagu, in the introduction of inoculation for smallpox, bitterly fought by our profession of the time, should not be passed without recognition.

All the sayings of a wise man are not necessarily wise, and Solomon, probably when tired or dyspeptic or worried with some family strife, said that there is nothing new under the sun. New things, certainly new in their relation to us, are coming forward every day. Not only so, but the new things spread abroad with wonderful rapidity in these telephonic days, becoming common property.

I have brought you nothing new to-night. I have simply tried to illustrate from the history of the past, how imperfectly, I only too well realize, the apparently inconsequent advance of knowledge, the correlation of the sciences, the way in which a fact seemingly perhaps unimportant is always potentially fruitful, often bearing fruit of a totally unexpected kind, it may be after many days. In a positive sense we know more than our predecessors; in a relative sense we may be said to know less. The farther we advance into the empire of ignorance the larger we find it to be, each mountain peak showing higher peaks in the distance.

Life consists in the exercise of our faculties, happiness in the performance of duty and in achievement. We have an abiding faith that "all things work together for good."

OBSERVATION HOSPITAL FOR MENTAL DISEASE.

SOME REASONS WHY THERE SHOULD BE ONE IN BOSTON, OR AT LEAST AN OBSERVATION WARD; STATISTICS OF THOSE AT ALBANY AND GLASGOW.

BY L. VERNON BRIGGS, M.D., BOSTON.

For some years the project of an observation hospital for mental disorders in the city of Boston has been discussed, but no concerted movement among physicians has ever taken place, owing to various discouragements, and to their difference of opinion, as to the best plan for bringing relief

to the class of patients who in the early stages of mental disorder have now no place to go for treatment. Quite a large number of physicians consider that the present hospitals for the insane are sufficient, and they answer those who favor a special hospital by saying that the present institutions for the insane are able to take care of all people in all stages. Dr. George F. Jelly, senior examiner of the Institutions Registrations Department, nearly ten years ago recommended a detention hospital for ten patients, near or adjoining the Court House; and in his reports since then he has referred to the urgent necessity of a detention or observation hospital. I think that he may be called the pioneer of such a movement in this city, and no one to-day is better able to judge of its necessity or the best plan for carrying it out, and any movement in this line should be done under his wise direction.

In the first place, most of the present institutions for the insane are situated at inconvenient points, and have so many chronic cases that most people in the early stages are not willing to go to them.

The internes who are in insane hospitals as a rule see only the chronic cases, and have no opportunity of observing or studying the early stages of mental disease. There is no provision at the present time for systematized study of mental diseases in their early stages by physicians or students, except in the one department of the Boston Dispensary which has the only strictly mental clinic in the city, and, so far as I know, in any other city in the United States, most of the clinics being mixed, — nervous and mental. It is the studying of the incipient cases which seek relief in the dispensary that impresses one with the necessity of an observation hospital, where patients in the early stages may be sent, and their disease often aborted; where the dangerous patient or the possible suicidal patient may be taken for protection from himself for a few days; where the officer may send the lunatic arrested on the street, for immediate care and treatment, and where the physician or student may have an opportunity of studying these early cases which is now denied him. The cases which find their way to the hospitals for the insane are usually so far advanced that they are committed as insane, and are well along in the progress of their disease. Seldom a day passes during which clinics are held in the mental department of the Boston Dispensary, when one of the three physicians to that department, Dr. A. C. Jelly, Dr. L. A. Roberts or myself, do not feel the crying need for such a hospital. Many patients come to the dispensary to-day, or are attended at their homes by physicians, who have to remain in their present surroundings which often are the cause of their trouble, until such time as they are insane enough to commit, for no treatment can be carried out in the homes of many of these patients, and the physician is powerless to do anything but wait for them to get insane enough to commit to a large insane hospital. Again, if an insane individual is arrested on the street, in

the evening or late afternoon, there is no hospital that will receive him. He has to be put in a padded cell at the tombs, if violent (or, if a woman, in the House of Detention), and there remain until the following day when he is examined and committed, and transferred to some insane institution; twenty-four hours in an acute case may prove fatal, certainly to the mind, if not to the body. How much more humane to send these emergency cases to a hospital where they will have immediate care and protection or treatment.

So far, the general hospitals have refused to take apparently insane patients even for a day, unless they have injured themselves and require surgical treatment. There is no place where you may send such cases, excepting to the insane hospitals, and many of them are not insane, for their mental disorders are often the result of disturbed metabolism or acute auto-intoxication, or of disturbed habits of mind and body, brought about from their surroundings, or improper food and sleep. I do not believe that a separate building on the grounds of any insane institution is going to give relief to these people. They would prefer to wait until nature reacts and they recover, or become worse and are obliged to be sent to the main building of such an institution. The class that would go to an observation hospital connected with an insane institution will be of two kinds:

First, The voluntary patient, who is often a patient who has been there before, and feels a recurrence of his disease coming on and applies for relief.

Second, The occasional patient who is incapacitated, but not seriously ill, whose family find his support burdensome, or his care confining and urge him to go, or send him to the hospital instead of keeping him until he recovers, or is insane enough to commit.

I know that this advance in the treatment of those mentally ill will meet with a great deal of opposition, as every new movement does. One physician, president of one of our neurological societies, told me the other day that he did not believe in such a hospital, that it was not necessary, that he did not believe in the Haymarket Square Relief Hospital; he thought the general hospitals could take care of all the patients without loss of time sufficient to endanger the life of the patient; that if I asked for an observation hospital, I might as well ask for a temporary hospital or stand on every corner of the street, with physicians stationed there to take particles out of people's eyes, that there would be no limit to the number of hospitals if things kept on.

It is only a few years since mental diseases were made a part of the obligatory course in any of our medical schools, it was entirely optional as one of the several studies students could choose from. The result is to-day that the average physician in general practice knows little or nothing about mental diseases, and as for having charge or care of mental cases, he has

no such opportunity in the general hospitals, and the only men who have any valuable experience are graduates of our largest medical schools, who see a few such patients at medical lectures. Some students who fail to get appointments in the general hospitals drift to the insane institutions as internes for a year or so. This does not mean that these men are not as bright or as efficient as those that get appointments in general hospitals, but it does mean that the standard to-day is for the so-called physical to come first and the so-called mental diseases last, because in general practice the student seeks for the experience which is going to be of most value to him in his practice; and the general hospitals have everything but mental diseases, and the mental hospitals have only the general diseases that occur in mental cases. So to-day, the externe and interne who have the advantage of hospital experience are launched into the world often without being able to recognize a mental case when they see it. This would not be so had we an observation hospital or observation ward connected with the general hospitals. Comparatively little is known to-day about mental diseases, and if the field is once properly opened to the students and professors, more material would be available for progressive medicine than in almost any other direction, and a larger proportion of humanity benefited.

In the report of the superintendent of St. Luke's Hospital, New York, for the year ending Sept. 30, 1904, I find among the applications declined under Rules of Admission (which include contagious, incurable and unsuitable headings), under the heading "Ensuitable," "Insanity, six cases." Under the Rules of Admission the insanity cases are included in the list of those which are inadmissible. This is only an example of the rules of most, if not all, general hospitals. People must get over the idea that a diseased brain is something to be ashamed of. They are not ashamed of having a diseased heart, or lungs or kidneys, and to have the physician limit them in these directions; why should they not welcome and follow his advice without being ashamed when he warns them that they have weak brains, or that they must not overtax their brains. If the toxin or poison originates in some organ outside the control of the central nervous system, the disease is not fully a disease of the brain. Dr. Paton says: "Leaving out of consideration for the moment the adventitious lymph spaces, practically nothing is known in regard to the passage of the blood through the brain."

New York is alive to the fact that insanity is constantly increasing. In 1892 there were 47,275 patients in the insane institutions of the state, a ratio of one person to 377 of the population of the state. On June 1, 1905 there were 27,300 patients in the insane institutions, a ratio of the insane to the general population of 1 to 299. The number of cases developed during the year was 5,346. Of all treated in hospitals, 1,412 recovered and 1,257 were discharged in an

improved condition. New York State asks for \$2,000,000 for the improvements desired this year by the state hospital managers and \$4,950,000 is asked of the legislature for the support of the insane the coming year.

Stewart Paton, M.D., of the Johns Hopkins University, and director of the laboratory of the Sheppard and Enoch Pratt Hospital, Towson, Md., in his recent valuable book on Psychiatry, goes into the subject of observation hospitals or wards connected with general hospitals most carefully, and I can only briefly quote from his exhaustive work on the subject. He says: "Unfortunately, as a rule, so few individuals afflicted with insane ideas come under the observation of the alienist until the systematization is more or less complete and immobile, that little satisfactory progress has been made in the study of the development of these phenomena. For this reason the large amount of material which presents itself at the dispensaries of any of the large city hospitals is of greater value for study than are the cases which are admitted to our hospitals for the insane. In practically every case of alienation which comes under observation early in the development of the malady, it will be found that the patient frequently complains of changes in the organic sensations of such a nature as to interfere with the integrity of the sensations upon which the idea of individuality depends." "Unfortunately, in institutions in the United States, with few exceptions, the detention character is still primary, and opportunities for successfully treating patients are still few and incomplete, inasmuch as the existing organization and imperfect equipment do not make it possible to give them the benefit of the best medical skill. Nor will this defect be remedied until we in this country have learned to appreciate that proficiency in psychiatry can be obtained only in institutions in which the interest of the alienist in his profession is kept alive by abundant facilities for study and his energy is stimulated by the presence of students for whose training he is responsible. The establishment of psychiatric hospitals in close proximity to other university clinics affords the only possible solution of the fundamental problems with which we are now confronted. There is no branch of medicine in which the ounce of prevention is of greater value. Many cases which now become hopelessly chronic, if the diagnosis were made earlier in the disease, and the proper conditions for treating the patient were provided, might readily be cured."

"In order that we may be able to strike at the root of the matter we must devote our best efforts to curing all recoverable cases, and this can be done only by taking them in hand at the earliest possible moment, when the disorder is still in its incipient stage, and by giving as many physicians as possible the chance of receiving a thorough training in psychiatry, in order that cases of insanity may be recognized by the general practitioner before it is too late." "If such an institution be located at a distance from a center

of population, the commitment of cases of incipient insanity would be rendered more difficult, and not a few patients would lose the opportunity for speedy treatment, which in some cases is equivalent to missing their only chance for recovery." "Again, the easier of access the institution is to a fairly large center of population, the less will be the antipathy of patients towards a residence there, since they will feel that they are not shut up in some remote asylum away from the world and all their friends, and, moreover, they will be spared a long and tedious journey, which is distressing alike to patient and relatives. Such an institution, when situated in a city, will afford the medical profession an opportunity of becoming as intimately acquainted with its organization, its methods and its results, as is the case with the medical hospital, while at the same time, the medical staff will not be isolated, and will have every chance of keeping in touch with the advances that are being made in general medicine, of which their own is a most important branch." "Roughly speaking, institutions varying in capacity from 80 to 100 beds represent the size which best lends itself to an efficient organization."

"Physicians connected with out-patient departments every day meet with individuals suffering from incipient insanity, whom they are unable to benefit at their homes, because facilities for putting the patients to bed, isolating them and employing the other necessary procedures are lacking." "The fact that an examination of an average insane patient takes two or three times as long as when one has to deal with an ordinary sick man, means that a much larger staff of physicians can find full employment. The sole responsibility of a clinic must rest upon the medical director, who should be in absolute control of all medical matters, and who should have a continuous and not an interrupted service." "It is far better that the director should not live in the hospital. During the night and for a few hours of the day during which he is absent, his place can perfectly well be taken by the first assistant." "For the benefit of the patients, admission to these hospitals should be made as easy as possible, and there should be a minimum amount of formality and red tape."

In summarizing Paton states that: "Briefly, then, the economic advantages to a community of a psychiatric hospital with a well organized out-patient department may be summed up as follows:

"(1) A large number of patients would receive the benefit of skilled medical care at a stage of the disease at which there is great hope of either aborting or cutting short an attack of insanity."

"(2) Numerous fatalities, suicides and homicides would be prevented by the timely commitment of individuals suffering from acute attacks of insanity."

"(3) The asylums proper, in contradistinction to psychiatric hospitals, would be relieved of many of the more troublesome cases, and would therefore be much better fitted to carry out their appropriate work."

"Frequently the individual does not come under observation until the original cause has ceased to operate and a condition so complex has developed that it is impossible to determine the essential factor or factors in the etiology. A rich reward awaits the clinician who will patiently study the early symptoms of imperfect functioning of the cerebral cortex, as they appear in connection with the slight changes in functions of many of the internal organs."

In the monthly consular reports of May, 1905, of the department of Commerce and Labor at Washington, where is a report from United States Consul General Mason, of Berlin, Germany, under date of April 8, 1905, on "Modern Hospital for the Insane," giving illustrations and descriptions of the psychiatric clinic at Munich, under the medical staff of such men as Prof. Emil Kraepelin, Dr. Guapp and Dr. Alzheimer. Consul General Mason says: "The inestimable service to the community is that these wards provide for saving an indefinite but considerable percentage of the victims of incipient mental disease, and restore them to lives of usefulness, instead of leaving them to degenerate into a menace to society and a burden to the state. It provides the most consummate examination and treatment at a stage of the disease when there is the most chance of averting or arresting an attack of real insanity. It detects and takes timely charge of the smaller but important class of patients who, without the knowledge of their friends, are on the border line of insanity, and liable at any time to become suddenly dangerous to themselves or others. Public benevolence and private philanthropy can fulfill no higher or more valuable purpose than to bring the ultimate resources of science to the support of a cause like this." He also says: "Notwithstanding the rapid and deplorable increase in mental diseases which has followed the stress and strain of modern business and social life, it must be admitted that in the United States, and even in Great Britain, governmental benevolence has not progressed beyond the ecdemosynary function of providing asylums in which the more or less hopelessly incurable victims of insanity, who have become a burden and menace to their friends, can drag out in safety and physical comfort the remnants of their stricken lives. If here and there a private clinic has made a hopeful beginning with the pathological treatment of mental diseases, it has been due to individual initiative and the ministrations of such institutions are restricted mainly to patients of the well-to-do class, leaving the great majority of poor unfortunates to drift on to a stage of mental alienation, in which they become dangerous to themselves and those about them, and therefore entitled to the attention and support of the state. Germany has taken a long and important step beyond this, and to give a simple statement of the means employed and some of the results attained is the motive and purpose of the present report. There are in this country twenty-two psychiatric clinics or hospitals for the treatment of mental diseases. Most

advanced and worthy of study are those located at Kiel, Glessen, Strassburg, Berlin, and, latest and most important of all, the new clinic at Munich, which in all that relates to perfection of equipment and arrangement as well as to the scientific enlightenment of methods employed, stands undoubtedly at the head of all institutions of its class in this or any other country."

In 1751, the General Assembly of the Province of Pennsylvania adopted a law entitled "An Act to Encourage the Establishing of an Hospital for the Relief of the Sick Poor of This Province, and for the Reception and Cure of Lunatics, Collecting the Patients into One Common Provincial Hospital Properly Disposed and Appointed, where they may be comfortably subsisted, and their health taken care of at a small charge, and where by the blessing of God, on the endeavors of skillful physicians and surgeons, their diseases may be cured and removed."

Bethlem had been in existence a great many years, and St. Luke's, also in London, was opened in 1751.

To-day there are no psychiatric clinics hospitals in this country or in Great Britain such as they have in Germany, but we have an observation ward or psychiatric clinic connected with the Albany City Hospital, New York, and Scotland has one connected with its hospital in Glasgow.¹ Except those on the continent of Europe, these are the only observation wards which have been in existence long enough to furnish statistics of value. In November, 1905, I visited Albany, and had a most interesting day with Dr. J. Montgomery Mosher, who is responsible for Pavilion F, as it is called, in the Albany City Hospital. Here are received cases of insanity for observation; also cases of drug habit and delirium tremens; and also delirium patients who become delirious from the effects of poisoning from pneumonia, typhoid or other diseases, and are transferred from the other hospital wards to this pavilion. Sixty per cent are discharged as recovered or improved. Dr. Mosher showed me many interesting cases. Patients are all voluntary, there are no commitments. The police used occasionally to bring drunks in there, but now it is a most unusual occurrence. The treatment consists of flushings with water and liquids, enemas and infusions, also, for quieting, Dover's powder and calomel, castor oil and salts are given for house cleaning.

About two years before Pavilion F was opened (which was in May, 1900) Dr. Mosher was writing papers urging the care of insane in general hospitals. Among other things which he said, I quote the following: "All attempts at separate care of acute cases have been premature and have failed, because prior to the development of the large modern state hospital, its possibilities and him."

¹In a later article I shall speak of the new psychopathic ward in a building by itself but in connection with the University of Michigan under the direction of Dr. A. M. Barrett, late pathologist of our Bayview State Hospital. This is the first psychopathic hospital and clinic for the observation, care and treatment of persons afflicted with incipient insanity established in America in connection with or by any university. I expect also to later give an account of what is being done elsewhere along the lines of this paper.

tations have not been revealed. It is advisable that provision for both these classes be made in the large public hospitals. Hospitals for the insane are not always available; the natural reluctance of patients and their friends to commitment often prevents this step until the disease has reached a stage at which the chances of recovery are jeopardized. A considerable class need skilled medical observation before the advisability of removal is determined. When home care is no longer possible, the unfortunate victim, in an outburst of violence or delirium, is hurried away to jail, or some other convenient receptacle, his life in the balance, while precious time is consumed in judicial proceedings. A statement of the abuses arising from this condition of affairs would present an appalling record. An insane woman gave birth to a child in jail, her only attendant being the jailor. A physician, delirious from neglect and the decrepitude of old age, was locked in a cell. A maniacal patient who was allowed to wander about until he developed a state of great mental confusion was found in an interior unventilated cell, entirely stripped of his clothing. To meet this want, the erection of special hospitals or special pavilions in connection with the general hospitals has several times been suggested. Under the stimulus of repeated abuses that occur in the disposition of acute cases, the physicians of Albany represented to the county supervisors the need of such a building, and it received a generous response, in an appropriation of \$18,000, the administration to be in the hands of the governors of the hospital as a part of the general organization, the county's rights being protected by agreement to care for its patients at rates conforming to those for other public patients. The plans were prepared by Mr. A. W. Fuller, architect of the hospital. It is anticipated that this pavilion will furnish: 1. Transient accommodation for insane patients committed to a state institution. 2. For patients who need observation before the advisability of commitment to a state institution is determined. That it would be available (3) for mild cases of insanity, who may recover in a general hospital. 4. For victims of drug addiction; and, lastly, as an emergency resort will minister to (5) rapidly developing and critical cases of delirium; and (6) to the sudden and often dangerous forms of mental disorder which occur in the course of general diseases, or after the shock of surgical operations and anesthesia. It is in this legitimate extension of its work that the general hospital in no way conflicts with the institution for the insane, but becomes an adjunct or integral factor. As a clearing house, opportunities are offered for the discrimination and preparation of patients for the latter which should add greatly to its effectiveness."

In a series of papers on "Hospital Construction and Administration," read before the American Surgical Association, during a visit to the Albany City Hospital, June 4, 1902, J. Montgomery Mosher, M.D., in his paper on Pavilion F, says: "The small pavilion for mental and nervous dis-

orders which you have just seen is the only one of its kind in the United States, and shows, we think, a step forward in hospital administration, and in the treatment of this class of cases. This work has not been undertaken by the general hospital since the removal in 1841 of the insane patients from the Pennsylvania Hospital to its special separate department for the insane at West Philadelphia." "The greatest wrongs to persons mentally afflicted arise from the lack of understanding of the illness by the family and the practicing physician. Mismanagement and delay in removal from home are the obstacles to recovery, which our new pavilion has been built to overcome. In less than four months there have been 40 admissions." "The principle of treatment is expectancy. The plan of the pavilion is such that the uneasiness and noise of mania and delirium give no annoyance to others, and no repressive measures, either mechanical or chemical, have been necessary. The elimination of toxic products and the re-establishment of nutrition have led to natural sleep, and after the first prolonged sleep, the patient causes no further anxiety to the physician."

In the first report of Pavilion F for the year ending Feb. 28, 1903, Dr. Mosher reports the total admission of 174 cases; of these 110 recovered or improved; 49 were unimproved or died; 14 remained. He says: "The number of malcontents is not greater than in other departments of the hospital. The length of time patients should remain is still undetermined, and probably no definite rule can be established. It is well known that developed cases of mania and melancholia require for successful treatment at least three months and usually from six months to a year." "It appears that we have done more than establish an emergency hospital for temporary care. The prospect of cure has been extended to many patients whose minds have been seriously involved. The principle may be stated that any patient whose case may be regarded as curable with the means at hand should be offered the ministrations of this pavilion. The satisfactory result of the year's work is in the greatest measure due to the nurses, who have met our requirements with enthusiasm. The employment of trained women has been largely adopted in institutions for insane, but this ward is probably the first instance where women nurses have been intrusted with the entire care of all cases; the order and neatness of the men's wards, the absence of objectionable behavior, and the respect for the gentler sex, which mitigates even the greatest mental restlessness, give valuable evidence of the success of this innovation. The governor of the state, in his annual message to the legislature, notes the work of Pavilion F, and recommends the construction of institutions of this character in other cities. The local public officials have been enthusiastic in praise and co-operation, and a liberal appropriation for an enlargement has been made by the county supervisors. The average income from each patient per week has been \$8.61."

In a paper read by Dr. Mosher, on Sept. 22, 1904, at Atlantic City, on "Mental Wards in General Hospitals," he speaks of McLean Hospital at Waverley, as a branch of the Massachusetts General Hospital, and also a branch of the New York Hospital, which is run as a separate insane department under an independent executive head at a distance. He says that if the calamity which sends a patient to a hospital for help be mental in character, he might demand and he would be justified in demanding, that he be not spurned, when his neighbor with a surgical lesion, or an infectious disease has at his disposal every means known to science for the restoration of his health. For two years ending Feb. 29, 1904, 331 patients were treated of whom 110 recovered; 96 improved; 88 were unimproved; 25 died and 14 remained under treatment; 24 patients were transferred from other departments of the hospital. It is now possible to close six doors between a noisy patient and the rooms occupied by others. There is little use for interference with the activity of the patient on other grounds than his own safety. The motor restlessness characteristic of active mental disturbance may be permitted; this does away with the need of coercive measures, and the therapeutic plan from the mental standpoint may be said to be entirely conciliatory. Our strong conviction is that disregard of this architectural feature would practically destroy the efficacy of the ward; the necessity of subduing one patient to promote the comfort of his neighbor leads to resistance and resentment on his part, and harshness from his caretakers. This is an outrage on the patient and a species of malpractice which may easily bring an institution, however meritorious in other respects, into disrepute. The hospital governors further require that no patients shall be treated in this pavilion except by a physician of known and approved training in the specialty of mental diseases.

"It is not to be expected that the work of a hospital for the insane can be done in a general hospital, nor can the work of a general hospital be done in a hospital for the insane, but there are many forms of mental disorder having the character of an acute illness with disturbance of bodily function, and there are many forms of acute physical disease with disturbance of mental function, for which the general hospitals should provide; otherwise, it is not a general hospital." "It means a great deal to patients suffering from mental disorders, especially in incipient stages, and it means a great deal to the hospital."

In his report for the year ending Feb. 29, 1904, he says: "We may imagine for example, a requirement involving a delay of two or three days, or one day, or even twelve hours, for the decision of a court before a patient suffering with appendicitis or pneumonia could be placed under proper medical treatment, and yet the mental case is just as acute and critical, requires as much skill and care, and with this skill and care promises as good results as a case of appendicitis or pneumonia." "The cases for which Pavilion F

is especially adapted are, in common with other departments of the hospital, those of acute disease. Conditions of excitement, delirium or stupor arising from shock or exhaustion, with accompanying toxic states predominate. It is necessary in these cases to check the action of injurious causes; to eliminate the accumulation of waste products, and to restore nutrition and strength by rest, over-feeding and tonic measures." "Shouting, rattling of furniture and pounding on the walls or door are symptoms of active mental disorder and should only be controlled within certain bounds when endangering the patient. By adapting the building to the needs of the patient, so that isolation and retirement may be secured, a plan of treatment may be carried out solely in his interest, and not based upon the comfort of his neighbors." It is now required that all nurses spend several weeks in the mental ward before the granting of the diploma of the training school. This instruction is a part of the three years' course for nurses. The opportunity afforded in Pavilion F to groups of two or three students at a time to make examination of mental symptoms, and observe the patient during a period of several weeks, perhaps through the entire attack, have been rarely, if ever before, given to undergraduate students.

Arnold E. Smith, Esq., Odgensburg, N. Y., for several years associated with the management of the St. Lawrence State Hospital, writes to Dr. Mosher as follows: "One hundred and seventy-four mentally ill people have come voluntarily to the Albany Hospital for help, which otherwise, as a rule, excepting for your Pavilion F they would have been unable to obtain without being officially declared insane, and you have demonstrated that over 100 of the number did not deserve that mark. You are making a record that cannot be wiped out. They may appropriate your plans, adopt the methods of your administration, fail to give credit, but Pavilion F of the Albany Hospital will nevertheless stand as a pioneer of this idea."

The report of Pavilion F to Feb. 28, 1905, gives a total of the patients from the opening of the pavilion to date of 570, with a total percentage of recovered or improved at 58. Dr. Mosher says: "*Two striking indications are presented by our acute cases; first, exhaustion, and, second, a toxic state due usually to irregularities of excretion, particularly of the digestive tract.*" It has consequently been customary to promote elimination by the bowels, kidneys and skin. Not infrequently the combined amount of water, broth and milk drink has reached more than a gallon in twenty-four hours. In September 1903, saline infusion was first attempted, the patient being a young woman suffering from hysteria, complicated by acute delirium. Normal saline solution, by which is meant water containing 6-10 of 1% of common salt, has long been known to possess a certain affinity for animal tissues. By the use of a small needle permitting a slow current, so that absorption and injection are simultaneous, it has been found possible to introduce

as much as 1,700 cc. at one time, and this has been repeated twice daily. As a modification it has been found possible in certain cases to introduce the saline solution into the bowels instead of under the skin." In the report of Pavilion F for the year ending Feb. 28, 1906, Dr. Mosher lays stress on the advantage of the patients being treated in their home locality under the scrutinizing eye of their friends; also of the value of the ward in educating the people that mental disease is to be looked upon the same as any other disease and that the surroundings may be the same. He has had gratifying results from the use of rectal injections of normal salt solutions. During the year ending Feb. 28, 1906, there were 234 cases admitted of which 126 recovered or were relieved, 74 did not improve, 20 died and 14 remained.

In England, especially London, they are striving for this same thing now. They feel the need of an observation hospital much more than we do. But, as Dr. Mott and Dr. Pitt and Dr. Pye-Smith and others tell me, it is uphill work, and the superintendents of the insane hospitals naturally want the early cases for themselves and their clinics, and many of them really believe that such patients are best taken care of in wards connected with an insane institution. In England, there is also a fair amount of opposition from the strictly neurological specialists. It was this same opposition, as well as the opposition against the admittance of such patients to the general hospital, that Dr. John Carswell, of Glasgow, had to meet for nearly fifteen years before he brought about his present splendid arrangement. To-day he has a large ward connected with the City Hospital of Glasgow, the statistics of which speak for themselves, and I give them herewith.

The annual report to the Glasgow Parish Council on the Certification of Lunatics for the year ending May 15, 1904, made by Dr. John Carswell, says on page 13: "Table IV shows the number of cases treated in the observation wards during the year to have been 261, of whom 24 were afterwards removed to the asylum, 13 died and 219 were discharged recovered or relieved, leaving 5 under treatment. This is the largest number treated, and the largest number of recoveries. With the opening of the new psychiatric department at the Eastern District Hospital there will be a decided increase in the number of patients treated without recourse to the asylum."

TABLE IV.

The following table shows the number of cases treated in Observation Wards and results of treatment since 1890:

| Barony Parish. | Insane and Certified removed in O. W. to Asylum. | Died. | Discharged, recovered, or relieved. | Remain- ing. |
|-----------------------------------|--|-------|---|-----------------|
| Average of 5 years, 1890-94 | 87 | 6.6 | 4.8 | 75.6 |
| Average of 4 years, 1895-98 | 97 | 11 | 4 | 80.3 |
| *1890 | 169 | 24 | 14 | 124 |
| 1900 | 248 | 39 | 19 | 182 |
| 1901 | 212 | 28 | 10 | 167 |
| 1902 | 213 | 32 | 22 | 147 |
| 1903 | 242 | 36 | 8 | 193 |
| 1904 | 261 | 24 | 13 | 219 |

*Amalgamation took place in middle of this year.

In the report of the Glasgow Parish for the year ending May 15, 1905, Dr. Carswell gives the following statistics:

| Certified Insane and Asylums | Removed direct to Asylum | M. | F. | Total. | M. | F. | Total. |

† This is the only hospital of the kind in Great Britain, but the Commissioners of Insanity of Scotland are loud in its praise, and are urging the duplication of such wards in the different cities.

‡ Being 61.4% of cases admitted.

I hope that the physicians who read this article will seriously consider the need we have for a psychopathic hospital or wards in Boston. As we cannot now be the first to establish such a hospital let Boston at least be among the first in this as she has been in so many advances for relief of humanity.

GRAND JURY ADVOCATES HYGIENIC RULES. — The Philadelphia Grand Jury has recommended that consumptive prisoners be isolated; and that street cleaning and flushing and ash collecting be done at night, because the consequent dust is injurious to the health, — two most excellent recommendations. — *New York Medical Journal*.

A CASE OF MULTIPLE ULCERS OF THE GALL BLADDER.

BY EDWIN A. LOCKE, A.M., M.D., BOSTON.

Assistant in Clinical Medicine, Harvard Medical School; Assistant Visiting Physician, Long Island Hospital; Physician to Out-Patients, Boston City Hospital.

AND

R. B. WOLBRACH, M.D., BOSTON.

*Instructor in Pathology, Harvard Medical School; Pathologist to Long Island Hospital.**From the service of Dr. James J. Minot, Long Island Hospital.*

Summary.—Woman of fifty-six with varicose ulcers of the leg; sudden onset of severe abdominal symptoms suggesting appendicitis; operation and

slight nausea and she vomited once. The bowels had not moved for three days. On examination the abdomen was found to be moderately distended and the muscles held somewhat rigidly. There was moderate general tenderness to pressure, but distinctly more marked in the mid-epigastric region and the right iliac fossa. There was no tumor to be felt and no ascites.

Liver, normal size and gall bladder not made out.

Rectal examination revealed no mass, but high up, more on the right, tenderness was evident. Temperature, 101° ; pulse, 120; respiration, 28. White count, 22,400 per c.mm. Otherwise the physical examination was as at entrance.

At the termination of the patient seemed critical and after consultation with Dr. J. H. Cunningham, an operation was performed. Probable diagnosis: Acute appendicitis. Operation by Dr. J. H. Cunningham, 12.15 P.M., Jan. 30, 1906. Ether narcosis. No abdominal mass. Muscle splitting incision one inch above umbilicus. Bowel normal in color, but everywhere edematous. The lower half of the cecum was opened, but the appendix appeared normal. Cecum removed and the stump invaginated by two sutures of linen thread. The gall bladder was seen because of the intestinal distention, but it was not enlarged. The surface was smooth and it emptied readily with pressure. The surface was smooth. The pelvic organs were normal. The mesenteric nodes were not enlarged. The peritoneum was closed by a continuous chromic.

The muscle and fascia were approximated in the usual manner, and the skin closed by a subcutaneous gut suture. A dry sterile dressing was applied. Duration of operation, eighteen minutes. The patient received 1-30 of strychnine during the operation.

There was no marked shock immediately following the operation, and the patient recovered promptly.

For several days, subsequently, however, the patient had persistent vomiting which finally approached retching, and a moderate watery, offensive, bloody diarrhea. Twenty-four hours after the operation the stools contained a considerable amount of blood and pus. In spite of these symptoms the patient's condition seemed improved, the temperature at the end of the second day to 99° . Leucocytes, 10,000 per c.mm.

Vomiting ceased, but diarrhea still persisted, and the dejections contained more blood and pus.

About an ounce of blood passed this morning, vomited once to-day. Patient in weak condition, looks septic.

Temperature elevated (100°). Wound reddened and marked tenderness in surface. Wound opened and several ounces of foul pus evacuated. Deep sinus passing right iliac fossa. This sinus was thoroughly irrigated (believed to be fecal fistula). Pus, cloudy, acid; specific gravity, 1.042. Bile, absent; albumin, a trace; sediment, none.

On Jan. 31, blood corpuscles, many pus, round and oval cells, fairly numerous hyaline and fine and coarse granular casts, some with fat drops adherent.

Jan. 31. Patient gradually sinking. Wound irrigated and dressed daily. Discharge still fecal in character. Subpectoral infusions of saline solution, nutrient emulsion.

Feb. 3. Patient complains of dyspnea and pain in left chest with cough or deep inspiration. Temperature, 102.8° ; pulse, 130; respiration, 30. Examination of chest showed dullness at left apex to spine of scapula behind, and to third rib in front. Over this area the

GALL BLADDER—LOCKE

Half of the gall bladder, seen about two-thirds normal size.

Diagnosis: Arteriosclerosis, myocarditis, chronic bronchitis, emphysema and varicose ulcers.

Jan. 15, 1906. About midnight the patient complained of abdominal cramps and soon after vomited with considerable relief. She slept fairly well until morning, but the pain then returned and was described as of a dull character, occasionally paroxysmal. It was felt all over the abdomen, but with greatest intensity in the epigastrium. A few hours later she stated that the pain had become definitely localized just below, and to the right, of the navel. There was

as much as 1,700 cc. at one time, and this has been repeated twice daily. As a modification it has been found possible in certain cases to introduce the saline solution into the bowels instead of under the skin." In the report of Pavilion F for the year ending Feb. 28, 1906, Dr. Mosher lays stress on the advantage of the patients being treated in their home locality under the scrutinizing eye of their friends; also of the value of the ward in educating the people that mental disease is to be looked upon the same as any other disease and that the surroundings may be the same. He has had gratifying results from the us injections of normal salt solutions. I year ending Feb. 28, 1906, there were admitted of which 126 recovered or were 74 did not improve, 20 died and 14 re-

A CASE OF MULTIPLE ULCERS OF THE GALL BLADDER.

BY EDWIN C. LOCKE, A.M., M.D., BOSTON.

Assistant in Clinical Medicine, Harvard Medical School, Visiting Physician, Long Island Hospital; Physician to Out-Patients, Boston City Hospital.

AND

R. B. WOLBACH, M.D., BOSTON.

Instructor in Pathology, Harvard Medical School, Pathologist to Long Island Hospital.

From the service of Dr. James J. Minot, Long Island Hospital.

Summary—Woman of fifty-six with varicose ulcers of the leg; sudden onset of severe abdominal symptoms suggesting appendicitis; operation and nothing abnormal found; local abscess with peritonitis following; terminal lobar pneumonia; death twenty-three days after operation; autopsy; entire gall bladder lined with chronic ulcers, two of which had apparently perforated, causing a general peritonitis.

J. B., a cook, aged fifty-six, entered the Long Island Hospital, Dec. 11, 1905.

Family history, not important.

Past history: General health excellent. Never any serious illness. She has been in the habit of taking nine or ten cups of tea daily, but never any alcohol. Menopause at fifty.

Present illness: The patient came to the hospital because of painful ulcerations on the anterior part of the right lower leg, of six months' duration. For several weeks a troublesome dry cough which is worse at night; pain in chest with deep inspiration or cough; night sweats of moderate severity. No cardiac, gastric or renal symptoms. Appetite poor; bowels constipated.

Physical examination: Well developed and healthy appearing woman with some evidence of senility. Pupillary reactions and ocular movements normal; areus senilis. Tongue coated, teeth decayed and many missing. No enlargement of the lymph nodes.

Over the whole of both lungs, the expiration is prolonged and low pitched and the percussion note hyper-resonant; numerous medium râles at both bases posteriorly, especially on the right where the resonance is somewhat diminished.

Heart: Slight enlargement to left 10 cm. from midsternum in the fifth space; sounds short and valvular; moderate irregularity in force and rhythm. At the apex and transmitted to the axilla, is a very soft, blowing, systolic murmur. Aortic second sound accentuated. Pulses synchronous, low tension, arteries slightly tortuous and palpable.

Abdomen: Nothing abnormal made out. Liver, dullness to costal border; edge not felt.

Extremities: Patellar and plantar reflexes normal, no clonus. Over the anterior surface of lower right leg there are three small, shallow ulcers, the largest 3 x 7 cm. in diameter. The floors are covered by unhealthy granulations and necrotic tissue and each is surrounded by marked infiltration with redness. The veins of the lower leg are dilated and tortuous.

Diagnosis: *Arteriosclerosis, myocarditis, chronic bronchitis, emphysema and extensive ulcers.*

Jan. 15, 1906. About midnight the patient complained of abdominal cramps and soon after vomited with considerable relief. She slept fairly well until morning, but the pain then returned and was described as of a dull character, occasionally paroxysmal. It was felt all over the abdomen, but with greatest intensity in the epigastrium. A few hours later she stated that the pain had become definitely localized just below, and to the right, of the navel. There was

slight nausea and she vomited once. The bowels had not moved for three days. On examination the abdomen was found to be moderately distended and the muscles held somewhat rigidly. There was moderate general tenderness to pressure, but distinctly more marked in the mid-epigastric region and the right iliac fossa. There was no tumor to be felt and no ascites.

Liver, normal size and gall bladder not made out.

Rectal examination revealed no mass, but high up, more on the right, tenderness was evident. Temperature, 101 $\frac{1}{2}$; pulse, 120; respiration, 28. White count, 22,000 per c.mm. Otherwise the physical examination was as at entrance.

The condition of the patient seemed critical and after consultation with Dr. J. H. Cunningham, an operation was advised. Probable diagnosis: Acute appendicitis.

Operation by Dr. J. H. Cunningham, 12:15 p.m., Jan. 15, 1906. Ether narcosis. No abdominal mass palpable. Muscle splitting incision one inch above McBurney's point. Bowel normal in color, but everywhere distended. The lower half of the cecum was slightly injected, but the appendix appeared normal. Appendix removed and the stump invaginated by two purse-string sutures of linen thread. The gall bladder could not be seen because of the intestinal distention, but by palpation it was not enlarged. The surface seemed smooth and it emptied readily with pressure. The liver surface was smooth. The pelvic organs normal. The mesenteric nodes were not enlarged. The peritoneum was closed by a continuous chromic-gut suture. The muscle and fascia were approximated in a similar manner, and the skin closed by a subcutaneous silk-worm gut suture. A dry sterile dressing and swathe applied. Duration of operation, eighteen minutes. The patient received 1-30 of strychnine during the operation.

There was no marked shock immediately following the operation, and the patient recovered promptly from ether. For several days, subsequently, however, there was persistent vomiting which finally approached a fecal character, and a moderate watery, offensive and, at times, bloody diarrhea. Twenty-four hours after operation the stools contained a considerable amount of blood and pus. In spite of these symptoms the patient's condition seemed improved, the temperature falling at the end of the second day to 99°. Leucocytes, 10,000 per c.mm.

Jan. 18. Vomiting ceased, but diarrhea still persists. This morning the dejections contained more blood and a large amount of pus.

Jan. 19. About an ounce of blood passed this morning. Vomited once to-day. Patient in weak condition and looks septic.

Jan. 25. Temperature elevated (100°). Wound somewhat reddened and marked tenderness in surrounding area. Wound opened and several ounces of brownish, foul pus evacuated. Deep sinus passing down into right iliac fossa. This sinus was thoroughly irrigated and wicked (believed to be fecal fistula). Urine: Pale, cloudy, acid, specific gravity, 1.012; sugar and bile, absent; albumin, a trace; sediment, few normal blood corpuscles, many pus, renal and bladder cells, fairly numerous hyaline and free and coarse granular casts, some with fat drops adherent.

Jan. 31. Patient gradually sinking. Wound irrigated and dressed daily. Discharge still fecal in character. Subperitoneal effusions of saline solution, nutrient and water.

Feb. 3. Patient complains of dyspnea and pain in left chest with cough and deep respiration. Temperature, 102.8; pulse, 140; respiration, 30. Examination of chest showed dullness at left apex to spine of scapula behind, and to third rib in front. Over the area the

respiration is somewhat bronchial in character, vocal fremitus increased; no râles.

Feb. 5. Definite and marked signs of consolidation at left apex and over remainder of both lungs many coarse, moist râles. Condition of patient very critical. Abdominal wound still discharging. Vomiting continues.

Feb. 7. The patient failed rapidly and finally died at 2.10 p.m.

Autopsy No. 06:15. Regular No. 22,230. Feb. 8, 1906. Dr. S. B. Wolbach. Autopsy, 42 hours post mortem.

ANATOMICAL DIAGNOSIS.

Lobar pneumonia.

General arteriosclerosis.

Fibrinous pericarditis.

Fibrinous peritonitis.

Abscess of abdominal wall.

Operation wound.

Absence of appendix.

Ulcerative cholecystitis.

Cysts of choroid plexus.

Granular ependymitis.

Body: Of a fairly well-developed and nourished white woman, 166 cm. long. Pupils equal, 5 mm. Rigor mortis present. Slight lividity of dependent parts. Both lower legs are pigmented, brown, over lower halves. The right lower leg is bluish red over the lower portion of the tibia.

On the right side of the abdomen, on a level with the anterior superior spine of the ileum, is a gaping operation wound, 3.5 cm. long, 1.5 cm. wide, running vertically, with dry glazed walls. The wound is 6 cm. internal to the anterior superior spine, and 9 cm. external to the median line. The floor is dirty gray and granular. Exploration reveals a recess running upwards and backwards for 10 cm. and several centimeters in width.

Peritoneal cavity: The intestines are everywhere glued together by fibrin. Several loops are similarly adherent to the pelvic walls. The sigmoid flexure is injected and adherent by fibrinous material behind the uterus. To the peritoneum below the operation wound there are adherent by fibrous tissue the ascending colon, the transverse colon and the omentum. The transverse colon is pulled downwards making a sharp bend to reach the site of operation; it overlies the ascending colon. The omentum is adherent to the abdominal wall, to the bend of the transverse colon, to the ascending colon below this and to the inferior ileocecal angle. On separating the transverse colon from its adhesions, about 5 cc. of thick, yellowish, puriform material is released from a cavity between the portions of large intestine and omentum. On cutting the adhesions between the cecum, ascending colon and abdominal wall, the anterior wall of the ascending colon is found to have formed the floor of the cavity seen through the operation wound. The cavity extends upwards and outwards between the abdominal muscles and the transversalis fascia. Below the ilium at its union with the cecum is a small cavity containing about 3 cc. of thick, yellowish, puriform material, which escapes on removing the adherent omentum. Removal of the adhesions also tears the wall of the cecum leaving a round aperture 0.4 cm. in diameter, the probable site of the appendix. The hepatic flexure of the colon is adherent to the pylorus and first portion of the duodenum. The mesenteric lymph nodes are not palpable. The vessels of the intestinal surfaces are injected over large areas of intestine. The retro-peritoneal glands are enlarged; soft, pinkish gray on section.

Pleural cavities: The left lung is loosely adherent over all surfaces by a layer of yellow fibrinous material, 1 to 2 mm. in thickness. The apex is adherent by fibrous tissue. The right lung is adherent at apex and along posterior border of upper lobe by firm fibrous adhesions.

Pericardial cavity: Contains about 30 cc. of slightly clouded liquid and a few fibrinous flakes upon the auricles.

Heart: Weight, 320 gms. Myocardium is dark red, firm. Aortic and mitral valves have irregular, yellow, thickened patches, otherwise valves and endocardium are normal. Coronary arteries show extensive patches of yellow thickening. No calcification. Measurements: Pulmonary valve, 7.5; tricuspid valve, 11; Aortic valve, 7; mitral valve, 9; thickness of left ventricle, 2; right ventricle, 0.5 cm.

Lungs: The whole upper lobe of the left lung is solid, completely filling upper part of chest cavity. On section it is granular, gray with areas of red and yellow, the whole bathed in thin puriform material. Bronchi yield pus. The apex is puckered by thickenings of the pleura. No evidence of tuberculosis on section. The lower lobe is bluish red, boggy and on section, is wet, dark red, yields much bloody liquid and air on pressure. Bronchi yield pus. Right lung: Partially collapsed. All lobes are heavy, boggy and bluish red in color. On section all are wet, dark red, yielding much blood and frothy liquid on pressure. Bronchi contain pus.

Spleen: Weight, 65 gm. Is small, salmon red in color. Capsule smooth. Consistency is loose, elastic; on section is red. Trabeculae are prominent. Malpighian bodies visible.

Liver: Weight, 1,400 gm. Surface is smooth, color pale, brownish red. On section is mottled pale, brownish red and gray. Consistency normal. Nothing abnormal found on close sectioning. The gall bladder is moderately distended, is 7 cm. long, 5 cm. in diameter, ovoid in shape. On separating the adherent colon, two small circular apertures with thin, regular pigmented edges are left on the fundus of the gall bladder. The gall bladder contains thick, viscous, stringy, grayish green fluid with numerous soft black masses of pigment. The inner surface has many (over 30) deep circular undermined ulcerations from 1 to 8 mm. in diameter. They are most abundant on the wall attached to the liver, where a group of nine large ones are separated only by interlacing columns of tissue. Many are surrounded by a dark zone, several millimeters wide, which on section is seen to be due to lateral extension and pigmentation beneath the mucous membrane. The cystic duct is tortuous, of small caliber but patent upon careful dissection. The hepatic and common ducts and the duct of Wirsung are normal.

Pancreas: Normal.

Gastro-intestinal tract: Normal.

Kidneys: Weight, 390 gm. Are large, pale. Cortex measures 0.5 to 0.7 cm. Glomeruli visible as colorless points. Pyramids injected. Capsule strips easily from a smooth surface.

Genitalia: Normal.

Aorta: Markedly sclerosed and calcified.

Head: Hair scanty, gray, moderately long. Scalp and calvarium are normal. Dura and sinuses are normal.

Brain: Weight, 1,180 gm. Pia is moist, vessels injected. Cortex, basal ganglia, pons, medulla and cerebellum are negative. Apendymal floor of both ventricles over tenia semicircularis in anterior horn shows fine translucent granulations. Both choroid plexi contain a few cysts 1 to 4 mm. in diameter.

Middle ears are normal. Vessels at base show slight sclerosis.

MICROSCOPICAL EXAMINATION.

Heart: Negative.

Lung: The alveoli are filled with an exudate in general of a purulent type, but in large groups of alveoli composed mainly of fibrin. A few alveoli contain chiefly mono-nuclear phagocytic cells and granular detritus with few polynuclear leucocytes. The bronchi contain pus.

Spleen: Injected. The follicles are of good size and numerous and contain many plasma cells with an occasional mitotic lymphocyte. The sinuses of the pulp are distended with blood, the lining cells show a small amount of light brown pigment. Arteries present marked hyaline change.

Liver: Moderately injected. Peripheral cells of lobules show marked vacuolation due to fat. The central cells contain a small amount of dark brown pigment.

Pancreas: Negative. Marked hyaline changes in the arteries.

Kidneys: There are a few small foci of connective tissue increase inclosing a few atrophied tubules and an occasional sclerosed glomerulus. The capsular spaces of the glomeruli inclose considerable granular exudate. The epithelium of the tubules is pale, granular, swollen, the lumina contain circular reticulum and granular detritus. Many hyaline casts seen in the collecting and Henle tubules. The arteries show slight endarteritis.

Adrenal: Negative.

Appendix stump: The wall of the cecum is markedly infiltrated with lymphoid and plasma cells. The surface is covered with fibrin, necrotic material and leucocytes.

Gall bladder: There are in several places on the inner surface attached remnants of necrotic mucous membrane. The wall is infiltrated with lymphoid cells, plasma cells and eosinophiles. The ulcers are deep and have widely undermined edges with marked destruction of tissue. The floors of the ulcers are very thin and consist of separated strands of connective and smooth muscle tissue infiltrated with lymphoid and plasma cells and eosinophiles. The peritoneal surfaces are covered with fibrin. In the overhanging edges and in the tissue surrounding the cavity of the ulcers are many polynuclear leucocytes. The predominating cells are the lymphoid, plasma, eosinophilic and large mononuclear phagocytic cells. There are many small bacilli in the walls of the ulcers, free and within polynuclear leucocytes.

Cerebral cortex: Negative.

Floor of lateral ventricles: There is an increase of neuroglia tissue with many corpora-amylacea beneath the ependyma.

REMARKS

The above case of ulcerative cholecystitis not occurring in association with gallstones and leading through perforation to an infection of the peritoneum and finally to death is almost unique in the literature. Courvoisier¹ found 74.5% of his series of 51 cases of suppurative cholecystitis to be secondary to gallstones. In our case the history gives no suggestion of any antecedent cholelithiasis, neither were calculi found at the operation or post-mortem section, hence the evidence seems complete that the

inflammation of the gall bladder occurred independent of this condition. Orth² speaks of extensive ulceration and perforation of the gall bladder as occasionally combined with purulent cholecystitis, especially when the latter is secondary to gallstone, typhoid fever, dysentery, cholera or pyemia.

Moore³ reports a case of a man of sixty-seven, who, while confined to his bed by an attack of acute bronchitis, was seized with severe symptoms of general peritonitis. At operation the peritoneal cavity was found infected and contained a considerable amount of pus and bile. The gall bladder was distended, elongated, thickened and contained a considerable amount of fine gravel, but no calculi. All over the inner surface were many minute, shallow ulcers containing pus and mucus. These were most abundant at the fundus where two had apparently perforated causing the peritonitis. No obstruction to the common duct existed.

Chiari⁴ records a case of cholecystitis in a boy of twelve years, occurring during the course of typhoid fever. At autopsy the entire inner surface of the gall bladder showed an intense phlegmonous inflammation with extensive ulceration and resulting peritonitis. These lesions in several places closely resembled the typhoid ulcers in the small intestines and from the purulent contents of the gall bladder a pure culture of the typhoid bacillus was obtained.

In the above case we could find no indications as to the etiology. The question naturally arises if the local infection of the gall bladder might not have been caused by an infection following the operation, but the character of the changes in the tissues is unquestionably of a more chronic character than would have been possible in such a case. Furthermore, the clinical evidence is important. The symptoms are so well explained by cholecystitis that in the absence of any condition found at operation or autopsy to account for them, the existence of the ulcerations previous to the laparotomy cannot be doubted. The sudden onset of the severe symptoms in an obviously chronic ulcerative condition we are unable to explain. Certainly they were not due to perforation as at the operation twelve hours after there was no evidence of peritonitis either local or general. Two possible explanations present themselves for the peritonitis following operation. First, the local sepsis at the wound may well have been the point of origin though a much more definite one is through the perforations in the gall bladder which were found at necropsy. Perforation probably occurred spontaneously, although it is evident from the extremely thin floor of many of ulcers found at autopsy, that the emptying of the gall bladder by pressure at the operation might have caused them to give way, thus permitting the infectious material to escape into the peritoneal cavity. If the contents were not forced through these perforations into the peritoneal

cavity, but into the duodenum, as was supposed, this may have been the source of the pus observed in the dejections after operation. No lesions of the gastro-intestinal tract were found at the post-mortem section to indicate a possible origin of the malena.

New Instrument.

APPARATUS FOR LOCAL APPLICATION OF DRY COLD AND HEAT.

BY ADDISON W. HAIRD, M.D., NEW YORK.

HEAT and cold by local application are remedial measures possessed of great power for good in properly selected cases; either of them may be applied for superficial and limited, or for deep-seated and more distant, affections. Cold or heat causes relief of pain in inflammation by producing contraction of local blood-vessel walls; and, as a result, inflammatory exudates do not occur, congestion is relieved, and as pressure on nerve filaments ceases, the pulsating pain passes away. Cold in particular diminishes engorgement in swollen and reddened tissues, and benumbs the nerve endings, so that relief from pain is often immediate and enduring.

Cold has been used with no small degree of success in many of the deeper inflammations, notably in the treatment of pneumonia and

is dependent on the sensations of the patient, who generally can tell which affords him the greater comfort. Heat, however, is usually most grateful and efficacious in painful conditions of the nerves, and more soothing in those disorders accompanied by disturbance in the peripheral nerves. Happy results are frequently obtained in certain gynecological cases; indeed, local heat and cold find a field of great utility in the vesical, vaginal and rectal region.

There has been designed an apparatus called the *currodon*, which has a capacity of three quarts, and is so arranged that a continuous flow of its contents may be produced. Due to its syphonic action, the machine is practically automatic, and may be placed either above or below the level of the patient. Filled with ice and water, or full of hot water and having a small lamp beneath, the *currodon* will furnish a steady flow through coil, bulb, or hollow applicator, at an equable temperature, the flow being maintained by simply drawing up the handle every half hour. The apparatus is furnished with a carefully graduated thermometer, which projects through the dome. The *currodon* is adapted for use in office, hospital, or home, and produces beneficent and gratifying results in the treatment of many conditions.

Clinical Department.

A CASE OF DOUBLE UVULA IN A CHILD.

BY W. P. COUER, M.D., BOSTON.

ANNIE S., seven years, was seen Feb. 12, 1906. The case was brought to my attention on account of the child's thick speech. The child was of Russian parentage and the abnormality had been noticed since birth.

Examination showed a fairly well developed and nourished child. There was slight internal strabismus, the nose was flat and broad; and the two lower lateral incisor teeth were crowded together on each side. There was marked pigeon breast; there was no rosary or enlargement of the epiphyses.

Examination of the heart, lungs and abdomen was negative.

Examination of the throat showed a somewhat reddened pharynx as well as tonsils, the submaxillary glands were enlarged.

There were two distinct uvulae arising from either side of the soft palate just beyond the pillars of the fauces. The uvulae were perfectly formed of normal size for the age and hung directly downward in a straight line just back and to the side of the tonsils.

According to McKenzie¹ this is one of the rarest of embryological curiosities. He has met with the condition in several forms, however, and this case belongs to the second variety in his classification.

McKenzie classifies these abnormalities of the uvula into five groups:

No. 1. Two separate distinct uvulae hanging on either side of median line of soft palate.

No. 2. (The reported case belongs to this group.) No central uvula, one on each side

pleurisy. In pericarditis and endocarditis cold relieves palpitation and distress, and quiets the heart. In acute and chronic prostatitis the abstraction of heat by the local application of a suitable hollow prostatic instrument introduced into the rectum may be both palliative, and curative to some extent.

In like manner heat is used locally for a number of purposes; and in the treatment of many forms of acute inflammation, the choice of heat or cold

projecting from the soft palate at the junction of the anterior and posterior faucial pillars.

No. 3, in which there is a well-formed lateral and externally deflected uvula, its fellow on the other side being rudimentary.

Nos. 4 and 5 represent a transition from bifid to double uvula. 4, two central uvulae, joined at the insertion into the palate; and 5, the central uvulae joined into their insertion into a sort of hemispherical bulging downward of the central portion of the soft palate.

Double uvula in a child

The first variety of the classification is the rarest.

Coleman² says entire absence of the uvula is of much more common occurrence than a double one; he reports a case of double uvula, the rarest type, in a boy.

H. Foster³ reports a case of two distinct uvulae, side by side, separated all the way to the Arch O twenty-three years. This is the same type as the case reported.

R. W. Shufeldt⁴ reported a case, O 23, of latid uvula.

Some⁵ reports a case in a boy, bifid uvula with degeneracy, and states that Berens in examining 3,000 cases found the uvula abnormal 84 times; 14 were deeply cleft.

It is of interest in connection with my case that examination of the mother showed a normal uvula, also the youngest child, but the second child, age five, had an abnormally short uvula, not more than half the normal length.

The father was not examined but the mother states that she is very certain that he had no such abnormality.

Medical Progress.

PROGRESS IN GASTRO-INTESTINAL DISEASES.

BY ELLIOTT P. JOHNS, M.D.

(Continued from No. 24, p. 682.)

HYPERSECRETION OF MUCUS IN THE STOMACH.

KUTTNER⁷⁰ understands by this name a hypersecretion of gastric mucus in the empty stomach. He considers the presence of more than 25 cc. mucus to be, as a rule, pathological. Such cases are not very rare. To deserve this designation the mucus should be constantly present, or at recurrent intervals. The reaction of the mucus is neutral, alkaline or weakly acid. Hydrochloric acid, however, is absent in the typical cases. Mixed forms occur with those of hypersecretion of gastric juice, and in these hydrochloric acid may be present. There are two forms of the hypersecretion of mucus,—intermittent and chronic. The intermittent begins with headache, anorexia, nausea, or with sudden vomiting, beginning early in the morning and almost uncontrollable. These attacks last sometimes only a day, and suggest the gastric crises in locomotor ataxia, but they occasionally last from three to twelve days, and greatly weaken the patient. They often suddenly end. In the beginning one can at times break up the attack by gastric lavage. On other occasions even injections of morphine fail. In two cases the hypersecretion of mucus was accompanied by nasal hypersecretion. The chronic form of hypersecretion of mucus often presents no suggestive symptoms, but is most frequently found in chronic catarrh and in nervous diseases of the stomach, in the same way as the intermittent form chiefly occurs in nervous and easily excitable persons. Nervous influences play a corresponding rôle in hypersecretion of mucus as in the secretion of hydrochloric acid, and treatment must bear this fact in mind. Gastric lavage with plain water or mineral water together with the complete withdrawal of food and drink during the severe attacks are suggested for treatment.

GASTRO-ENTEROSTOMY AND PYLOROPLASTY.

Cannon and Blake⁷¹ sum up their work on gastro-enterostomy and pyloroplasty in the following conclusions:

The stomach is not a passive bag. During digestion the cardia and slowly contracts, pressing its contents into the pyloric end. Over the pyloric end during digestion peristaltic waves are continually running, churning the food with the gastric juices and forcing the chyme into the intestine. Observations on the functioning human stomach show that as it empties it shortens, especially along the greater curvature. Therefore, the part of the stomach lowest when the organ is full or relaxed is not lowest as it empties. The pylorus then becomes the lowest point.

Even if "gravity drainage" occurred, the pylorus is the natural outlet so long as the stomach retains its power of contracting.

The pressure within the abdomen is approximately atmospheric pressure. The pressure in any part of the passive alimentary canal depends on the weight of the overlying abdominal organs. If the canal is inactive, the food therefore is as if surrounded by water. Gravity cannot act, and gravity drainage does not occur.

After an ordinary meal, the peristalsis of the pyloric end of the stomach makes the contents of this part more fluid than the contents of the cardiac end. Because peristaltic waves move towards the pylorus, the intragastric pressure is three or four times greater at the pylorus than in the cardiac end. Observations on large cats with gastro-enterostomy openings of various sizes at various parts of the stomach showed that unless the opening, or stoma, was in the antrum (*i. e.*, close to the pylorus) the food, even when fluid, was pushed through the pylorus rather than through the stoma.

With peristalsis only in the pyloric end of the stomach, with the intragastric pressure much greater at the pylorus than elsewhere in the stomach, and with the food in the pyloric end normally more fluid than that in the cardiac end, the food is forced into the intestine through the pylorus, and not through the artificial opening, when both ways are offered.

Circulation of the food through the pylorus to the duodenum and back to the stomach through the anastomosis has been repeatedly observed, but it was not followed by the clinical symptoms of the "vicious circle." The circulation was observed best when the stomach was very full. The stretching of the stomach separates the lips of the stoma and draws the intestinal wall into line with the gastric wall. The openings into the intestine at the stoma then become mere slits, and act like valves, permitting the entrance, but preventing the exit, of the food.

The clinical symptoms of the "vicious circle" have been observed in animals in which a kink of the intestine has been found just distal to the anastomosis. Kinks at this point cannot be straightened by peristaltic activity because the circular fibers of the intestine are cut at the nearby stoma.

It is important that food be mixed with the secretions poured into the duodenum; these juices are highly effective in digestion, and also neutralize the acid chyme. If food leaves the stomach by the stoma it is not mixed with these secretions. Jejunal ulcers after gastro-enterostomy may be due to the presence of acid in a region in which inorganic acid is not normally found.

From the above considerations, it was concluded that the stoma should be large and as near to the pylorus as possible; that the circulation of the food be rendered less probable by avoidance of overeating, and that so far as possible kinks be obviated by attaching a narrow band of the distal gut to the stomach for several centimeters

beyond the stoma, thus permitting peristalsis to become an effective force.

The probability of a circulation of the food whenever the pylorus is left open, the non-mixture of the food with the digestive and neutralizing fluids in the duodenum, and the ever present danger from kinks in gastro-enterostomy make the operation not an ideal one.

In pyloroplasty (preferably the Finney operation) these objections are avoided. And a too rapid exit of the food through the pylorus is prevented by the rhythmic segmentation of the food in the duodenum, an activity which in part replaces the functions of the pylorus, and also mixes the food with the pancreatic juice and the bile.

OPERATIONS FOR CANCER OF STOMACH.

Moynihan²² reports the results in 59 cases operated upon between Aug. 23, 1897, and July 1, 1905. Nine patients died soon after the operation. Of 35 patients upon whom gastro-enterostomy was performed one lived two years and four months; six others were living at the time of the report. Of ten cases upon whom gastro-ectomy, partial or complete, was done, one is alive and free from recurrence at the end of four and a half years, two died within a week and four are still living at intervals of five months to two and a half years since the operation. Of the remaining cases, upon whom there were five gastrostomies, three jejunostomies and six exploratory laparotomies, none lived over eighteen months after the operation.

Sixteen of the gastro-enterostomies gave a history of an ulcerated stomach.

Moynihan calls attention to the fact that at autopsies cancer of the stomach may occasionally still be a local condition.

Clairemont²³ reports upon the 258 operations upon the stomach which have been performed by Professor v. Eiselsberg between March, 1896, and January, 1904. The total mortality was 23.3%. This is in contrast to a mortality of 31.6% in his previous operations. The mortality among the 94 cases of gastric ulcer and sequela was 16% and for the 134 cases of new growth was 31.3%.

THE PASSAGE OF DIFFERENT FOOD-STUFFS FROM THE STOMACH AND THROUGH THE SMALL INTESTINE.

Cannon²⁴ has arrived at the following conclusions from his work on the passage of food through the stomach and intestine.

Fat, carbohydrate and proteid foods, uniform in amount (25 cc.) and consistency, were mixed with a small amount of subnitrate of bismuth and fed to cats deprived of food for at least twenty-four hours. The rate of gastric peristalsis observed by means of the Röntgen rays was usually slower for fats (5.2 waves per minute) than for carbohydrates (5.8 waves per minute), but the

²² British Med. Jour., 1906, Feb. 17, p. 370.

²³ Archiv. f. klin. Chirurgie, 1905, Bd. 76, p. 180.

²⁴ Amer. Jour. Phys., 1904, vol. xli, p. 387.

variation was so great as to make a more definite statement unsafe.

At regular intervals for seven hours after feeding, the shadows of the intestinal contents were traced on transparent paper by means of a fluorescent screen and the Röntgen rays. Since the intestinal contents vary only slightly in diameter, the aggregate length of the shadows can be taken to indicate the relative amount of food present in the small intestine at various intervals, and in various animals at the same interval after feeding. In the early stages of intestinal digestion, before much absorption has occurred, the aggregate length of the shadows at different intervals indicates the rate of discharge from the stomach.

Fats remain long in the stomach. The discharge of fats begins slowly and continues at nearly the same rate at which the fat leaves the small intestine by absorption and by passage into the large intestine. Consequently, there is never any great accumulation of fat in the small intestine.

Carbohydrate foods begin to leave the stomach soon after their ingestion. They pass out rapidly, and at the end of two hours reach a maximum amount in the small intestine almost twice the maximum for proteids, and two and one-half times the maximum for fats, both of which maxima are reached only at the end of four hours. The carbohydrates remain in the stomach only about half as long as the proteids.

Proteids frequently do not leave the stomach at all during the first half hour. After two hours they accumulate in the small intestine to a degree only slightly greater than that reached by carbohydrates an hour and a half earlier. The departure of proteids from the stomach is therefore slower at first than that of either fats or carbohydrates. An exception to this general statement was found in egg-albumin, which, both in its natural state and in coagulated form, was discharged from the stomach at about the carbohydrate speed.

When carbohydrates and proteids are mixed in equal parts, the mixed food does not leave the stomach so slowly as the proteids, nor so rapidly as the carbohydrates; the discharge is intermediate in rapidity.

In a mixture of fats and proteids in equal parts, the presence of the fat causes the proteid to leave the stomach even more slowly than the proteid itself. Fat mixed with carbohydrate in equal amounts also causes the carbohydrates to pass the pylorus at a rate slower than their normal.

Doubling the amount of carbohydrate food (50 cc. instead of 25 cc.) increases the rapidity of the carbohydrate outgo from the stomach during the first two hours; whereas doubling the amount of proteid food strikingly delays the initial discharge of proteid from the stomach.

The process of rhythmic segmentation is seen with all three kinds of food-stuffs, and the frequency of its occurrence corresponds roughly to the amount of food present in the intestine; a measurement of the length of the segmenting

masses in a given number of cases shows that at the regular intervals of observation, during the first seven hours after feeding, the amount of segmenting activity in the presence of carbohydrates was much greater than in the presence of either fats or proteids. Egg-albumin is excepted in this general statement.

The interval between the feeding and the appearance of food in the large intestine is variable, but the mean for carbohydrates is about four hours, for proteids about six hours, and for fats about five hours. After time is allowed for the later start of proteids from the stomach there still remains a probability that the proteids pass through the small intestine more slowly than do the carbohydrates.

GALLSTONES.

Naunyn² has contributed another of his interesting articles on gallstones.

The modern era of cholelithiasis began thirteen years ago. Agreement was soon reached that the cause of the formation of the gallstone lay in an infectious cholangitis, and the important rôle which infections of the gall bladder played was recognized by every one. Great advances have been made by the aid of surgery. In general, early operation has been given up, but chronic recurrent attacks of gallstones are in the domain of surgery. Medical treatment consists in rendering the gallstones latent, not in their solution, and warm applications and hot Carlsbad water still remain our best therapeutic aids. It still is not generally understood that chologogues are not of advantage. It is not secretion of the liver cells which is needed, but a freer flow through the ducts. The sphincter ductus choledochi opposes a strong resistance to the flow of bile, and as long as it is closed it is of no avail to increase the secretion. The sphincter will withstand a pressure of 700 mm. water, while the bile is secreted with a pressure of only 300 mm. Chologogues therefore cannot avail much.

The following can be said of the solubility of the calculi: These consist of cholesterol, calcium bilirubin, calcium carbonate and phosphate. Calcium bilirubin and the inorganic calcium salts are insoluble in the bile, but cholesterol on the other hand is soluble in considerable amount.

Indeed normal bile practically never contains so much cholesterol but that still larger quantities can be dissolved in it. There is then no question but that the cholesterol stone can be gradually dissolved, and this was proved thirty years ago by Labes. If the cholesterol dissolves from a stone it is possible that the stone may break up and the different portions be expelled by the force of the bile current. Such a solution and breaking up of a well formed gallstone occurs most seldom in man. Even if the stone falls to pieces on account of the interference with the normal motility of the gall bladder the various portions will not be wholly expelled. A residuum of bile remains. Out of one thousand autopsies on

² *Mitt.* 1. u. 2. Grenzgebiete d. Medizin u. Chirurgie, 1905, vii, 14, p. 537.

patients in whom gallstones were present, Naunyn has seen not more than ten instances of evidence of solution of a stone. These occurred with stones of the size of cherry stones. Such stones consist of cholesterin, but they are not the massive, crystallized cholesterin stones. The change in the stone is quite probably due to the action of bacteria, and not a simple solution, though the latter may be possible, and as proof of this he adduces the layers of inorganic calcium phosphate and carbonate. These inorganic calcium bearing stones are often recognizable by their green color, showing that the bilirubin has been oxidized to biliverdin, and this goes hand in hand with the activity of the oxidizing bacteria. The deposition of inorganic calcium salts in the secretion of the mucous membranes and the formation of calculi out of inorganic calcium in animals everywhere is due to the action of the bacteria.

The marked petrification of the biliary calculi often is seen together with the solution of the non-petrified substances of the stone, thus indicating the action of the bacteria. But there are other, and indeed more numerous evidences of the solution of gallstones without the simultaneous formation of inorganic calcium, and such cases are the ones to study; perhaps by the aid of modern surgery a litholitic form of bacteria may be discovered.

The demonstration of biliary calculi with the x-ray is often mentioned, but the results are of no great value in diagnosis. It is true, Naunyn says, that one may see with the x-ray stones, and obtain these at a later operation, but he does not believe that the shadows seen were due to the stones, for it may be found that the bladder in which the stones lay was filled with concentrated bile which may transmit the x-ray far less than the stones themselves. If one lays one of these stones on the front or back of the body of a fairly corpulent person, it might be seen with the x-ray. If, however, the stone is first placed in an ox gall bladder filled with thin ox bile, the stone scarcely makes a shadow, and placed in the gall bladder of a man filled with thick human bile no shadow at all is obtained, and if the bile is very thick the stone may show as a bright spot. This does not, however, settle the whole question. The power of a stone to give a shadow with the x-ray depends on its content of calcium, and this is extraordinarily variable. Cholesterin stones and common gallstones often contain .5% or less of CaO , while others have as much as 21%. These could be seen even when placed in thick human bile. It is on account of these stones which are not so very uncommon that an attempt at demonstration with x-rays is indicated.

Gallstones may form rapidly, and without doubt even in a few days, perhaps hours. The cholesterin stones of large size are unquestionably old. Calculi with a soft nucleus and many calcium bilirubin stones, even though they may be large, may have more rapid development. Secondary infiltration with cholesterin always speaks for an old stone. Naunyn then describes stones which illustrate these points.

The diagnosis of simple gallstones causes little trouble, not so the differential diagnosis of gallstones and cancer of the bile ducts or liver. The diagnosis of gallstones alone in the difficult cases means a differentiation from disease of the stomach. Localized tenderness over the gall bladder and jaundice are the most important aids, and when these fail the history of the first attack cannot be too much emphasized. In the later course the symptoms may depend upon the meals on account of adhesions near the pylorus and duodenum. The first attack comes unannounced, seldom after a meal or error of diet, but rather at a time — midnight — when disturbances with the stomach seldom occur, though the opposite holds for intestinal pain. It is, further, seldom that the attack though beginning in the stomach does not clearly show a relation to the right hypochondrium. This is a decided advance toward a diagnosis.

Acute cholecystitis is characterized by either fever, local pain, sensitiveness or edema. Quite difficult is the diagnosis of empyema of the gall bladder when associated with cholelithiasis.

Acute choledochus obstruction Naunyn holds not possible of diagnosis. It is made in those cases of gallstone colic in the old sense when it was reported that jaundice was due to the obstruction of the ducts by the stone. This premise does not now hold. The diagnosis of a chronic obstruction is not much more satisfactory. Jaundice in gallstones is far oftener due to an inflammatory condition than to an obstruction with a stone. The infectious cholangitis is at the bottom of the matter. Jaundice, even of the chronic type, may occur with gallstones without these having left the gall bladder, and without stones in the larger ducts. Conversely, jaundice may be absent when there is marked obstruction of the ducts with stones.

Ehret suggests that when complete absence of bile from the feces can be excluded, and thus suspicion is diverted from cancer, a good history of gallstones in a patient without fever, who is rather frequently attacked with sudden, yet not very painful, exacerbations with sudden rises of temperature, points to stones in the common duct. A stone impacted in the duct near the duodenum renders infection of the ducts easy, and the resulting inflammation results in a slowing of the biliary flow with severe consequences, though these may be temporary.

The diagnosis between gallstones and cancer is of the greatest importance. The cancer may be alone or associated with gallstones. The surest symptom of cancer is the persistent acholia of the stools. This is not absolute any more than variation in the presence or absence of bile in the stools speaks definitely for a gallstone; yet the general rule is a good one. Naunyn no longer puts much value on the condition of the gall bladder, whether contracted or dilated, but he does believe the absence of an enlarged spleen, with the prolonged existence of a questionable jaundice, to be a strong argument against gallstone obstruction. Other things being equal a

large palpable splenic tumor speaks for cholelithiasis.

A neoplasm with gallstones is still more difficult of diagnosis. Gallstones in old people with chronic jaundice make one suspicious. Cachexia suggests cancer only when of rapid development. Gallstones combined with marked jaundice and even large and repeated hemorrhages give rise to it only after months. Ascites requires consideration. Metastatic lymph glands in the left supraclavicular fossa occur too late to be of value.

The following test²⁸ for bile in the feces is most useful: It is often of great advantage to know whether bile is present or not in the feces, but previous methods have been too cumbersome for the general practitioner. The following method which is essentially that of Schorlenmar will be found most useful: Mix thoroughly a portion of feces, equivalent to a walnut in size, with 100 cc. of a concentrated aqueous solution of corrosive sublimate. Set aside for twenty-four hours in a wide-mouthed covered glass dish. All particles containing hydrobilirubin are colored red, while simultaneously all particles with bilirubin assume a green shade.

Reports of Societies.

SOCIETY OF AMERICAN BACTERIOLOGISTS.

SIXTH ANNUAL MEETING, ANN ARBOR, MICH., DEC. 27, 28 AND 29, 1905.

EDWIN O. JORDAN, PH. D., Chicago, President; F. P. GORHAM, Providence, Secretary.

SPROCHETAL INFECTION OF WHITE RATS AND OBSERVATIONS UPON THE MULTIPLICATION OF THE SPIROCHETES IN FLUID MEDIUM.

(Preliminary communication.) DIS. NOBIS, PAPENHEIMER and FLORENZO, Pathological Laboratory, Bellevue Hospital, New York. The authors have been able to inoculate successfully white rats and to keep the organism alive through about twenty-five generations. A subcutaneous inoculation of blood containing spirochetes is followed in two or three days by the presence of spirochetes in the circulating blood. These persist for from one to three days. In rats, no relapses occur, there are no obvious symptoms of illness, no local reaction and no visceral lesions of consequence except turgescence and enlargement of the spleen.

Immunity is probably conferred by previous infection. Inoculation of spirochetes into blood plus small doses of serum from animals that have gone through a previous infection retards or inhibits the development of the organism in the blood of the rats.

In human and rat blood, to which sodium citrate has been added, to prevent coagulation increase in the number of organisms evidently occurs. The authors have not been able to grow the organism in this medium beyond the third generation. Citrated rat blood, kept at room temperature for six days, retained unimpaired its infectious qualities.

AGGLUTINATION AND BIOLOGICAL RELATIONSHIP IN THE PRODIGIOSUS GROUP.

MARY HEFFERNAN, University of Chicago. A series of organisms with cultural characteristics like those of *B. prodigiosus* were examined for agglutinative

activity. This series had been under the writer's observation for five years, and the biological relationship of the twenty-two different members of the group had been fairly well determined.

Agglutination tests showed

(1) A high degree of interaction among those members of the group which were classed together by the sugar fermentation test.

(2) Identity of reaction of races known to have been derived from the same culture eight or ten years previously, and kept in different laboratories.

(3) Agglutinative reaction among those members of the group which tend to lose the power of pigment production, including one race which produces only a soluble red pigment. No reaction was obtained in this case with *B. fluorescens liquefaciens* or *B. lactis erythrogenes*.

(4) Much confusion and inequality of interaction among other members of the group closely related biologically.

The difference between agglutinogenic power and agglutinability was clearly due, in some cases, to a viscid capsular condition of the bacilli. On the other hand, readily agglutinable cultures did not possess correspondingly high agglutinogenic power.

Experiments made to determine the optimum temperature for the agglutination process showed that better results were obtained at either 0° or 55° C. than at room temperature or at 37° C. The action of convection currents in the tubes of serum dilution and bacilli at high and low temperatures was suggested as an explanation.

It was found that the addition of 1% formalin to salt solution suspensions of cultures made no difference in the agglutinations results, if the cultures thus formalized were allowed to stand for some time. Freshly added formalin seemed to inhibit agglutination.

Further experiments are under way to determine more exactly the action of formalin in the agglutination process.

A STUDY OF THE LAWS GOVERNING THE RESISTANCE OF *B. COLI* TO HEAT.

STEPHEN DEM. GAGE and GRACE VAN E. STOUTIGTON. Experiments were made in which it was determined that the great majority of the bacteria in any *B. coli* culture are destroyed by five minutes' exposure between 50° and 60° C. A few individuals, however, in each culture will survive much higher temperatures, in some cases remaining alive after exposure to 90° C. The very close range, about 10° C. of temperature at which the destruction of the majority of the individual bacteria occurred, as compared with the considerable range about 35° C. in the temperatures at which complete sterilization was effected, would indicate that the determination of this majority death point would be of more value in species identification than is the determination of the absolute thermal death point as at present employed.

Using thermal death point tests alone, this culture of *B. coli* would be included among the sporulating bacteria, although there was no morphological evidence that true spores, endospores, were produced.

Experiments were also made to determine whether, by successively selecting cultures originating from individual organisms which had survived temperatures above the majority death point and submitting these cultures to the death point tests, a race of organisms could be propagated in which the majority of the individuals would be able to resist higher temperatures than was the case with the original culture. The experiments ruled not only to produce such a race, but the results indicated the tendency toward

²⁸ Outlines of Medical Diagnosis, Eighth Edition, 1906, p. 30.

the production of a degenerate race whose majority death point remained the same as for the original culture, and whose absolute thermal death point was reduced toward the majority death point as the number of successive generations was increased.

BIRD PLAGUE.

(A preliminary note.) J. J. KINYOUN: Beginning in May, 1905, the writer examined several dead birds received from a dealer in Washington, D. C. On examination, all these presented certain definite lesions. The organs notably affected were the liver and spleen. A provisional diagnosis was first made of tubercle, but on examination it was negative. The lesions found in the liver and spleen were yellowish nodules of varying size which projected from the surface of the organs. The majority of the nodules were surrounded with a well-marked zone of inflammatory tissue. There were also spots of coagulation necrosis interspersed between the nodules. There was also found a catarrhal exudate affecting the upper air passage. In a few instances, there was enteritis. Direct microscopical examination showed a small bacillus with rounded ends, and morphological and tinctorial propensities resembled bacillus pestis. The organisms were present in enormous numbers in the nodules, particularly in those of the spleen. It could also be identified and easily isolated from the heart's blood and all other organs. The cultural characters are: it grows rather slightly on peptone bouillon, agar; it does not liquify gelatin, nor does it ferment any of the sugars except mannite. Grown on Hankin's salt agar it assumes pleo-morphism; closely resembles the organism of Bubonic plague. It grows best in bouillon or on agar containing a small amount of sterilized horse or calf serum. Calf serum agar containing 2% is coagulated. It is pathogenic to rabbits, sparrows, canaries, finches, mocking birds, thrushes and parakeets. Chickens are immune.

HOW SHALL THE POTENCY OF ANTITETANIC SERUM BE DETERMINED?

E. M. HOUGHTON, Ph.C., M.D., E. C. L. MILLER, M.D., and F. O. NORTHEY, M.D., Detroit, Mich.: Experience has shown that the Ehrlich test for determining the strength of antiphtheric serum is very reliable and has been adopted by the United States Department of Public Health and Marine Hospital Service as a method of standardizing this serum. Many methods are employed for measuring the strength of antitetanic serum, but none have been generally adopted in this country. The results of laboratory tests indicate that the sera found on the market vary enormously in strength, as tested by the modified Behring method. It would seem desirable that a method be adopted for testing antitetanic serum similar to that in use for determining the strength of antiphtheric serum, but it seems to the writers that the test animals should be guinea pigs and that the units of strength should be such that a curative dose of 10 cc. of antitetanic serum would contain approximately the same number of units as the curative dose of antiphtheric serum, as recommended by the United States Pharmacopeia.

A committee was appointed to consider the question of standardization of serums.

THE ACTION OF SO-CALLED COMPLEMENTOID IN IMMUNE SERUM.

W. H. MANWARING, Indiana University: Working with goat serum, immunized against sheep corpuscles, the action of so-called "complementoid" was estimated quantitatively and plotted graphically. From the

curves so obtained, the following conclusions are drawn:

(1) Hemolytic complementoid, added in increasing amounts to hemolytic serum, or to an artificial hemolytic amboceptor-complement mixture, causes, at first, a rapid increase in hemolytic power.

(2) This increase soon reaches an apparent maximum, after which a further increase in complementoid causes (i) no change, (ii) a rapid diminution in hemolytic power or (iii) a slow increase in that power.

(3) This variability in the action of complementoid when used in large amounts depends, at least in part, on the length of time the serum is heated to produce the complementoid.

(4) The action of complementoid is so pronounced that quantitative work that does not take its presence into consideration is practically valueless. This applies to such experiments as those forming the basis for the doctrine of "deviation of complement."

(5) It would be difficult to explain the action of complementoid by means of any of the existing hypotheses regarding the action of immune serum.

(6) No conclusion is yet drawn as to whether the so-called "complementoid" is really a degeneration product, or whether it may not be a mixture of split-products of other serum components, or, in part at least, certain thus far unrecognized thermo-stable components of normal serum.

NOTE ON THE THERMAL DEATH POINT OF B. DYSENTERIÆ SHIGA.

FROST and SWENSON, University of Michigan: Three strains of the Flexner-Harris type and one of the shiga type were used in the experiments. The technique employed was that recommended by the Bacteriological Committee of the American Public Health Association except in a few minor details.

It was found that the majority of organisms were killed between 55° and 60° C., but that frequently a relatively small number would persist up to 70° C. It was proven that the difference in resistance was due neither to the reaction nor to variations in the composition of the medium used.

During the discussion of this paper, it was suggested that the high resistance of some of the organisms might be due to masses of bacteria, the inner cells of which were protected to a certain extent from the heat.

A METHOD OF ISOLATING THE PNEUMOCOCCUS FROM MIXED CULTURES.

REUDIGER, Institute Infectious Diseases, Chicago: Basing his work on the demonstration of Hiss that pneumococci ferment inulin, while streptococci do not, the author has devised a litmus inulin agar medium in which the pneumococci develop as red colonies. By adding 1 cc. of sterile ascites fluid to each tube of media just before plating, a satisfactory growth is obtained in twenty-four to seventy-two hours. None of the other mouth bacteria studied produced red colonies on this medium. Twenty-two cultures of the pneumococcus were isolated and studied in detail.

OBSERVATIONS UPON THE PHAGOCYTIC POWER OF THE BLOOD OF NORMAL HUMAN BEINGS.

JOSEPH MCFARLAND and L'ENGLE, Philadelphia: The blood of fifteen presumably normal individuals were examined by the method devised by Leishman and modified by Wright and Douglas and the authors. The experiments were all performed between three and four in the afternoon, Staphylococcus pyogenes aureus being selected for the tests.

It was found that a uniform suspension was desirable since the number of bacteria taken up by the leucocytes varied with the strength of the suspension, and this was practically accomplished by comparing suspensions with a permanent turbidity standard. The clinical bearing of these experiments is indicated by the fact that those individuals whose phagocytic index was lowest had suffered from carbuncles, boils or became infected from slight causes. The authors approve of Marino's stain for demonstrating the leucocytes and contained bacteria and believe that the modified technique is adapted to clinical application. They conclude that there is no uniformity in the phagocytic indexes of the bloods of supposedly healthy individuals, that the phagocytic index of the same individual may or may not vary on different days and that while an exceptionally low phagocytic count usually indicates a present or past predisposition to suppuration, the phagocytic index may not be below the average in all cases in which there is a tendency to suppuration. The phagocytic index varied in the fifteen persons from 4.35 to 23.125.

THE VALUE OF THE VOGES-PROSKAUER REACTION.

N. McL. HARRIS, University of Chicago: The red coloration sometimes seen in fermentation tubes on standing, after the addition of caustic potash solution, and first described by Voges and Proskauer in 1898, has recently received renewed attention owing to the more recent work of Durham and MacConkey and Howe and MacConkey who recommend it for differentiating certain groups of bacteria. Harris, however, finds that the reaction is not confined to any one particular group of bacteria but occurs widespread and irregularly amongst bacterial species. The nature of the reaction is unknown.

THE PRODUCTION OF ACID AND ALKALI BY BACTERIA.

E. O. JORDAN, University of Chicago: Not only muscle sugar as shown by Theobald Smith in 1895 but other substances in ordinary nutrient media under the influence of bacterial activity produce strong acid reaction.

The liquefaction of gelatin by bacteria or their sterile enzymes always gives rise to a marked acid reaction which in some cases may be diminished by the simultaneous production of ammonia.

In nutrient agar, on the other hand, an alkaline change takes place. A standard reaction for culture media, therefore, is valid only as an initial reaction. Alkali production is not a synthetic process, as has been claimed by some but the result of decomposition of nitrogenous bodies.

Bacteria make their own reaction in broth, gelatin or agar. That reaction depends upon the nature of the bacterium, the composition of the medium and the precise period of growth when the reaction is tested.

MOSQUITO TRYPAOSOMES.

F. G. NOVY, W. J. McNEAL and H. N. TORREY, Ann Arbor, Mich.: Flagellates present in mosquitoes do not represent stages in the life history of intracellular parasites but are actually cultures in vivo of trypanosomes present in the blood of the animals or birds fed upon.

Of more than 800 mosquitoes captured along the river bank and fed upon perfectly clean animals such as rats, guinea pigs and pigeons and examined at varying intervals of thirty-six to seventy-two hours after feeding, 15% were found to have a flagellate infection of the intestinal tract.

Several distinct forms of trypanosomes were met with. With much difficulty, mixed cultures of two

forms were obtained,—*Herpetomonas subulata* associated with a minute coccus and *Crithidia fasciculata* in association with a yeast, these cultures now having been grown in the laboratory for six months.

The cultural forms of these two organisms are exactly the same as those seen in the gut of the mosquito. Animals inoculated with the cultures failed to show an infection.

The fact that the trypanosomes met with by various investigators in the stomachs of Tsetse flies, leeches, etc., are distinctly "cultural forms," showing the blepharoplast anterior to the nucleus, indicates that all such forms can be cultivated in the test tube. The *Herpetomonas* forms found are true cultural trypanosomes and future studies will probably reveal the blood parasite from which they are derived. The *Crithidia* show no undulating membrane in the ordinary truncated form, and on account of their peculiarity are to be considered for the present, at least, as representing a distinct genus.

SPIROCHETE OBERMEIERI.

F. G. NOVY and R. S. KNAPP, University of Michigan: In from thirty-six to forty-eight hours after an intraperitoneal inoculation of infected blood into white rats, the organism appeared in the blood but disappeared again within twenty-four hours, owing, as it was shown, to the formation of antibodies, and failed to reappear. The rats were then immune to subsequent inoculation. Spirochetal blood when kept *in vitro* retained its virulence for fifteen days.

The blood of rats, which have received repeated injections of spirochetal blood, shows marked preventive and curative action. If such blood be injected at any time before or after the injection of spirochetes up to the time when under normal conditions the organisms should appear in the blood, they fail to appear, although numerous in control animals. The injection of immune blood into rats having from 5 to 10 spirochetes to $\frac{1}{2}$ the oil immersion field causes disappearance of the organisms within one hour, with no subsequent reappearance, while in controls they persist for twenty-four hours. Spirochetal blood filtered through a Berkefeld filter under 50 lbs. pressure caused a typical infection when injected into rats. This result would appear to have a bearing on the so-called ultra microscopic organisms. While the relapsing fever of Europe and the sick fever of Africa are probably caused by different spirochetes, the authors think they have a basis for curative treatment for both.

ABNORMAL CHEESE TROUBLES DUE TO LACTOSE FERMENTING YEASTS.

H. L. RUSSELL and E. G. HASTINGS: The defective trouble in cheese here described is due to the presence of a milk sugar fermenting yeast. This yeast grows rapidly on milk or whey, especially when there is considerable acidity, producing alcohol, carbonic acid and undesirable flavored products. It is sterilized at 60° C. in ten minutes but resists 55° C. (the temperature used in the manufacture of Swiss cheese) for thirty minutes. This type of organism is much more abundant in regions where Swiss cheese is made than where the American cheddar system is practiced. Its presence is due to methods of manufacture which favor the production of lactic acid and the infection of the fresh milk.

THE EMPLOYMENT OF GLYCERIN AS A DIFFERENTIATING MEDIUM FOR CERTAIN BACTERIA.

EDUARDO ANDRADE, Florida State Board of Health: The addition of glycerin to nutrient media increases the acid-producing power of certain intestinal bacteria.

Acid fuchsine (Gruebler) neutralized to the point of decolorization with caustic potash has proved to be a very sensitive indicator. It does not affect the growth of bacteria. The results obtained with the more common media were not satisfactory owing, probably, to changes of reaction in sterilization. The best results were obtained with Dunham's peptone solution containing 6% glycerin and 2% acid fuchsine.

The dysentery group shows quite a range in acid production as regards both time and amount. Of this group; the bacillus Y of Hiss and Russell, B. paracolon, Strong and Kurth, form a distinct group of themselves.

ABSORBENT COTTON AS A MEDIUM FOR DISTRIBUTING *PS. RADICICOLA*.

H. A. HARDING and M. J. PRUCHE, New York Agricultural Station: Absorbent cotton wrapped in paper and tin foil is now widely used by nitro-culture companies as a means of distributing *Ps. radicicola*.

Experiments have shown that the organisms are unable to withstand the dessication accompanying this method.

Repeated examinations of twenty-five separate packages of cotton gave only a occasional colony resembling *Ps. radicicola*, and in most cases not a single suspicious colony was found.

As a check on the accuracy of these examinations, duplicate samples from six packages were examined in other laboratories.

Two separate laboratory trials with bouillon cultures of *Ps. radicicola* placed upon absorbent cotton showed that all but an occasional organism died within a few days.

The details of the work are given in the New York Agricultural Experiment Station *Record*, Bulletin 270

ISOLATION OF TRYPANOSOMES FROM ACCOMPANYING BACTERIA.

F. G. NOVY and R. S. KNAPP, Ann Arbor, Mich.: By means of a small glass spatula made by drawing out the end of a glass rod, a little of the mixed culture was spread in a series of streaks over six Petri dishes containing solidified blood agar. The sealed dishes are then set aside at room temperature for ten to twelve days. The last plate or two of the series will be found to show isolated colonies of trypanosomes which can then be transplanted in the usual way to the test tube. In studying the flagellates found in the intestinal canal of insects and other sanguivora, the intestinal contents can be spread directly over the plates in the manner indicated.

A NOTE ON THE INDOL PRODUCING BACTERIA IN MILK.

S. C. PRESCOTT, Massachusetts Institute Technology: The occurrence of indol-producing bacteria in milk suggests the possibility of some connection between these organisms and the intestinal diseases often so prevalent in children fed on milk.

A large number of samples of fresh milk from 175 different farms have been examined to determine the relation between the indol-producing bacteria and the total number present. The samples were in general about six hours old at the time of examination.

In all, 524 samples were examined ranging in total numbers from less than 5,000 to 121,000,000 bacteria per cubic centimeter.

Twenty-five per cent gave strong indol reaction.

There was a constant relation between total count and the occurrence of indol, the high count samples giving the largest per cent with indol reaction. In samples having above 1,000,000 bacteria to the cubic

centimeter, 70% showed indol production, while in those below 25,000, indol production was found in but 12%.

KINDS OF BACTERIA CONCERNED IN SOURING OF MILK.

P. G. HEINEMANN, University of Chicago: All so-called lactic acid bacteria belong to two groups—the colon-aerogenes group and the streptococcus group. Investigations lead to the following conclusions: *Bacillus acidilactici* is a myth. The ordinary bacteria producing lactic fermentation are *Bacillus aerogenes* var. *lacticus*, and *Streptococcus lacticus*. The possibility of *B. coli* participating in lactic fermentation is not excluded. *Streptococcus lacticus* (Krusse) agrees in morphological, cultural and coagulative properties with pathogenic, fecal and sewage streptococci.

Souring of milk is caused by co-operation of both groups of bacteria and is participated in by peptonizing bacteria always present in milk. Gas is produced by *Bacillus aerogenes*, var. *lacticus*, but, as a rule, is checked and finally stopped by the ascendancy of the *Streptococcus lacticus* (Krusse). Acids produced during fermentation by both classes to a marked degree. Lactic acid bacteria are of intestinal origin and gain access to the milk with particles of cow feces.

Artificial lactic acid fermentation in sterilized milk can be produced by inoculation of cultures of either group, or better, by the two groups combined. Since *Streptococcus lacticus* (Krusse) is invariably present even in fresh milk collected with good precautions, the sanitary significance of streptococci in market milk will need further investigation.

THE MICROSCOPIC ESTIMATE OF BACTERIA IN MILK.

DR. F. H. SLACK, Boston Board of Health Laboratory: A definite quantity of milk (2 cc.) is centrifuged for ten minutes in a special apparatus by which the sediment is collected on a rubber stopper and the sediment thus obtained is smeared evenly over a known space (4 sq. cm.), dried and stained with methylene blue.

Microscopic examination shows approximate number and morphology of bacteria present as well as the presence of pus and streptococci.

As a rough estimate, each bacterium found in a representative $\frac{1}{2}$ oil immersion field represents 10,000 bacteria to a cubic centimeter in the sample of milk examined.

Advantages are: rapidity of examination, accuracy, easily learned technique, lack of much costly apparatus.

The writer believes the method applicable for certifying milk.

THE QUANTITATIVE DETERMINATION OF LEUCOCYTES IN MILK.

ARCHIBALD R. WARD, University of California: A series of duplicate determinations from the same sample of milk were made by the method of Doane and Buckley of the Maryland Agricultural Experiment Station and by the method described by Dr. Stewart of the Philadelphia Bureau of Health.

The Doane-Buckley method gave more satisfactory results with determinations than did that of Dr. Stewart.

The numerical results by the Doane-Buckley method varied from four to forty times higher than those obtained by the Stewart method.

LACTIC ACID BACTERIA.

W. M. ESTEN, Wesleyan University: Samples of milk were studied from nearly every section of the United States and Canada. Two distinct classes of

lactic acid bacteria were found. First, the gas-forming or aerobic group consisting of the *B. coli communis* and *B. lactis aerogenes* with all of its varieties. This group may be considered as a detrimental contamination to milk and its products. Second, the non-gas-forming, or facultative anaerobic group which in the author's opinion consists of but one species of bacterium (*Bacterium lactis acidii*) with its variations of form and of power for curdling milk. Owing to these differences the organism has been described under various names by different investigators. Its characteristics of growth on various media are, however, always distinctive, the most favorable media being milk, milk agar, agar and dextrose bouillon. Its presence in milk is beneficial as it opposes the growth of putrefactive and disease organisms.

Recent Literature.

Differential Diagnosis and Treatment of Disease.

A Textbook for Practitioners and Advanced Students. By AUGUSTUS CAILLÉ, M.D., Fellow of the New York Academy of Medicine; Member and ex-President of the American Pediatric Society; Professor of Diseases of Children, New York Post-Graduate Medical School and Hospital; Visiting Physician to the New York Post-Graduate and German Hospitals; Consulting Physician to Isabella Home and Hospital, etc. Illustrated. Pp 867. New York and London: D. Appleton & Co. 1906.

The aim of the author in offering this book to the medical profession is stated in his own words, as follows: "To bring the broad domain of practical medicine fairly within the grasp of the family physician, and to assist the advanced student in acquiring a clinical foundation has been my aim." It has further been the desire of the author "To re-establish the relations of internal medicine, surgery and the several specialties," and so far as possible to break down what he considers, with much justice, the artificial and arbitrary barriers which appear to separate the various branches of medicine. Although assisted by various collaborators, the author has written the great bulk of the book himself.

In carrying out his very worthy aim Dr. Caillé has discussed briefly and with the aid of numerous illustrations a large variety of subjects connected with medicine in its broad sense. The brevity of the various sections is a noticeable feature of the work, and should commend itself to the reader who must, however, recognize the fact that such brevity is not in all cases compatible with the proper appreciation of the importance of the subject matter. We recommend the book as a well arranged and adequate epitome of the present status of diagnosis and treatment in the broad field of so-called general medicine inclusive of what have come to be known as specialties.

It is altogether advisable that such a survey as this should appear from time to time not that it is likely to check the beneficent progress of specialism, but that it may do its share towards impressing the unity of the various departments of medical theory and practice.

Lectures upon the Principles of Surgery, delivered at the University of Michigan by CHARLES B. NANCY, A.M., M.D., LL.D., Professor of Surgery and of Clinical Surgery in the University of Michigan; Professor of Surgery in Dartmouth Medical College; Chief Surgeon, United States Volunteers, etc. With an appendix containing a résumé of the principal views held concerning inflammation by WM. A. SPITZLEY, A.B., M.D., Late Senior Assistant in Surgery, University of Michigan. Second edition, thoroughly revised. Philadelphia and London: W. B. Saunders & Co. 1905.

This is the second edition of this series of lectures on a most interesting subject. The book is divided into thirty-six lectures which the author gives to his students at the University of Michigan. It takes up the fundamental principles of injury, inflammation and repair, the various systemic infections, hemorrhage, the treatment of wounds, sterilization of materials, shock, collapse, the various types of delirium, and anesthesia.

The lectures are written in a facile style and are interesting to read. A concise résumé of the principal views held concerning inflammation is appended at the end by Dr. W. A. Spitzley.

There are few subjects in surgery that have undergone more rapid changes than that of the process of repair. The term "inflammation" has been regarded by some pathologists as so inexact that it would be desirable to abolish it. The term, however, expresses a condition which is so common and so well recognized that it would be impractical to give it up.

On the whole, although we differ from some of the views expressed by the author, we like the book.

The Animal Parasites of Man. A handbook for students and medical men. By MAX BRAUN. Third enlarged and improved edition with 294 illustrations in the text. Translated from the German by PAULINE FALKEL, brought up to date by LOUIS W. SAMPSON, M.D., and FRED. V. THEOPHIL, M.A. New York: William Wood & Co. 1906.

The study of animal parasites, spoken of more frequently as medical zoology or parasitology, has grown within the past decade into a specialty which can no longer be ignored by medical schools. Parasites are evidently growing more numerous in temperate climates, owing to more extensive intercourse with the tropics and the influx of parasite-ridden foreign populations. Some of these introduced parasites will without doubt permanently establish themselves. The future physician and sanitarian will do well to prepare himself to recognize and deal with them. In the teaching of this subject the difficulty hitherto has been to recommend a textbook which would supplement the laboratory instruction by familiarizing the student with technical terms and furnishing satisfactory illustrations. The compact textbook of Max Braun has been the best

within reach for this purpose. Yet few medical students are capable of using textbooks in German or French. Hence the translation before us is very welcome although, unfortunately, the original price of the German edition has been more than doubled. Little need be said in praise of Braun's textbook as it is now a well-recognized aid in teaching this subject. The author has handled a difficult subject with skill, and the various editions have kept pace with the rapid growth of the subject.

Those concerned with the translation have been faithful to the original text and nomenclature and have placed their additions and emendations in brackets.

Inasmuch as this book appears for the first time before the English-speaking public it may not be amiss to outline briefly its contents. Beginning with the protozoa we find 127 pages devoted to them. To the flatworms (flukes and tapeworms) belong 134 pages. The round worms, those perhaps most frequent in our climate, are discussed in 84 pages. The remainder of the volume, about 100 pages, describes the most important ecto-parasites, such as ticks, itch-mites, lice, flies and mosquitoes, together with many rarer forms only occasionally encountered. Among the additions to the original text made by the English editors may be mentioned 5 pages on the recently discovered fluke, *Schistosomum japonicum*, with illustrations, a number of pages on various species of filaria and rather full accounts of ticks, their life-history and classification. The chapter on mosquitoes has also been considerably enlarged and illustrations of various parasite-carrying flies inserted.

The book may also be recommended as a valuable general guide to the physician, although the more careful study of any forms which he may undertake will demand larger works, such as those of Leuckart, Railliet, Blanchard and others.

Gefässkrisen. Von PROF. DR. J. PAL, k.k. Primararzt und Vorstand der I. medicin. Abteilung des k.k. Allgem. Krankenhauses in Wien. Illustrated. Leipzig: S. Hirzel. 1905.

In this volume of 275 pages Pal has brought together a large array of valuable facts from a special standpoint relating to certain symptoms on the part of the vascular apparatus. The design is not only to widen our view of the symptomatology of certain distressing and dangerous vascular conditions but also to pave the way for a rational prophylaxis. Considerable experimental work has been added to the clinical details. The general types of disturbance taken up are the vascular crises occurring in lead poisoning, in arteriosclerosis, in tabes and in certain affections of the kidneys and of the gall bladder. Preceding the clinical descriptions is an admirable systematic exposition of the general subject of what the author calls "Gefässkrise," and which he thinks may often be regarded as a separate affection. The book is a valuable addition to our knowledge of an important subject from an un-

usual standpoint, and is to be commended to the attention of all interested in the fundamental problems of internal medicine.

Adjuster's Manual. For the Settlement of Accident and Health Claims. By C. H. HARRBAUGH, M.D., Medical Director American Assurance Company, formerly Demonstrator of Syndes-mology in the Jefferson Medical College of Philadelphia, Examiner and Adjuster for Insurance Companies and Other Corporations, President Philadelphia Medical Examiners' Association. New York: The Spectator Company. 1905.

This is a small book mainly designed to make certain practical suggestions relating to the settlement of claims, and as such contains many facts of interest and of value to those engaged in this sort of work. The book naturally suffers from its brevity, and many of the questions discussed are hardly to be despatched satisfactorily in so small a compass. The book is attractively bound in flexible leather covers.

A Practical Treatise on Fractures and Dislocations. By LEWIS A. STIMSON, B.A., M.D., LL.D. (Yalen.), Professor of Surgery in Cornell University Medical College, New York; Surgeon to the New York and Hudson Street Hospitals; Consulting Surgeon to Bellevue, St. John's, and Christ Hospitals; Corresponding Member of the Société de Chirurgie of Paris. Fourth edition, revised and enlarged. With 331 illustrations and 46 plates in monotint. New York and Philadelphia: Lea Brothers & Co. 1905.

Dr. Stimson's "Treatise on Fractures and Dislocations" has become a standard work. The previous edition was published five years ago, and this last edition (fourth) has a great deal of new and valuable information. The knowledge gained by the use of the x-ray in fractures near joints and the so-termed "open" treatment of fractures are thoroughly presented.

The writer's position in reference to the operative treatment of fractures is conservative, and while he considers that operations may be done in the treatment of fractures, yet he by no means advises their indiscriminate application.

The operative treatment of old dislocations is considered at length. Many new illustrations have been added and many of the time-honored ones have been retained.

The valuable material of the Hudson Street Hospital (House of Relief) has furnished a large number of cases that have come directly under the observation of the author. In the period from 1894 to 1903 over 12,000 fractures and over 1,000 dislocations were treated at this hospital.

Dr. Stimson's book stands forth prominently as one which contains authentic material, carefully collected and thoroughly analyzed. New information is continually being obtained regarding fractures and dislocations, and it will be a relatively short time before a new edition will be necessary.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, JUNE 21, 1906.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico. \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 707 Paddock Building, 101 Tremont Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money order, draft or registered letter, payable to

D. C. HEATH & COMPANY,
120 BOSTON STREET, BOSTON, MASS.

A CONGRESS ON QUACKERY.

THE multiplication of congresses seems to go on steadily. One of the latest which has been called to our attention is a Congress on Quackery which has recently met in Paris for the purpose of discussing illegitimate methods of medical practice and of repressing charlatanism. The papers read at this meeting no doubt brought out many facts not hitherto generally known. The ingenuity of the fraudulent practitioner was amply demonstrated and a vast number of more or less illegitimate methods of practice were brought to light. It appears that sorcery yet flourishes in France. Miracles as we know, are still performed, there are also bone setters and others who claim special virtue for some ointment or herb. In fact, quackery flourishes in its diversified forms in France as elsewhere in the world, and we imagine it will continue to flourish so long as men find inevitable disappointment in the regular practice of medicine and the claims of false systems are sufficiently advertised. The secret which lies at the basis of the multitudinous quack systems is on the one hand human gullibility and the inherent desire for life and health, together with our fundamental lack of knowledge of the healing of many diseases. It is altogether natural that a man ignorant of the limitations of medical knowledge should try any system when his life is at stake if the legitimate practice of medicine fails in its efforts at cure. It is a pitiable fact but one none the less to be reckoned with, that freedom of choice in matters of personal health except as detrimental to the body politic cannot be interfered with by legislative

enactment. Experience has unquestionably shown that increasing intelligence on the part of the people at large is its only safeguard against the systems of quackery which, without such legislation, they are only too willing to adopt if it offers even a vague hope of relief from their sufferings. The campaign which must be waged by the regular practice of medicine is not one of restrictive legislation, except in flagrant cases, but rather of unceasing effort toward the education of the public, that the great mass of useful knowledge regarding medical matters may be found within the ranks of the regular medical profession, and that, however striking individual so-called cures may appear, they are explainable on principles well understood by legitimate practitioners. Although it is somewhat appalling to see what a mass of fraudulent practice and gross superstition was brought to the surface at this French congress, we are none the less optimistic enough to believe that quackery is, on the whole, diminishing and that intelligence among the people regarding medical matters is increasing. There is considerable evidence to show that, as the people at large become better acquainted with disease and its mystery is lessened through legitimate publicity, a change will be noticeable toward the fraudulent methods which now flourish in our midst. Education in a broad sense can alone bring this result to pass, and, although we have small confidence that charlatanism can be ultimately repressed by any other means, we can certainly see in the work of this French congress another step in the work of freeing the popular mind of those superstitions and false hopes which must always in the long run result to their detriment.

COOPERATION IN PREVENTION AND CONTROL OF TUBERCULOSIS

Few movements in preventive medicine have recently made such rapid and wide-spread progress as that relating to the prevention and control of tuberculosis. The professional and lay minds have been aroused alike to a degree bordering upon enthusiasm. That erroneous ideas should be formed relative to many of the questions involved was inevitable. The danger from such errors became all the greater on account of the fact that in many localities lay organizations have undertaken the work independent of medical advice or supervision. For this reason the recent action of the district committees of the Massachusetts Medical Society in organizing for

co-operative work for the prevention and control of tuberculosis is most important. The retiring president of the Massachusetts Medical Society, Dr. Arthur T. Cabot, in his visits to the various district societies, pointed out how effective action might be taken, with the result that each district appointed a committee to consider the question in its various phases. These committees met Tuesday, June 12, at the new buildings of the Harvard Medical School and organized a state association. Dr. Arthur T. Cabot was elected president and Dr. Thomas F. Harrington, of Lowell, secretary. The chairmen of the various district committees with the above officers are to constitute an executive committee. Each district is to report upon the conditions within its borders, and from these reports it is hoped to present a clear and comprehensive view of conditions prevailing throughout the state. Such a report will be invaluable as well as authoritative in directing the energies of those individuals or societies undertaking this line of work. We know of no other state organized along these lines and we congratulate the state society and its officers.

MEDICAL NOTES.

PLAGUE IN INDIA. — Deaths from plague in India for the week ending April 28 are said to have been 1,700 with a total of over 20,000 cases.

CANCER RESEARCH. — An international conference on the subject of cancer, it is announced, will be held at Heidelberg from Sept. 24 to 27, in connection with the opening of the institute for cancer research.

A CENTENARIAN. — The death is announced of Fanny Lomax in Washington, at the reputed age of over one hundred and five years. She was formerly a slave, and it is said that her age is authenticated through the family Bible belonging to the family of her former master. Born in 1801, she lived in the administrations of every president excepting the first.

BENEFICIARIES OF THE CARNEGIE FUND FOUNDATION. — Last April Mr. Carnegie gave \$10,000,000 in steel corporation bonds, the income of which was to provide retirement allowances for teachers in the universities, colleges and technical schools of the United States, Canada and Newfoundland. The available income, about \$70,000, is to be distributed this year to approximately fifty persons. Among these are distinguished

men from Columbia, New York University, Cornell, Princeton, Western Reserve, Yale, Lafayette and Harvard.

AMERICAN INSTITUTE FOR SCIENTIFIC RESEARCH. — As an outgrowth of the Society for Psychical Research a new organization has been perfected to be known as the American Institute for Scientific Research. This organization has been granted a perpetual charter by the state of New York. The object of the institute will be to organize investigations in abnormal psychology and to extend knowledge of this branch along scientific lines. Prof. James H. Hyslop has been appointed secretary, and among the Board of Trustees occurs the name of Dr. James J. Putnam, of Boston.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, June 20, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 36, scarlatina 34, typhoid fever 10, measles 56, tuberculosis 38, smallpox 0.

The death-rate of the reported deaths for the week ending June 20, 1906, was 14.19.

BOSTON MORTALITY STATISTICS. — The total number of deaths reported to the Board of Health for the week ending Saturday, June 16, 1906, was 190, against 185 the corresponding week of last year, showing an increase of 5 deaths and making the death-rate for the week 16.65. Of this number 94 were males and 96 were females; 184 were white and 6 colored; 130 were born in the United States, 55 in foreign countries and 5 unknown; 50 were of American parentage, 117 of foreign parentage and 23 unknown. The number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 35 cases and 4 deaths; scarlatina, 17 cases and 1 death; typhoid fever, 15 cases and 1 death; measles, 58 cases and 1 death; tuberculosis, 40 cases and 19 deaths; smallpox, no cases and no deaths. The deaths from pneumonia were 23, whooping cough 3, heart disease 23, bronchitis 5 and marasmus 6. There were 17 deaths from violent causes. The number of children who died under one year was 37; the number under five years 56. The number of persons who died over sixty years of age was 34. The deaths in public institutions were 82.

There were 4 cases and 2 deaths reported from cerebrospinal meningitis during the week.

A CENTENARIAN. — The death of Mrs. Jane Mansfield, of Lynn, is announced at the reputed age of one hundred and five years.

PRESIDENT OF THE MASSACHUSETTS MEDICAL SOCIETY. — Dr. George W. Gay, of Boston, has been elected president of the Massachusetts Medical Society for the ensuing year. This is a worthy recognition of Dr. Gay's long service to medicine in this state.

BEQUESTS TO HOSPITALS. — By the will of the late Miss Ella A. Bartlett, of Kingston, the Hale Hospital of Haverhill receives \$5,000 for the benefit of Kingston patients, and the Cottage Hospital of Exeter \$3,000 for the benefit of East Kingston patients.

DEFEAT OF BILL IN RELATION TO FREE HOME FOR CONSUMPTIVES. — After much effort had been made in its behalf the bill before the legislature to pay from the state treasury ten thousand dollars to the Free Home for Consumptives in Boston has been defeated. It is rare that a bill has been so vigorously pushed as this, and it is certainly a source of satisfaction that in spite of all efforts in its behalf it has not been allowed to pass. The principle involved in such a bill is a dangerous one, committing the state, as it would have done, to the support of a purely private enterprise. Without reflecting in the least on the enterprise which the Free Home is undertaking, it is evident that as a private institution it should be maintained by private funds and not, even in part, by the state.

APPOINTMENT OF DR. GEORGE BLUMER. — Dr. George Blumer has been appointed to the Chair of the Theory and Practice of Medicine in Yale University to succeed the late Dr. John S. Ely. Dr. Blumer was formerly a director of the Bender laboratory at Albany, and Professor of Pathology at the Albany Medical College, and until recently connected with the Medical Department of the University of California.

HOSPITAL FOR CRIPPLED CHILDREN. — A hospital for crippled children is projected to be located on the north end of Prudence Island in Narragansett Bay. This has been made possible through the liberality of Mr. James A. Garland, of New York. The hospital is intended for children who cannot be properly taken care of at home and for those sent to the Rhode Island Hospital in Providence who could be more effectually treated away from the city.

NEW YORK.

BEQUESTS. — Among the charitable bequests in the will of the late Mrs. Catharine L. R. Catlin, of New York, are \$5,000 to the New York Hospital and \$4,000 to St. Luke's Home.

ISABELLA McCOSH INFIRMARY. — Among the gifts announced at the commencement of Princeton University, was the sum of \$31,000 raised by the Ladies' Auxiliary toward the endowment of the Isabella McCosh Infirmary.

APPOINTMENT OF DR. A. B. LAMP. — On June 8, Dr. Arthur Becket Lamp, who has been filling the chair of Dr. Richards at Harvard during the absence of the latter in Europe, was appointed director of the Havenmeyer Laboratory of Chemistry, New York University, to succeed Dr. Morris Loeb.

DR. W. F. HORNADY HONORED. — At the one hundred and nineteenth annual commencement of the Western University of Pennsylvania held June 12, the degree of Doctor of Science was conferred on Dr. W. F. Hornady, the director of the New York Zoological Park.

GIFT TO VASSAR COLLEGE. — At the commencement of Vassar College, Poughkeepsie, on June 13, it was announced that Dr. Henry M. Saunders, of New York, a member of the board of trustees, had made a gift to the college of \$75,000 for the erection of a building, as yet undesignated, as a memorial to his wife.

CORNELL UNIVERSITY MEDICAL COLLEGE. — At the annual commencement of Cornell University Medical College, held June 13, there were fifty-eight graduates, six of them women. The vice-president of the class was Toyohiko Takamizawa, son of a prominent Japanese official.

YEARLY FINANCIAL REPORTS OF HOSPITALS. — The superintendents of the New York, St. Luke's, Roosevelt and Presbyterian hospitals have decided to adopt and recommend a uniform system of yearly financial reports and statistics for the benefit of their patrons. This, it is stated, is in response to criticism of hospital management and a falling off in contributions to these institutions.

DEGREES AT COLUMBIA UNIVERSITY. — At the annual commencement of Columbia University, held June 13, 1110 degrees were conferred. Among the honorary degrees, that of Doctor of Science was conferred on Daniel Grand Elliot, Curator of Zoology, Field Columbian Museum,

Chicago, Ill., and Baron Kanehiro Takaki, M.D., F.R.C.S., Surgeon General (Reserve) of the Japanese Navy. In the medical department (The College of Physicians and Surgeons) fellowships of the Alumni Association, value \$500 each, were awarded to Oliver Smith Strong, Ph.D., for research work in pathology and Herman von W. Schulte, M.D., for research work in anatomy. The Alonzo Clark scholarship, to promote the discovery of new facts in medical science, annual value about \$600, was awarded to A. B. Wadsworth, M.D.

Miscellaneous.

COUNCILLORS' MEETING.

THE annual meeting of the Councillors of the Massachusetts Medical Society was held in the Medical Library, Boston, on Tuesday, June 12, 1906, at 5 P.M. One hundred and forty-three councillors were present.

The secretary reported that 283 Fellows had been added to the society since the last annual meeting, and that 41 deaths had been recorded.

The treasurer, Dr. Buckingham, reported that the receipts of the society, including the balance of \$11,199.05 a year ago, had been \$27,178.96; the expenditures \$15,544.37, leaving a balance on hand of 11,634.59.

In accordance with the recommendation of the Committee on Membership and Finance, it was voted that \$4,500 of the surplus in the treasury be distributed among the district societies.

Dr. G. G. Sears, for the Committee on State and National Legislation, reported that during the present session of the legislature they have appeared, either personally or by representatives, before the committees of the state legislature in favor of the following bills:

To regulate the height of buildings outside of the city of Boston.

To provide for the better care of the health of pupils in the public schools.

To regulate the sale of patent, proprietary and other medicines containing poisonous drugs.

To regulate the sale of adulterated foods and drugs.

According to the last bulletin issued by the legislature the only one of these bills which has been enacted is that regulating the sale of adulterated foods and drugs.

The others have passed one branch of the legislature, but have not been reached in the other. We have not succeeded in all cases in obtaining as stringent legislation as was desired.

Opposition to the bill to prohibit vivisection was left in the hands of Dr. H. C. Ernst. The bill was defeated in committee. The hardest work done by the committee was in opposing a bill to establish a state board of examination and registration in osteopathy. It was finally

defeated in the legislature as a result largely of the work done by the auxiliary Legislative Committee of the Massachusetts Medical Society.

The committee believes that the Auxiliary Legislative Committee is of great use in directing popular opinion and in bringing proper pressure to bear upon the members of the Legislature; and that a larger committee, in which each senatorial district shall be represented by a member, would be a more useful body than the present one in which each district of the society is represented.

The report of the committee was accepted.

In accordance with the report of the Committee on Nominations the following were elected for the offices of the society for the ensuing year:

President, Dr. G. W. Gay, of Newton; vice-president, Dr. Leonard Wheeler, of Worcester; corresponding secretary, Dr. C. W. Swan, of Lowell; recording secretary, Dr. F. W. Goss, of Roxbury; treasurer, Dr. E. M. Buckingham, of Boston; librarian, Dr. E. H. Brigham, of Brookline.

Dr. J. F. A. Adams, of Pittsfield, was chosen orator for the annual meeting of the society in 1907.

The following standing committees were appointed:

Of Arrangements: A. P. Perry, G. S. C. Badger, Lincoln Davis, L. W. Gilbert, C. C. Simmons, G. H. Francis. On Publications: O. F. Wadsworth, G. B. Shattuck, H. L. Burrell. On Membership and Finance: C. M. Green, F. W. Goss, Walter Ela, A. Coolidge, Jr., H. A. Wood. To Procure Scientific Papers: R. C. Larrabee, J. B. Blake, B. P. Croft, M. D. Clarke, Charles Harrington. On Ethics and Discipline: C. G. Carleton, Leonard Wheeler, Edward Cowles, J. F. A. Adams, J. A. Gage. On Medical Diplomas: H. E. Marion, O. F. Rogers, H. W. Newhall. On State and National Legislation: G. W. Gay, G. G. Sears, H. P. Bowditch, S. D. Presbrey, D. D. Gilbert.

The resignation of Dr. C. W. Swan, as corresponding secretary, was accepted.

Dr. Cheever spoke of the prolonged service of Dr. Swan as an officer of the society, and moved that the sincere thanks and sympathy of the councillors be presented to Dr. Swan. Adopted unanimously.

The recording secretary, Dr. Goss, was elected also as corresponding secretary for the ensuing year.

Dr. F. C. Shattuck, for the committee appointed at the last meeting of the councillors, to consider and report on the advisability of such changes in the By-Laws as may bring them into conformity with present-day practice, reported, recommending the following changes:

1. In By-Law 1, line 9, omit "and surgical." Omit lines 9 to 13 inclusive, "and" — "years." In line 16 substitute "treat" for "cure."

In lines 16 and 17 omit "Spiritualism, homeopathy, allopathy, Thomsonianism, Eclecticism or" — and "other"; omit "irregular or."

If the proposed changes in By-Law 1 are adopted, the amended By-Law would read:

"Candidates for admission into the Massachusetts Medical Society may be either male or female; and every candidate must by examination, as hereinafter provided, satisfy the Censors of the Society that he is not less than twenty-one years of age; that he is of sound mind and good moral character; that he has a good general English education; that he has a knowledge of the principles of experimental philosophy; that he has such an acquaintance with the Latin language as is necessary for a good medical education; that he has studied medicine at an authorized medical school, recognized by the Councilors of the Society, and has received a diploma from such school; that he does not profess to treat diseases by, nor intend to practise, any exclusive system, generally recognized as such by the profession or declared so by the Councilors of the Society; and that he possesses such other qualifications as the Society may deem necessary."

II. Omit By-Law IX, *in toto*.

III. Change By-Law X so as to read:

"Any Fellow of this Society who advertises for sale, or otherwise offers to the public, any medicine the composition of which he keeps secret, or who offers to treat any disease by any such secret medicine, or by any secret treatment, shall be liable to expulsion, or to such other penalty as the Board of Trial may have power to inflict."

Dr. Cheever moved to amend the Committee's report by inserting in By-Law I, line 16, after the word "practise," the words, "or to assume the name of" so that the clause would read "that he does not profess to treat diseases by, nor intend to practise, or to assume the name of, any exclusive system," etc.

Discussion, but no action, followed the offering of these resolutions and they were reserved in accordance with the By-Laws, for presentation to the Society on the next day.

[At the meeting of the Society on June 13, after an animated discussion participated in by Drs. F. C. Shattuck, Cheever, Folsom, Harvey, Whentley, Lambert and F. B. Harrington, the amendment proposed by Dr. Cheever was not adopted, and the amendments offered by the Committee were passed.]

Correspondence.

THE HOUSE OF DELEGATES, AMERICAN MEDICAL ASSOCIATION.

Boston, June 14, 1906.

Mr. Editor.—To those who remember the methods of transacting the business of the American Medical Association in vague forty years ago the plan in use at the present time, as exemplified at the recent meeting in this city, possesses no little interest. Formerly too much of the valuable time of the Association was frittered away in useless discussion, which not infrequently resulted in proceedings that were anything but dignified or worthy of any medical association.

In these later years all of that has been changed for the better, and the business of the Association is transacted

in a body especially designed for that purpose, the House of Delegates. The necessity for a comparatively small working body will be apparent when one remembers that this Association has nearly 24,000 active members, and that through its constituent associations it is affiliated with about 60,000 physicians. The circulation of its *Journal* last year reached nearly 10,000 copies.

The House of Delegates is composed of delegates from the constituent associations or state medical societies, from the scientific sections of the American Medical Association, from the army and navy departments, and from the United States Public Health and Marine-Hospital Service.

Each state society is entitled to send one delegate for every 500 active members or fraction thereof. New York heads the list with 13 delegates, all of whom were present at this meeting. Illinois comes next with 8 members, 7 present. Pennsylvania has 7, and all were registered. Massachusetts stands fourth on the list with 6 delegates, and all were in attendance. The total number of delegates registered at this meeting was 123. The number is limited to 150. A committee of apportionment is appointed every third year, this being the triennial year, to decide as to the number of delegates each state is entitled to send.

The delegates are appointed by the president of the state associations, and confirmed by the council (in Massachusetts). Members of not less than two years' standing are eligible, and are appointed for two years.

The House of Delegates elects all the general officers of the Association, the president, four vice-presidents, general secretary and treasurer. It also elects the nine trustees, three each year for terms of three years each. The officers are elected annually and hold office one year, or until their successors are chosen and installed. With one exception the officers are nominated orally in open meeting of the House of Delegates, but the nominating speech must not exceed two minutes. The general secretary is nominated by the Board of Trustees. The election of the general officers is by ballot, and takes place on the afternoon of the third day of the annual meeting.

The importance of the position of delegate will be apparent when it is remembered that the major portion of the business of this great representative association, one of the largest in our profession in the world, is transacted by this body. The financial affairs are in the hands of the trustees, who must be members of the House of Delegates, but they have no vote.

It is especially essential that only men of sound business ability and of a considerable experience, who can and will give their time and attention to the work, should be sent to the House of Delegates. They can give little time to the sections or to anything else while the House is in session. The meetings of the delegates begin the day previous to the general meetings, and usually occupy a good portion of four days.

Probably as little time was wasted and as few personalities were indulged in at the late meeting as can be expected in assemblies of this character. As a rule the work was done harmoniously and with reasonable expedition.

One of the more important acts of this House of Delegates was the adoption of an amendment to the By-Laws placing the arrangements for the annual meetings in the hands of the trustees instead of in charge of a committee of arrangements, as heretofore. It is to be hoped that hereafter by this action the Association will assume the running expenses of the meetings, as the rent of halls, clerk hire, printing, etc., instead of requiring the local profession to bear that expense. The attendance has grown so large in recent years that in some places the expense has been prohibitory of meetings.

The ordinary expenses of the annual meeting now amount to several thousand dollars and are constantly increasing. For this reason, if for no other, it would seem only just and reasonable for them to be assumed by the Association. The same profession will find plenty of ways of disposing of money in the various entertainments that have come to form a part of the annual meetings. The Association has a good property, a handsome surplus, and the financial officers seem to have been admirably managed. It is worthy of the cordial support of the entire profession of the country.

Very truly yours,

GEORGE W. GRAY, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MAY 26, 1906.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JUNE 6, 1906.

IRWIN FAIRFAX, surgeon. Granted leave of absence for one month and twenty-five days from July 9, 1906. June 6, 1906.

CARRINGTON, P. M., surgeon. Granted leave of absence for three days from June 4, 1906, under paragraph 189 of the regulations.

WILLIAMS, L. L., surgeon. Granted leave of absence for one month and fifteen days beginning July 16, 1906. June 6, 1906.

McINTOSH, W. P., surgeon. Granted extension of leave of absence for three days from June 4, 1906. June 1, 1906.

WERTENBAKER, C. P., surgeon. Granted leave of absence for nine days from June 5, 1906. June 2, 1906.

ROSENAT, M. J., passed assistant surgeon. Granted leave of absence for one day, June 1, 1906, under paragraph 189 of the regulations.

NYDEGGER, J. A., passed assistant surgeon. Granted leave of absence for three months from Aug. 10, 1906, with permission to go beyond sea. June 5, 1906.

WICKES, H. W., passed assistant surgeon. Granted leave of absence for two days from June 5, 1906. June 2, 1906.

WICKES, H. W., passed assistant surgeon. Granted extension of leave of absence for three days from June 7, 1906. June 6, 1906.

MOORE, DUNLOP, passed assistant surgeon. Granted leave of absence for two months from May 7, 1906. May 29, 1906.

WILSON, R. L., passed assistant surgeon. Granted leave of absence for seven days from May 28, 1906, under paragraph 191 of the regulations.

WILSON, R. L., passed assistant surgeon. Granted extension of leave of absence for seven days from June 4, 1906. June 2, 1906.

STIMSON, A. M., assistant surgeon. Granted leave of absence for seven days from May 25, 1906, under paragraph 191 of the regulations.

RYCKER, W. C., assistant surgeon. Granted leave of absence for three days from June 5, 1906. June 1, 1906.

HUNT, REID, chief, Division of Pharmacology. Detailed to attend the meeting of the American Medical Association at Boston, Mass., June 4-8, 1906. June 2, 1906.

KASTLE, J. H., chief, Division of Chemistry. Granted leave of absence for eleven days beginning June 12, 1906. June 2, 1906.

ABDIS, W. E., acting assistant surgeon. Granted leave of absence for twenty-six days from June 4, 1906. June 2, 1906.

GRAY, R. H., acting assistant surgeon. Granted leave of absence for thirty days from June 16, 1906, and excused from duty without pay for sixteen days from expiration of above leave. June 2, 1906.

GREGORY, GEORGE A., acting assistant surgeon. Granted leave of absence for seven days from June 4, 1906. June 1, 1906.

HALLET, E. B., acting assistant surgeon. Granted leave of absence for two days from June 2, 1906. June 2, 1906.

JAMES, WILLIAM F., acting assistant surgeon. Granted leave of absence for thirty days from Aug. 1, 1906, and excused for fifteen days without pay from date of expiration of above mentioned leave. June 2, 1906.

NUTE, A. J., acting assistant surgeon. Granted three days' leave of absence under paragraph 210 of the regulations.

SAPFORD, V. G., acting assistant surgeon. Granted leave of absence for three days under paragraph 210 of the regulations.

SIMONSON, G. T., acting assistant surgeon. Granted leave of absence for two days from June 5, 1906. June 4, 1906.

STEVENSON, J. W., acting assistant surgeon. Granted leave of absence for thirty days from June 11, 1906, and excused without pay for period of two months so much thereof as may be necessary, from expiration of leave of absence. June 6, 1906.

GOODMAN, F. S., pharmacist. Granted leave of absence for sixteen days from June 18, 1906. May 31, 1906.

RICHARDSON, S. W., pharmacist. Granted leave of absence for ten days from June 3, 1906. June 2, 1906.

VAN NESS, G. J., pharmacist. Relieved from duty in the Bureau and assigned to temporary duty in Purveying Depot, Washington, D. C. May 31, 1906.

APPOINTMENTS.

LOUIS SCHWARTZ, GEORGE C. BALLARD and ELSWORTH WILSON appointed acting assistant surgeons for provisional periods of six months from date of oath.

RECENT DEATHS.

DR. ANDREW D. BLANCHARD, said to have been the oldest surviving surgeon of the Civil War, died last week in Melrose at the age of eighty-three. He was born in Medford, graduated at Harvard College in 1842 and at the Harvard Medical School in 1846. During the Civil War he served at Fortress Monroe.

DR. HENRY A. CARRINGTON died in Bristol, Conn., June 9, at the age of eighty. He was a graduate of the Harvard Medical School and for many years practised in the central portion of New York State. Later he removed to New Haven and afterwards to Bristol where he died.

DR. DONALD McLEAN BARSTOW, of New York, died suddenly at Portland, Me., on June 9, in the fortieth year of his age. He was the son of Dr. Josiah Whitney Barstow, who for many years conducted Sanford Hall at Flushing, Long Island, one of the best known private institutions for the insane in this country. He was graduated from the College of Physicians and Surgeons, New York, in 1892, and at the time of his death was clinical assistant in otology at Cornell University Medical College.

DR. EDWIN T. JONES, of Queens, Borough of Queens, New York, died suddenly of apoplexy, on June 10, at Uteka, N. Y., where he had stopped while on his way to Saratoga Lake to visit a son suffering from tuberculosis. He was graduated from the medical department of the University of the City of New York in 1883, and at the time of his death was chief of staff of the Jamaica (Long Island) Hospital.

DR. GILBERT L. GIFFORD, the oldest practising physician in Hamilton, Madison Co., N. Y., died suddenly, from cardiac disease, on June 11.

APPOINTMENTS.

DR. ALGERNON COOLIDGE, JR., has been appointed assistant professor of laryngology at the Harvard Medical School.

DR. F. T. LEWIS has been appointed assistant professor of embryology at the Harvard Medical School.

DR. J. L. BRUMER has been appointed demonstrator in histology at the Harvard Medical School.

PROF. PIERRE JANET, of Paris, has been appointed lecturer at the Harvard Medical School for the ensuing year, on the general subject of hysteria.

Address.

THE NATURE AND PROGRESS OF MALIGNANT DISEASE.

ORATION ON SURGERY AT THE FIFTY-SEVENTH ANNUAL SESSION OF THE AMERICAN MEDICAL ASSOCIATION, BOSTON, JUNE 5, 8, 1906.

BY JOSEPH D. BRYANT, M.D., NEW YORK CITY.

My first words are words of thanks, profound and sincere thanks, addressed to my colleagues of the American Medical Association because of my estimation of the high honor conferred in inviting me to address you on this occasion. My first desire, the dominating desire of earnest appreciation, is that I may say something that will justify the choice of my colleagues and my presence before you. My first hope, the fond hope which I most cherish at this time, is that someone who may be influenced by what I shall say will gain in comfort and life thereby; for, be the gain but little, even then those who are accessory to my presence may claim acquittal because of it.

Since it may not be known to all here present, I am prompted to say at once that sometime during the course of the meeting of this association, an address, denominated "An Oration on Surgery," is a part of the scientific proceedings. In this instance it is not my intention to attempt a review of the whole field of surgery, nor even of a year's experience, but, instead, to devote the brief time given me to the consideration of a surgical topic which to-day is engrossing more of the time and energy of scientific medical endeavor than is any other subject in the entire range of surgery. Hence the topic of the evening, "The Nature and Progress of Malignant Disease."

It seems not unfitting in a city whose early resistance to the oppressive encroachments on human liberty awakened the demand for American freedom that an earnest warning should be voiced against the advancing encroachments on human comfort and life of a malignant disease which obviously afflicts with dire results all classes of vertebrate beings. The expression malignant disease is used here in the general sense, just as later the term cancer will be employed. It is better thus than to attempt to speak of the varieties of malignant disease, since only a general idea of their nature and progress can be considered in the comparatively short time allotted for the purpose.

Cancer is a general and not a local variety of disease. The field of its activity is quite as extensive as is the world itself. The vertebrate order of creatures is more or less afflicted with cancer throughout the entire classified series. The highest vertebrate orders of life suffer from cancer more than do the other orders combined. The civilized and the domesticated classes of higher rank suffer more from the storm of affliction than do those of lower rank or of the natural state. Mankind everywhere pays distinctive vital tribute to this disease, not, however, in

equal proportions, but in accordance with the standard of the civilization of which he is a part. The higher the standard the greater is the contribution to malignant fate; the humbler and more natural the standard the less onerous is the demand. The rulers of mighty nations and the humblest human factors of savage existence, each in their respective ratios, succumb to the mysterious lethal influences of cancer. Also fish and flesh, staple articles of food of man, each, in a varying measure, is the abode of malignant action, and more especially is the latter class thus afflicted. The fish of pure streams and ponds and those of salty habitations are in no small degree the subjects of cancer. The genteel trout and the beneficent cod are examples of this fact, respectively. Even the invertebrate oyster in one instance is widely reported to have yielded to malignant change.

The myriads of oysters subject to the scrutiny of hosts of gustatory and scientific observers for many years, with apparently but one reported instance of malignant disease under all of these circumstances, suggested to us the idea of reviewing the facts in this particular case. A careful examination was made, therefore, of the acknowledged record¹ of the case the recital of the chief points of which merits your indulgence at this time. It appears that the late Professor Leidy, the famous anatomist of Philadelphia, came into possession of an oyster having a large tumor of the soft parts which he presented to the late Professor Ryder in January, 1887. In commenting on the growth at that time Professor Ryder spoke as follows: "The tumor seems to have been benign in character as the oyster in other respects appears to be healthy." A description of the tumor of quite minute and apparently of microscopic kind is reported along with the above statement which is now regarded by competent authority² as being congenital, thus sustaining the belief in benignity expressed by Professor Ryder at the outset.

I consider it proper to enter thus fully into the merits of this specimen, since, for some reason, it has been regarded as the first and perhaps the only proof of malignant invasion of invertebrate life. We will now return to the main channel of the discourse.

The flesh of cows and oxen is the seat of a tumor in the unsuspected proportion of 2 per 1,000, as is revealed by the careful inspection of their slaughtered products. The young animals, however, of divers kind, and of various ages, suffer under these circumstances.

Advanced age, both in the comparative vertebrate and in the invertebrate, is a factor which increases the probability of malignant progress, especially in mammals. Red age is evidenced by many years, and comparative age is ascertained by fewer, each stage inviting the progression of cancer. And, too, it is a fact that in a bulk of the age group, mortality is noted in those who are old, it is ended, who die young of infection, cancer is absent.

¹Proc. U. S. Nat. Mus., (N. S.), vol. 11, p. 104, 1888.

²Dr. J. K. Dunbar and H. W. B. Peck.

³Emp. & Cancer Research, p. 100, 1905.

become the frequent prey of cancer, while other contiguous tissues endowed with later function and those of the body at large remain in a healthy and useful state. In this connection it may be said that youth and youthful tissues comparatively seldom hold communion with cancer.

For a long time the solution of the problem of malignant disease has been uppermost in the minds of many of the best students of pathologic phenomena in the medical world. During the last few years the efforts directed to the solution of the mystery of malignancy, stimulated by the thought of the possible parasitic nature of the disease and the apparent increase in its extent and activity, have been markedly extended through the logical efforts of special commissions established for the purpose. Commissions organized under the patronage of crowned heads and public dignitaries of exalted station, and conducted by medical and lay minds of superlative attainment, supplemented by unlimited opportunity and ample financial support, are searching the animal world in the effort to shed light, beneficent light, on the mystery of cancer. In England and Germany especially, the resources of the governments and the sympathetic support of the king and the emperor, respectively, are directed to the benevolent purpose of determining the origin and the true nature of malignant disease. Also in this country notable institutions of learning are patiently engaged in the efforts to accomplish the same purpose. Individuals of eminent attainment are of themselves fighting in the battle along lines of their own selection with the same object in mind. Laymen of munificent means, prompted by humane motives or perhaps by personal dread, offer bountiful endowments for the discovery of the nature and the cure of cancer. The thoughts and efforts of the civilized world, as represented in scientific medical attainment and benevolent endeavor, are to-day mainly centered on securing the control of tuberculosis and on determining the true nature and the cure of malignant disease.

It is proper to say, I believe, that the widely separated instances of cancerous affliction as noted between the civilized and barbarous peoples, between the dwellers in the flesh and salt media, and between the lower classes of mammals seem to indicate forcibly that the circumstances of human life in the civilized state have not given origin to cancer, although they may have added much, indeed, to its frequency.

That cancer is a distressing part of the history of the animal kingdom cannot be gainsaid. And, unfortunately, the more comprehensively and critically the investigations relating to it are carried forward the more widespread it appears to be. As already expressed, mankind in the civilized and also in the undeveloped condition suffers from cancer, and it is probable that no race or condition of the human family is entirely exempted from this affliction. Also no organ or tissue of the human body is entirely free from its visitation. The dumb companions of man are similarly afflicted, but in a less degree, and it is

altogether probable that as the search progresses along the various lines of animal existence malignant manifestation will appear now and again, reminding us, perhaps, that the penalty of the violation of a universal law of development of organized beings is relatively promptly enforced on the object or on the part concerned in the offense.

In this connection it is not amiss to heed the fact that experimentally and practically the transmission of cancer from man to animals or from one animal to another of different species has not yet been successfully witnessed beyond gamsay, notwithstanding the repeated attempts to attain the purpose and the results of long critical observation. On the contrary, the apparent transmission of cancer between animals of like species and its unquestionable extension by metastasis in those already afflicted is of common knowledge.

The vegetable kingdom suffers at times and in isolated places from a form of local progressive disease apparently akin in nature to the malignant characteristics of the animal economy. In fact, the realization that these peculiar vegetable afflictions were caused by a parasite in many instances prompted the renewed suggestion on the part of Hutchinson that similar appearing growths of human origin might later be found to depend on the presence of parasites. Since that time, more especially during the last fifteen years, the contention in this respect between the supporters of the parasitic and non-parasitic ideas regarding this disease has been continuous and spirited, and as yet without a generally satisfactory conclusion.

It is no part of the purpose of this address to discuss the various theories relating to the nature of the inherent cell activity characteristic of cancer, or of any other form of malignancy. To the members of the medical profession here present such a course would necessarily be inconclusive and disappointing. To those of the lay order whose feeble hold on technical expressions would present unsurmountable difficulties of appreciation the result would be the same. Moreover, the chief aim of this discourse would be missing and, besides, as is expressed in a well-known play:

"The result is a very pretty quarrel as it stands;
We should only spoil it by trying to explain it."

The period at which this contention will be ended is too uncertain to merit other than hopeful anticipation, and too important to be neglected in any respect in opposing malignant advance.

The time when malignant disease first appeared in the path of human existence and added its insatiate affliction to the burden of human suffering cannot be stated except in a general way. It is fair to presume, however, that at a definite period of early recorded time malignant activity in some form was present and contributed its portion to the physical distress of the age. But it is difficult, indeed, to find ancient documentary evidence of cancer in such countries as India, China, Egypt and Greece, despite the fact that

their medical literature is quite extensive, especially that of Egypt, whose medical records contain descriptions of great antiquity, comparing favorably in forms of phrase and detail with many of those of the present day. Nor can the ancient history of cancer be correctly written at this late time, as it would not be possible to distinguish between cancer and benign tumor, on the one hand, and between ulcerated cancer and other severe forms of ulcer, on the other.

The comparatively limited knowledge in diagnostic discrimination at that time, as expressed in written characters, forbids the forming of definite conclusions in diagnostic purposes. It is apparent, however, that the ancient Greeks had a very good clinical idea of cancer, as a modern Greek writer, Couzis, of Athens (1903), in reviewing the past history of Greek medicine, says that the practical knowledge of the Hippocratic school was not inferior to that of his own day. The works of Hippocrates (460-370 B.C.) barely mention cancer, stating in connection with the treatment that "deep-seated forms are best untreated, for if treated the patient soon dies; otherwise he may hold on for a long time." It is not difficult for us of the present day to comprehend the full significance of this statement, as, no doubt, a few of us, at least, have witnessed the exemplification of this ancient expression written quite twenty-three hundred years ago. The old Greeks described fully the various distinguishing characteristics of cancer, noted the clinical differences in its various phases, portrayed quite accurately cancerous metastases and prescribed treatment not differing, especially in the palliative sense, from that in use at the present time. Galen (131-201 A.D.), in his extended works, considered cancer quite fully in its important aspects. But from his time to that of Ambrose Paré (1517-90 A.D.) little of special significance was added thereto.

Many of the notions entertained regarding the nature of cancer since Hippocrates' time seem dull to those whose enlightenment on the subject of bacteriology is a matter of recent years. The Galenic notion—probably that of Hippocrates—attributed cancer to the local effect of "overheated and unusually acid 'black bile' that cannot be purged away." Paré ascribed cancer to the effect of improper diet influencing unfavorably the liver and spleen, followed by "a shutting into the part to be attacked of thickened acid black bile." The emotions anger and hate aggravated the condition, he said. Harvey (1578-1657), the discoverer of the circulation of the blood, regarded cancer as a parasite on the body, living an independent existence at the expense of the latter.

John Hunter (1728-1793) seems to have been the first to recognize the influence of traumatism as a causative factor of cancer, aided by the consequent exudation of coagulable lymph into the interstitial tissues.

Many attempts to inoculate cancer date from the experimental period inaugurated by John Hunter. And early in the nineteenth century

positive results were reported and the parasitic doctrine became prevalent. The era of pathologic anatomy, which culminated in the histologic studies of Müller and Virchow, at first favored the idea of the parasitic nature of the cancer cell, but ultimately condemned it when Virchow showed, as then appeared true, that cancer cells were derived from pre-existing normal elements.

From this period to the present day, theories regarding the nature of cancer have multiplied to a bewildering extent. The two extremes at present are the following: (1) That cancer, like many other morbid processes, is due to a micro-organism; (2) that cancer represents a morbid proliferation of certain normal cellular elements as the result of diminished inhibitory action.

A few words more relative to the parasitic theory may not be amiss at this time. The view that cancer itself is a parasite was expressed by Harvey in 1651. By Dupuytren in 1805, Laennec in 1816, Cruveilhier in 1827, and Lobstein in 1829, all adopted this view as part of their teaching of pathologic anatomy. A little later the positive results of inoculation experiments were recorded, seeming to confirm the view, and Müller's description of the histologic elements of cancer in 1812 give a remarkably clear exposition of this theory, making the cancer cell the actual parasite which, if implanted in sound tissue, caused a cancerous growth. The question of transmission of cancer, however, remained unsolved, for it was then believed that cancer cells in the natural state could live but a short time outside of the body, and that their great size seemed to preclude their being taken up by the ordinary ports of entry. Also cancer did not appear on abraded surfaces, but in the parenchyma of tissues. In the face of these facts the parasitic origin appears to have languished, and to have been superseded by the later teachings of Virchow and others, which derived cancer from pre-existing normal elements.

It was quite apparent at an early period of investigation that the study of the nature and activity of this disease could not shed substantial light on the problem of its control, when based alone on the few cases falling under the notice of a small number of individual observers. The logical corollary of this situation had the foundation for statistical inquiry and collective investigation. It was not, however, until a comparatively recent date that statistical knowledge attained sufficient rank in this regard to arouse apprehension respecting the presence of cancer. In fact, it was not until the possibility of its being of a parasitic nature was again set forth, and the fact that perhaps it was communicable, that observers of cancer were impressed with the acute sense of a new danger.

It should be stated, although perhaps superfluous, that the deductions based on statistical estimates are not always conclusive, except perhaps to the minds of those whose contentions are encouraged or supported by the calculations. A preconceived notion relative to a disease, or a prejudiced opinion regarding it, can usually

gain substantial comfort from the study of plastic statistics. The product of the data may be "very like a camel," "or a weazel," or perhaps "like a whale," accordingly as a biased statistical Polonius may fancy. One has only to keep pace with the conflicting deductions often drawn from isolated examples of statistics, whether amended or not by additional knowledge, to realize the wealth of uncertainty that frequently attends statistical conclusions. Especially is this true in the instances of afflictions with subtle natures and divers environments, such as characterize cancer.

The geographic and time-of-life distribution of cancer especially concern statisticians and sanitarians. The anatomic distribution appeals directly to practicing physicians and surgeons. The local occurrence-center feature of the infection invites the reflections of pathologists and students of morphology. Geographically considered, cancer, as already stated, is a heritage of the human race in nearly all, if not in all, parts of the world. While it is yet unknown in some parts of South Africa (Snow) and other obscure places, it is not at all certain but that it exists, remaining hidden, however, from civilized view, because of the restraining influence of some heathen conception relating to it; especially as such conceptions have before this time thus controlled the doings of savage or superstitious peoples in other matters. Among the chief objections to the scientific value of statistical facts relating to cancer may be mentioned the inability to secure authentic complete diagnosis. The statement that a growth is malignant, when determined only by macroscopic examination, is so often fallacious as not to merit scientific confidence. Only microscopic reports of morbid growths should be given the privilege of membership in the rank of trustworthy data. I am aware that there are not a few distinguished observers who to-day seem to place quite as much confidence in the macroscopic findings of experience — their own experience — as in the conclusions of those with equal experience whose senses are fortified by the mechanism of a more exact knowledge. In any event, such reports as these should be classed by themselves, unless confirmed by reliable microscopic testimony. According to the report of qualified authority, the frequency of error thus arising is 7% in accessible growths, and for apparent reasons is increased when the growths are deep-seated.

The undoubted increase in human longevity of recent time adds many, indeed, to the list of those who from augmented years fall within the age limit of cancer attack, and thus apparently increase the spread because of a seeming greater morbid activity. And, too, it should not be forgotten that many from without seek harbor in a city for the relief which its hospitals and extended experience afford, some of whom, unfortunately, add their sad contribution to the city's death-rate from cancer. On the other hand, the life-saving means now employed in defending and rescuing the young from the baneful

ful onset of infectious disease is increasing the number of the living, and, therefore, neutralizing proportionately the apparent increase in death from cancer.

It is not impossible that the significance of the so-called "cancer localities" may be reduced to the standard of other fields of importance, when subjected to closer analyses of circumstances that are no essential part of cancer development or propagation. It is certainly evident that the slow and continuous increase of cancer, regardless of preventive measures and of human understanding, is controlled by influences of such subtle kind, as thus far to perplex beyond satisfactory solution the minds of the most astute observers.

The relative extent of cancer invasion of the accessible,³ of the inaccessible and of the intermediate parts of the human body in England and Wales during a three-year period affords an interesting study of this disease of great apparent significance, as will appear a little further along. Those superficial parts of the body falling readily under the scrutiny of the unaided eye and the touch of the physician are manifestly the seat of accessible cancer. Those deep and internal parts of the body, conveniently placed beyond the limits of unaided vision or mere touch are the sites allotted to inaccessible cancer. Those portions of the body within the reach of the finger and aided inspection are, for the most part, the sites of intermediate cancer.

The development of cancer of the parts included in each of the foregoing divisions of the body is comparatively much less manifest in individuals under twenty-five years of age than in those above that period, standing in this respect nearly as 1 to 70. The male sex suffers nearly 22% greater infliction from malignant disease than the female, during this time, which can be accounted for in part, I think, by the greater strenuousness of the male and the effect of the exposures incident thereto. The probable reasons for the greater infliction of the sexes under, than over, twenty-five years of age, it seems to me, have been considered sufficiently already.

The comparative difference between the frequency of occurrence of accessible and inaccessible cancer in both sexes, under and over twenty-five years of age is astonishing, even when proper deductions are made for the greater uncertainty of diagnosis in the latter kind. Inaccessible cancer in males of twenty-five years and under is 80% more frequent than the accessible kind. Inaccessible cancer in females of twenty-five years and under is nearly twice as frequent as accessible cancer. Inaccessible cancer in males above twenty-five years of age is three times more frequent than the accessible variety. Inaccessible cancer in females above twenty-five years of age is about 21 times more common than accessible cancer. Inaccessible cancer in males, regardless of age, is approximately three times more frequent than the accessible variety. Inaccessible cancer in females, irrespective of age,

is $2\frac{1}{2}$ times more common than the accessible. Inaccessible cancer is, without regard to age or sex, a trifle more than $2\frac{1}{2}$ times more common than cancer accessibly located.

While it is now, and has long been, conceded that external influences, traumatic and otherwise, contribute to the frequency of accessible cancer in a greater or less degree, it is also self-evident, I think, that other and more potent agencies than these must be invoked to account not only for the occurrence of inaccessible cancer, but also for its great preponderance over those accessibly located at all periods of life, more especially the dominant one, that above twenty-five years of age. The increase in cancer visitation, in connection with advancing years, has long been a matter of common knowledge. But that the location of cancer, at all times of life and especially in adult life, should be of inaccessible rather than of accessible nature, is more than remarkable; it is even startling, suggesting in no common tone the idea that, directly or indirectly, subtler influences than external traumatism or infecting agents can exercise are active in the development and spread of cancer. Perhaps it may be consistently said that the traumatisms thoughtlessly inflicted on the gastro-intestinal tract by the yielding to the temptations and pleasures of life — while less emphatic than those directed to the external surface — are none the less potent for evil because of the fact that their frequent and prolonged action may increase correspondingly an ill effect. However this may be, it appears quite reasonable to some that cancer organisms coming somewhere from without implant themselves in the tissues and develop there, notwithstanding the inhibitory effect of cooking, the power of digestion, the opposition of phagocytosis, and the feeble element of chance.

It is fitting now to remark that there appears to be no good reason to believe that the food of a people influences their relation to malignant disease in an appreciable degree.

Intermediate cancer in both sexes under twenty-five years of age is about half as frequent as is accessible cancer in both at the same period, possibly showing thus early in life the benign effect of protection of the intermediate parts from ordinary external influences. In the male after twenty-five years of age, intermediate cancer shows a comparative decrease in rate from that of the accessible form of about 32%, suggesting that the evil effect of external influences are superior in potency or greater in number in the male than are those causing intermediate cancer. In the female during this period (after twenty-five years) the rate of accessible cancer exceeds that in the male by about 37%. The intermediate variety, however, at this time in the female exceeds the accessible form by more than 48%, showing the rapid increase in the intermediate variety due to pelvic disease, which cannot be attributed in any practical degree to infection, but mainly to the traumatisms of maternity and the age limit of certain near by tissues. It should be stated in this connection

that the liability in both sexes to cancer of the gastro-intestinal tract gradually and quite uniformly diminishes from the stomach downward toward the external opening, but not including it. This fact seems to justify the thought already stated regarding the possibility of the effect of dietary traumatism on the stomach and the upper intestinal tract.

The age limit of the tissues of the stomach in health conforms to the nutritive requirements of the life to which they are all important; consequently this feature of the causation of cancer, which so freely contributes to the total of this disease in the mammary gland and the uterus, can play no part in the causation of cancer of the stomach, making it, therefore, the more apparent that alimentary traumatism and dietary abuses are dominant influences in the causation of gastric cancer. Another fact which seems to confirm this position is that cancer in the male in the alimentary canal is quite seven times as common as in the female, notwithstanding the further fact of the general tendency of females to suffer from cancer of the alimentary canal at an earlier age than males. Surely, if cancer of the stomach were dependent in an appreciable degree on parasitic infection of alimentary substances this great difference in the relative proportions of infliction of the sexes should not exist. Finally, in males 80% of all cancer affects the alimentary canal. In females 80% of all cancer affects the reproductive tract, including therewith the breast.

It seems that not a little that has been said in this relation is corroborative of the belief of those who regard cancer as a nonparasitic disease, which, in any circumstance, is not communicable.

A longer continuance in theoretical indulgence would necessarily deprive us of the opportunity of speaking in an emphatic manner, of an exceedingly important practical part in the contest against malignancy. This statement is prompted by the facts that cancer appears to be on the increase in civilized countries, and also that the limit of effective operative therapy, the only agent of cure of general, settled repute, has already quite reached the confines of highest efficiency, under the present established lines of action. It naturally occurs to thoughtful members of the profession, therefore, to inquire regarding what can be done by way of abatement and protective forethought, that will secure the holding of that already in hand, while the search for increased power in curative therapy is advanced, let us hope, to a more successful issue.

As in any other field of human contention so here the resources of every avenue of effort should be determined with care, and utilized with vigilance and pertinacity. The operative warriors in the conflict against malignancy have striven faithfully and logically during the last years of the struggle, gaining advanced foothold by means of approved technique and prompt aggressiveness. By these masterly means

in the cure of cancer of the breast, of the uterus and of the stomach, many, many years of comfort and happiness have been added to the lives of the afflicted and given to those who rejoice because of their preservation. These striking illustrations of cure in organs so profoundly concerned in the inception and preservation of life are also an earnest of the outcome in other fields of operative endeavor in this respect. Unhappily, our fond anticipations of approaching relief, encouraged by this gain on malignant disease, are so often demolished by the ruinous delay of the afflicted, in utterance and action, as well high to arrest the increasing hope from operative measures. Too often, indeed, during the consideration of operative interference is heard the utterance of the sad truth, "Too late," "Too long deferred," and the like, on the part of all concerned. The remedy for this lamentation is prompt surgical action; and prompt surgical action requires a prompt acknowledgment of the presence of an unwelcome growth or manifestation on the part of the sufferer, supplanted by earnest co-operation in diagnosis and treatment.

It is surely not amiss to repeat, that the outcome of operative endeavor in malignant cases, has well-nigh reached the highest possible success, unless aided by increased faith and lessened secretiveness on the part of the sufferers from a malignant infliction. Those who are afflicted with accessible growths are comparatively early aware of the presence of these unwelcome visitors. And when they shall have exercised the same degree of resentment because of physical intrusion on the part of a growth, as commonly distinguishes social or business intrusion on the part of a meddler, then, indeed, will much be gained for increased success in the struggle against malignancy. Since it now appears that cancer is located most often in the deep internal parts, beyond the safe limits of unaided sight and mere touch (inaccessible cancer) $2\frac{1}{2}$ times more frequently than is accessible cancer, regardless of age or sex, then, indeed, is the fact doubly impressed, of the necessity for prompt acknowledgment of the presence of morbid manifestations and prompt determination of their nature. The handicap by inaccessible cases because of their greater distance from the surface often enables the disease to advance undiscovered to a degree forbidding operative action when their presence is finally known. In too many instances of cancer, especially the inaccessible kind, the reasonable suspicions of its presence on the part of the patient or friends are quieted by the soothing platitudes of medical advice, until all opportunity of relief is at an end. The physician and the surgeon should join in the observation and treatment of all such cases as these, early, fostering a mutual plan of action that contemplates prompt explorative investigation in doubtful instances, and forbids delay in those of undoubted character.

It is "carrying coals to Newcastle" to state in this presence, or in that of any medical gathering of the present day, that cancer invades

contiguous tissues early in the course of its development. How early no one can know. How late no one can tell. Of this, however, we are assured: malignant activity is measured by the inherent nature of the morbid process, or by the receptive character of its host, and sometimes by both; and unfortunate indeed is the patient who is the helpless victim of both of these influences. But, on the contrary, correspondingly fortunate is one in whom each of these influences is at a minimum. A knowledge of such facts should admonish us to be charitable on the one hand, and discreetly aggressive on the other; charitable to the professional brother whose operative results may, therefore, be less fortunate than our own; discreetly aggressive so that the area of infliction may be timely removed by operative effort. Early explorative determination of the nature of disease, followed at once by operative relief in suitable cases, is to-day the potent measure of succor pending the advent of means of greater beneficence than those now at hand.

In emphasizing the pre-eminent importance of early measures of relief, one has only to point to the astonishing results which have attended the operative practice of many distinguished surgeons of this and foreign countries. And I believe that it will not be regarded by any one as evidence of unwarranted pride or of bad taste if, in this connection and on this occasion, we should mention the name of our distinguished president.

If to these means of cure there be now added another for the sake of greater security, the picture in this respect will be complete,—a means contemplating the education of the people on the great importance of overcoming reticence regarding such matters in their incipency, rather than sacrificing life by senseless delay. Patients should be taught that the evidences which they may regard as important and entitled to serious thought and decided recognition are but a step removed from the presence of hopeless despair and final destruction. They should be told that the subtle onset of malignant disease often baffles the keenest perceptions of the most experienced, requiring for arrest and for cure the best we have and, far too often, more than we can give. The exercise of vigilance in patients already operated on by those who are profoundly concerned in the cure, should be periodically and untiringly practiced in order that the first evidence of disease may be quickly detected and remedied by renewed operation. The stake of the contest in such cases as these is a human life, and all the comfort and happiness relating thereto. Every victory is another triumph over malignant infliction, of which there are very many in surgical experience. In the general struggle for victory against malignant disease, it should not be forgotten that all those fall who do not seek relief; and that all those who early seek relief will surely secure added years and increased comfort, and that not a few will be finally cured. And important it is to remember that the number

cured will be measured by the promptness of early diagnosis and curative action followed by untiring periodic scrutiny of the vulnerable points of return. The degree of fortitude required to sustain a patient under repeated malignant attacks and prompt operative defense is akin to that with which martyrs are endowed.

Finally, an emphatic warning should be given to all against the seductive influence exercised on the afflicted, by the "perversions of judgment and vain imaginings" which too often allure them from the path of scientific beneficence, trodden by honest, sympathetic aid, into the wilderness of arrant quackery, infested by ghouls of heartless gain. Nor should one hasten unduly to substitute for established method in operative cases means which are still on trial, even though encouraged to do so by honest yet unsettled opinion.

Rather than this, one should grow in courage, stimulated by examples of successive cures from early effort, and by sentiments attuned in verse by our profession's greatest poet and our hosts' brightest ornament:

"Here stand the champions to defend
From every wound that flesh can feel,
Here science, patience, skill shall blend
To save, to calm, to help to heal."

WHAT EFFECTIVE MEASURES ARE THERE FOR THE PREVENTION OF THE SPREAD OF SYPHILIS AND THE INCREASE OF PROSTITUTION?*

BY CHARLES GREENE SUMSTON, M.D., BOSTON.

It is not to be supposed that there exists at the present time a single moralist sufficiently severe, or rather insufficiently enlightened, who would dare to doubt the necessity of measures capable of combating the propagation of venereal diseases. Fortunately, the time has passed when syphilis was believed to be the result of depravity alone, and was considered as the legitimate punishment of *debauché*. The numerous sources of infection are too well known at the present time to uphold the old rigorous theories and to these I shall not revert.

Of all the diseases which may affect the human race by contagion and which brings about the greatest disasters to society in general, there is not one more serious, more dangerous, or more to be feared than syphilis. This I believe is generally admitted, and since this is the case why should not the proper authority profit by the knowledge that the progress of science dictates? Many years ago Michel Lévy said: "The extirpation of this leprosy of our time that is called syphilis is not above the power of government. The sequestration and leproseries put an end to the old scourge, leprosy—the plague has been the object of an extensive and expensive prophyl-

actic control, every nation has made sacrifices to do away with the germs of smallpox, yet syphilis has caused more harm than all these diseases put together. It silently deteriorates generation after generation, its contagion is more evident than that of the plague; why are not the same barriers and the same means of extinction built up in all countries? Such is the human race; the lightning of insidious epidemics which pass over our heads like an electric cloud, benumb and frighten people; they endeavor to prevent their return, while they become familiar with the slow and continued plagues which they carry in their flanks and which cause them to undergo hereditary ravage with the same patience that they show towards meteoric phenomena."

Syphilis is not, like smallpox, a disease whose miasms disseminate contagion to distant parts, neither is it like any of the exanthemata, susceptible of producing itself spontaneously; alone, immediate contact produces its development. Its extinction, although difficult, is not a chimerical dream; and if all nations would some day establish a complete system of international prophylaxis, much could be done for suffering humanity.

The word progress is upon everybody's lips, and modern civilization is justly proud of its numerous conquests. Scoury has disappeared from those localities where it formerly reigned endemically; vaccination has stopped the ravages of smallpox, but syphilis still continues to be propagated and for centuries has not ceased to eat the limbs of the human race. Leprosy was done away with; why should it not be the same for syphilis?

Here, however, I would say, I do not harbor too great an illusion. If the extinction of syphilis is not theoretically a dream, the universal consensus of opinion of all governments is that in the present condition of society it is a pure Utopia. In point of fact, nations vary in character as do individuals, and a kind of mutual and systematic opposition is constantly present acting as an obstacle to their united action, and it is to be feared that this antagonism by continuing will, for many years to come, offer a great resistance to the realization of any united efforts. If, at the present time, much has been done to prevent the extension of syphilis and other venereal disease, it nevertheless remains a glaring fact that there is still much to be done and that the large majority of prophylactic means now existing require great modification.

One of the most important means at our disposal for reducing the increase and spread of syphilis certainly resides in hospitalization, to which I shall now briefly refer. Formerly, all cases of infectious fever were placed in a common ward, but to-day all our modern hospitals have special wards or buildings reserved for diphtheria, scarlet fever, measles, etc. What has been done for acute infectious diseases, attempted in chronic infectious and for a number of years back we have watched the development of special hospitals or sanatoria for tuberculosis. No matter what may

* Read by invitation before the Section of Hygiene at the meeting of the American Medical Association, Boston, June 5, 8, 1900.

be the divergence of opinion existing relative to these establishments and the results which may be obtained, it is nevertheless true that it was to this prophylactic procedure that the ancients were able to attenuate, if not to cause to completely disappear, the hideous disease that leprosy was in former times.

Among those essentially contagious diseases which should receive the attention of modern prophylaxis and hygiene, venereal diseases should certainly be given a distinct and separate place. No one would to-day dare to uphold that the ills produced by the pathogenic agents of these diseases are not at least quite as considerable as those of tuberculosis, for example. I do not believe that I am going too far when I say that gonorrhea in the female is grave, prodigiously grave, and that it may be considered as the most fearful wound in young households. As to syphilis, with its high death-rate and infantile malformations, with the disasters that it produces in certain individuals, with the fearful affections whose development it favors and, although they bear the special name of parasyphilitic, which are none the less attributable to it, we will not insist upon this phase of the question.

Prophylaxis has, consequently, the imperious duty of considering these diseases, and among the arms which it has is certainly hospitalization. And, in the first place, let me say that I disagree completely with those who will not recognize an autonomy in venereal diseases, which I do not believe can be refused them, those who in principle believe that these patients should be placed in general medical or surgical wards corresponding to their cases, such as, for instance, urethritides and gonorrhoeal vaginitides in a service of genito-urinary surgery; mucous patches, cutaneous manifestations of syphilis and chancreoid ulcerations in the service of the dermatologist, etc. In a word, I believe in special hospitalization for the simple reason that the end to be attained is prophylaxis, and the first condition to fulfill with this end in view when dealing with venereal disease is isolation of the patients. Until this is done hospital treatment will remain completely ineffectual. This does not mean that I believe that hospitalization is in itself sufficient to furnish the solution of such a complex problem as venereal prophylaxis. If venereal diseases may be compared to infectious diseases on account of the factor *contagion* which is common to both, and if we make abstraction of extragenital infections, which, for that matter, represent a very small portion of cases, it must be recognized that they differ by the manner of contagion. While infectious diseases generally take on the epidemic type, while they may seize upon an individual who is endeavoring to defend himself against them, venereal affections never assume the epidemic type and only exceptionally seize upon an individual, who, knowing them fully, does what is necessary to avoid them. We possibly might, as has already been done by a number of authorities, assimilate to epidemics those instances where infection of a large number of healthy

individuals has taken place from a single infected subject. Military surgeons, especially those belonging to small garrisons, have frequently noted the contamination of a large number of soldiers from a single woman.

This assimilation I do not wish to make, believing that it is merely a simple way of looking at things, original without a doubt, but susceptible to much discussion. Is it because venereal diseases are not contagious in the same way as eruptive fevers, or because their mode of contagion is nearly always genital, that we are led to consider an entire group of diseases for which hospitalization is useless, or merely of a temporary nature? This category of patients might very well be kept temporarily in a hospital, for a time, just sufficient to initiate them into the manner of treatment that they should follow and to teach them to conform rigorously to the rules of general hygiene which are so important in the treatment of their disease. It is for this reason that in the case of syphilites, for example, I believe it would be well to detain them in a hospital for a few days with their consent, when they come to consult for the first time, and after their discharge from the wards, they may continue the treatment in an out-patient department.

Beside voluntary hospitalization and from the theoretical view point, hospitalization should be made obligatory for those individuals who are voluntarily contagious, for those who are perfectly well aware of the danger of their disease and who do not hesitate to communicate to others the affection of which they are possessors. There would probably be no division of opinion upon this subject in the medical profession if such measures could be applied to the male as well as the female. It would be quite as justifiable and legal as the modern means of prophylaxis in the case of other infections, such, for example, as the quarantine imposed upon ships, or the establishment of a sanitary cordon and so forth. Although a contagious venereal subject cannot be held by obligatory hospitalization, there is, however, a class which I believe should be compelled to submit to it; I refer to prostitutes. This measure has been considered arbitrary, illegal and inhuman, and certain people believe that prostitutes should be free to enter a hospital or not as they see fit. This question has given rise to long and ardent discussions to which I will not refer. It seems to me, however, that the only way to control the transmission of syphilis is to sterilize prostitution as we would sterilize our dressings for a surgical operation, and could this be accomplished the gonococcus and spirocheta pallida would, to a great extent, be removed from the list of pathogenic organisms.

I shall here ask to be permitted to make one reflection, namely, who is the most guilty from the view point of propagation of venereal diseases,—man or woman? I have no hesitancy in believing that it is the woman, and for these reasons. For example, a man contracts syphilis. Where does he contract it? Why, from contact with a female, who, from the very fact that she

entered into relations with him, leads an active genital life. To whom will the man transmit it? Evidently to another woman, who, just like the first, is also leading an active genital life. Thus, the infection being contracted from one woman returns to another woman. And this woman, what is she? An avowed prostitute only rarely; statistics prove this; far more frequently she is a clandestine prostitute and to this class I shall not refer. It occasionally, also, is a girl who has recently fallen, contaminated by her first lover, and who, forced by an exaggerated sexual instinct, or by misery, is perhaps called upon to descend one or more rounds of the ladder of vice. In other words, no matter what may be the cause of her fall, she nevertheless becomes a candidate for prostitution. This reasoning may appear upon the surface as a mere sophism, but in reality it is not so, because in the male no homologous condition is to be found like that of prostitution in the female.

Another and most excellent measure for the prevention of both venereal diseases and prostitution is the proper education of young people of both sexes in sexual matters, and many excellent contributions to this subject have appeared of late. To mention the various writers who have advised this very common-sense course would be far too long, and I would merely refer here to two recent articles, the first from the pen of Dr. Morrow, appearing in *American Medicine*, Jan. 13, 1906, and one from Valentine in the *New York and Philadelphia Medical Journal*, Feb. 10, 1905. The former writer says that the general principle is laid down that the education of the public is the most valuable of all measures for the prevention of communicable diseases. Its importance is emphasized in the case of diseases the communication of which lies entirely within the control of the individual. The object of the proposed education is to give the youth of this country a clear comprehension of certain physiologic truths which have a direct bearing upon the regulation of their sexual lives, and of the serious consequences in the shape of disease and death which follow a breach of hygienic laws. In other words, it is to teach them how to live according to the laws of a healthy nature. This instruction in the physiology and hygiene of the sex function should form an essential integral part of the education of youth.

Dr. Morrow criticises our present educational system, the policy of which is to launch the young into the world in complete ignorance of everything pertaining to the laws of life reproduction. In seeking this knowledge the youth is but obeying the law of his mental evolution. Since this knowledge cannot be had from legitimate sources—from parents and instructors—it is gained surreptitiously, and usually from depraved sources: dissolute companions or erotic or quackish literature. To be salubrious as a safeguard, therefore, this hygienic education should be given in youth, for it is during this period that the foundations of what may be termed the "sexual character" are laid, and habits of mind and

practices are formed which, in a great measure, determine the future sexual life of the individual.

Valentine concludes his most interesting paper as follows: "Sexual physiology and hygiene need not be formally taught girls, save in the exceptional instances in which the genic impulse is prematurely developed. Sexual physiology and hygiene should be taught every boy, when mental and sexual puberty makes him capable of beneficially utilizing the knowledge. The nature and scope of instruction on sexual subjects should be regulated according to each pupil's ability properly to appreciate the warnings inseparable therefrom.

The age at which a person may safely be instructed in sexual subjects is that age at which, in each individual case, such instruction becomes necessary for the purpose of moral and physical prophylaxis. The individuality of the parent, physician or teacher should be the guide to the choice of one or the other as the exponent of the facts.

Educational institutions may be utilized for instruction in sexual subjects, but such instruction must be given to small groups of pupils selected because of their mental parity as nearly as may be.

Textbooks on elementary hygiene should not contain chapters on sexual physiology. Those charged with imparting instruction on sexual subjects should be provided with separately printed chapters on the physiology and hygiene of these matters. These separately printed chapters could then be given with the greatest discretion to such pupils only whose mental development would preclude their misusing the information derived therefrom.

All instruction to the laity on sexual subjects should be directed essentially to serve as a groundwork for the following ideas:

(a) Many learned men hold that ante-nuptial coitus is not necessary for the health of the individual.

(b) Continence reduces the sexual desire.

(c) Gratification of the sexual impulse before marriage degrades the moral tone and exposes to serious infection.

(d) Venereal diseases are not disgraceful infections, but the result of unfortunate lack of self-control.

(e) The greatest danger at the inception of venereal diseases is in their being misdiagnosed by quacks.

(f) If a person is so unfortunate as to contract a venereal disease, self-preservation should cause him to immediately seek the advice of his family physician.

I believe that the public should be particularly enlightened on the dangers of gonorrhea, that it should be fully aware that recent statistics conclusively show that the number of gynecological operations increase each year, necessitated by lesions due to the gonococcus. The husband, either criminally or unconsciously, transmits the gonococcus to his wife, usually in the following manner: In his bachelor days he contracted a

gonorrhea, which was treated according to the usual methods; the gonorrhea disappears, but leaves in its place an insignificant gleet, a chronic discharge of such apparently little importance that the patient neglects to have it treated, supposing that it will cure itself. Upon this he gets married, usually without any thought of the past and without consulting a physician as to the seriousness of his little morning drop. After a variable length of time, and as soon as a congestion of the uterus predisposes the organ to microbic receptivity, the young wife presents all the well-known symptoms of a gonorrheal infection.

To a certain extent the public has surmised the dangers accruing from this disease, but not to the extent that it should. In face of the terrible consequences to which gonorrhea may give rise, the mortal dangers to which the spouse is exposed, sterility following gonococcal complications, certain members of the profession have declared open war against gonorrheal subjects culpable of contamination. In Germany, especially, a law is under consideration which tends to protect women against venereal contagion from the husband, or even the lover. Professor Hegar in Germany, Jullien, Cazalis and several other physicians in France have proposed an obligatory verification as to the genital innocuity of the future husband. As a conclusion to this I would advise that young men be told that, if they are unfortunate enough to contract gonorrhea or syphilis, they should loyally consult a reputable physician before their marriage to ascertain whether or not they are fit subjects for matrimony. It is high time that the profession put an end to public ignorance in these matters and thus to a great extent avoid many catastrophes and moral pain.

There is a sad commentary on the practicability of the work of the temperance reformer in the fact that each succeeding generation of medical men is brought face to face with the disheartening truth that alcohol is still the "open door" through which stalks the foul spectre, "venereal disease." Since the days of Noah alcohol has continued to be the most powerful weapon in the seducer's armamentarium. In this he has an agent more deadly to virtue than the most powerful implement of warfare is to life itself; and with it he has in his power to pave the way for suffering beyond human expression.

It is not my purpose to descant upon the horrors of intoxication, nor is it at all necessary for the purposes of my theme. I do not need to follow the victims of the drug beyond that point where it robs the intellect of its inhibitory powers and deprives it of free agency. Such a state of mind, by no means of necessity, implies drunkenness; indeed, it comes at a point well on the hither side of that condition, and the horror of it all lies in the very fact that brain activity is not actually annihilated, but only cruelly perverted.

In this state the ordinary calm, self-restrained,

discriminating man may be transformed for the time being into a rutting animal and the virtue of a similarly endowed woman may drop from her like a mantle.

In the presence of men of your training and experience of human frailty, it is almost supererogation on my part to pursue this line of thought in greater detail. Given two creatures of opposite sexes, created after the image and likeness of the Maker, reduce them by alcohol to the state of mind above described, and the inevitable results are familiar to you all.

The stage settings that serve for the act in which the luetic virus may be imparted vary from the most sordid and squalid to the most luxurious and artistically perfect the human intellect is capable of inventing; and the actors in this most unspeakable of human tragedies, in like manner, represent each and every stratum of the body social.

The foci of propagation of venereal disease and prostitution do not wholly reside in houses of ill-fame. The reformer must look to the comic opera company, the private dining-room, the furnished lodgings, the apartment house on the "easy virtue" style, the steamboat stateroom, the massage and manieure parlors, the automobile, the electric baths, the fortune telling outfits, and, lastly, the avowed *maisons de joie*. The American cities have two potent foci for the development of prostitution, of which continental cities cannot boast; I refer to the downtown office building and the bachelor apartment houses so much in vogue at the present time.

Prostitution, especially the clandestine form, is rampant in Boston, and in proportion to its population, the Hub can compare favorably in this respect with any European city of its size with which I am familiar.

Beside those causes of a general order which influence prostitution and criminality in general, are others which belong more particularly to the former. Leaving aside the culpability belonging to its authors, this crime is the consequence of other mistakes on the part of jurisprudence and public opinion. A large part of the responsibility rests upon public opinion, because it encourages the seducer by its indulgence, perhaps even by its admiration. Public opinion also directs the education of women, and the present system forces her especially towards the arts of seduction and coquetry, thus making her easy to seduce, rather than seductive. The seducer of the twentieth century generally does not understand the extent of his responsibility; he goes about the proceeding because he is fully aware that many others have done the same and he is covered by public opinion until the day that the scandal breaks out. Our up-to-date morals have taught him that to seduce a young girl, up to that time virtuous, and afterwards to abandon her, in other words, of dishonoring her, and making her a candidate for prostitution, is practically nothing, and jurisprudence in our country hardly takes into consideration the moral assassin.

Another important factor in the development of the prostitute is our modern education. In large cities young girls of the people and working classes are, by their clothes, their manners and even mentally, in a condition far superior to the men of their own class. From this very fact, they become easy conquests for men of the well-to-do and richer classes, and there would be fewer seduced girls and married clandestine prostitutes if the parents did not sanction their daughters' luxurious habits, far above their social rank and fortune.

Another potent cause forcing women to their fall is the insufficiency of salaries in large department stores and workshops. The conduct of a young girl, whose poverty prevents her from entertaining the hope of marriage, thus no longer becomes a moral question with her, but one of interest, and she reasons to herself that it is just as well to get as much out of life during youth as possible, if nothing but poverty-stricken old age and infirmity are to follow the pleasant days of the springtime of life.

On the other hand, the conception of marriage as the only possible mode of union has also disappeared from the minds of the mass of the population; marriage has ceased to be a sacrament and is looked upon merely as a contract, which in turn, under the influence of public opinion, law and jurisprudence in the matter of divorce, becomes every day still more fragile.

To sum up, it would seem to me that in order to deal with the spread of syphilis and prostitution, we should take into consideration the control of existing morals and opinions, teach the youth of our country the evils accruing from venereal diseases and the erection of proper hospitals for those already afflicted and who may become dangerous to society from this fact.

CONSIDERATION AND TREATMENT OF THE ACCIDENTS OF SURGICAL ANESTHESIA WITH SPECIAL REFERENCE TO PREVALENT DRUG TREATMENT*

BY D. H. CARROLL, M.D., BOSTON.

I WILL first consider the physiology of the vascular system, then general anesthetics, then the drugs commonly used for anesthesia accidents and lastly the accidents themselves, their cause and treatment.

The vascular mechanism may be divided into two factors, one constant or approximately so and the other variable. The constant is the length, natural bore and distribution of the vessels, the extensibility and elastic reaction of the walls and the valves. The variable is the beat of the heart, and the peripheral resistance. The variations of the latter being brought about by muscular contraction or relaxation of minute arteries, and also, the character of the circulating blood.

The two chief variables, the beat of the heart

and the width of the arteries, are governed and regulated by the central nervous system. But the central system is not the only means of government; there are other modes of regulation, and so other safeguards.

Heart. The object of systole of the ventricle is to secure the needed arterial pressure which drives blood through the capillaries back to the heart. To do this the ventricle must deliver at a stroke a certain quantity of blood, exerting the pressure required to send the blood into the arteries and repeating the stroke at appropriate intervals. Hence the work done will, in part, depend on the quantity of the blood collected in the ventricle during diastole, that is, on the inflow from the venous system. If the quantity be too small, then, though the whole contents of the ventricle be ejected with adequate force at each stroke and the stroke repeated regularly, the ventricle will fail in its object, that is, a lessened venous inflow will tend to lessen and an increased inflow will tend to increase the work of the heart. The venous inflow is dependent on various causes and may be modified by various events.

Blood in filling the ventricle distends its walls, and this distention, especially the fuller distention resulting from auricular systole, also influences the ventricular stroke; for contraction of cardiac muscular fiber is increased up to a certain limit by the fiber being put on the stretch. The influence is more distinctly seen on the arterial side. The greater the arterial pressure against which the ventricle has to deliver its contents, the greater the tension of the ventricular walls. Hence, high arterial pressure tends of itself to enforce ventricular systole.

The spontaneous beat of the heart is the outcome of nutrition of the cardiac tissues. In the absence of all interference by inhibitory or augmentor fibers the heart will continue beating with a certain force and rhythm, determined by metabolism going on in its muscle and nerve elements. Thus the heart will be influenced by anything which effects metabolism. The obvious and direct cause of changes in nutrition and so in the behavior of the heart lies in changes in the quantity and quality of the blood supplied to the cardiac tissues through the coronary arteries. If the coronary arteries be tied or otherwise occluded, the heart in a few seconds comes to a standstill. This illustrates to an extreme how closely rhythmic contraction of cardiac fibers is dependent on blood supply.

The quantity of blood flowing through the coronary arteries is dependent on pressure in the aorta or rather on the difference in that pressure and the pressure in the right auricle into which the coronary veins enter, and on the resistance offered by the coronaries. Hence, with high aortic pressure, more blood passes to the cardiac tissues. This is favorable to the beat and may be the direct cause of the stronger stroke.

More important than the quantity is the quality of the blood flowing through the coro-

* Read before the Clinical Meeting, Throat Department, Massachusetts General Hospital, March 31, 1906.

naries. Blood deficient in oxygen or overlaid with carbonic acid affects the heart beat; also blood with drugs, poisons or products of body-metabolism. When breathing is interfered with, the too highly venous blood, while it acts unfavorably on cardiac tissues, also stimulates the cardio-inhibitory center, whereby the heart is slowed and its expenditure of energy lessened.

The heart beat is regulated by inhibitory nerve fibers from the central nervous system through the vagus, and accelerated by augments fibers from the sympathetic. Any disturbance from the sensory nerves passing up and stimulating either of these, causes marked slowing or acceleration, according to its amount. The effect of inhibition is to lessen the expenditure of energy. The heart cannot be brought to final arrest by simple action of the vagus. The effect of the augment action is to increase the expenditure of energy. This can, at times, cause final arrest of the heart. Disordered cardiac nutrition shows itself frequently in a dilated condition of the ventricles; the systole is inadequate to secure adequate discharge into the arteries, the residual blood in the ventricle is increased. If the augment action is brought to bear on such a weakened and dilated ventricle, it may produce fruitless expenditure of energy. The beat though increased is still inadequate to secure needed discharge of the contents, while the fiber is exhausted by increased metabolism, and the final result is cessation of the beat.

The action of the minute arteries and peripheral resistance is of very great importance. The minute arteries are supplied with two kinds of mechanism which control the peripheral resistance. The vasoconstrictor mechanism of the central nervous system may be used as positive constriction or negative dilation. The vasodilator mechanism exerts its influence in only one way, to dilate. The constrictor mechanism seems to be in more general use. When the arterioles are constricted the blood pressure is high; conversely, when dilated the pressure is low. This is important to remember, as during surgical shock the pressure is low.

General Anesthetics, Ether and Chloroform.—These produce the same effect as alcohol on the central nervous system, a progressive paralysis commencing with the highest cerebral functions, those of self control, and passing downwards through the intracranial divisions. The spinal cord is affected before the medullary centers, which are the last of the central system to be paralyzed. Sensory functions are depressed before motor. Both anesthetics act, at first, as stimulants to the system. Their action on the respiratory center is partly direct, partly indirect. In the first stage the respiratory movements are slowed or stopped temporarily by reflex action set up by irritation of the terminations of the trifacial in the nose and throat and of the pneumogastric in the larynx and bronchi, but this is only of short duration. During the second stage the respiration is often rendered irregular by convulsive struggling which produces alter-

nately periods of asphyxia and deep gasping movements. During the third stage the respiration is regular and no reflex disturbances occur because the sensibility is so dulled that the continued irritation on the nerve ends causes no reflex response. In this stage the direct action of the drug on the center shows itself in slow and shallow respiratory movements. If pushed far enough, the slowness and weakness increase until finally respiration ceases entirely from paralysis of the center.

On the circulation the first change observed in the blood pressure tracing is often a slowing or temporary standstill of the heart due to reflex stimulation of the inhibitory center from irritation of the air passages, but in others a short rise in pressure is seen from similar reflex action on the vasomotor center, later, a fall in pressure and distinct slowing of the beat; eventually, if continued far enough, the pressure is zero and the heart ceases to beat. The majority of observers believe that this falling is due to failure of the vasomotor center, especially of the vasoconstrictor through repeated irritations of the sensory nerves, sending impulses to its center and thus tiring it out by repeated stimulations.

This has an important bearing on shock. The vessels themselves are not acted on directly by the anesthetics in question.

Both anesthetics dissolve the red corpuscles and free hemoglobin, when experimented on outside the body, but I can find no proof that this occurs in the circulation. Apparently, when absorbed chloroform exists not in simple solution, but in combination with cholesterol and lecithin of the red corpuscles.

The drugs generally used in anesthesia accidents are strychnia, the nitrites (nitro-glycerin, amyl nitrite, sodium nitrite), digitalis (digitalin), adrenalin, atropine, hyoseyamine, hyoscine, caffeine and alcohol.

Strychnine is a stimulant and acts on the central nervous system. It slows the heart action by stimulation of the inhibitory center. It stimulates the vasomotor center, causing constriction of the peripheral arterioles, and thus causes increased pressure. This is done by small doses.

The *nitrites* (nitro-glycerin, amyl nitrite, sodium nitrite) act chiefly on the circulation. They cause depression by action on the vasoconstrictor center negatively or by depression of the nerve ends and unstriated muscles of the arterioles, causing dilatation of small vessels with corresponding low pressure.

Digitalis (digitalin) acts as a stimulant on the central nervous system, but principally on the heart and vessels. The action on the central nervous system is of small amount. It stimulates the inhibitory cardiac and vasoconstrictor centers in the medulla only in small doses. In large doses it stimulates other parts of the medullary center causing vomiting, increased respiration and sometimes convulsions. The action on the heart itself is most important and is due to an alteration of the cardiac muscular tissue.

In our present knowledge, it increases the muscular tone of the heart, and thereby the relaxation of muscle is less perfect and contraction more complete and prolonged; but the inhibitory action on the vagus, on the contrary, tends to render the tone less complete and to produce less contraction and more complete diastole. Therefore its muscle and nerve actions are diametrically opposed to each other. In cases where the coronaries are affected by sclerosis or degeneration, it is not advisable to use this drug, on account of rupture. It is contra-indicated when quick results are needed on account of its slowness of action, as Bartholow expresses it, "we give digitalis to-day and expect results to-morrow." Most writers believe that it is only to be given in broken compensation.

Adrenalin chloride acts directly on unstriated muscle fiber and possibly on local nerves. It has no action on the central nervous system. It may cause stronger action of the heart and also constrict the arterioles, causing increased blood pressure. But on account of high pressure it may cause rupture in some of the internal organs, as the spleen.

Atropine acts as a stimulant to the central nervous system, followed by depression, and paralyzes the termination of a number of the nerves, more especially of those that supply involuntary muscle, secretory glands and the heart. It differs from strychnia, which acts on the lower parts of the nervous axis, spinal cord and medulla, while atropine acts more strongly on the higher divisions, motor of the brain. Atropine paralyzes the inhibitory terminations of the vagus in the heart. Blood pressure is increased by the augmented output of the accelerated heart and the stimulation of the vasoconstrictor center in the medulla which contracts arterioles in the abdomen. At the same time there is a compensatory dilatation of the skin vessels, due to the central action of the drug. It also stimulates and then depresses the respiratory center.

Hyoscyamine acts similarly to atropine except that it is a depressant from the start.

Hyoscine is more depressing than hyoscyamine.

Caffeine is a stimulant to the central nervous system. It causes a rise in blood pressure by stimulation of the vasoconstrictor center, similar to strychnia, but slower and of less strength.

The main causes of death under anesthesia are shock, collapse, shock with collapse, asphyxia from mechanical obstruction or otherwise, and status lymphaticus.

Status lymphaticus is a condition of which little is known excepting that it affects the lymph glands and channels in some manner. A few cases of death, during or following anesthesia, have been reported and all have been with chloroform, I believe. It is impossible to diagnose the case before death, and then only by an autopsy. No drug treatment has been suggested.

Asphyxia from mechanical obstruction, etc. is due to lack of oxygen entering the lungs. It is due generally to a foreign body in the air

passages or to paralysis of the respiratory center from an accidental puncture of the lateral ventricles during a brain operation. Treatment of a foreign body is quick removal or low tracheotomy and artificial respiration. There is no treatment for a puncture of a ventricle with its accompanying loss of fluid. Artificial respiration will help as long as it is kept up, to a certain limit, but if stopped the patient will die. Asphyxia may be caused by fluids entering the air passages in a sufficient quantity. Asphyxia may be due to the tongue falling back or a swelling of the base of the tongue or to edema of the glottis. The treatment of the first is to pull out the lower jaw and tongue by grasping with the fingers on the outside angles of the jaw with thumbs inside and at the base of the tongue, pulling forward and outward. For swelling and edema, tracheotomy must be done at once with artificial respiration following. No drugs.

Shock is by far the most important emergency which we have to deal with.

Shock and collapse though distinctly different as to cause will be considered together and differentiated as necessary. The most important feature of shock is the lowered blood pressure. I will briefly consider the mechanism regulating the blood supply. Blood pressure depends, first, on the force and rapidity of the heart beats; second, on the amount of the circulating blood; and, third, on the space which this given amount of fluid has to fill. Given impulses, which cause vasodilation, the great increase in the caliber of the smaller vessels all over the body increases the amount of fluid. The vessels of the body are dilated or contracted by impulses from the vasomotor center on the floor of the fourth ventricle. The impulses are sent from here to terminal plexuses in the muscular coats of the vessels. The best method of raising blood pressure is to produce intense vasoconstrictor impulses.

According to experiments performed by Dr. Crile, of Cleveland, the condition present in shock seems to be due to exhaustion of the center that continuously sends out vasoconstrictor impulses. The condition results in dilatation of the blood vessels, particularly the arterioles, thus making greater space for the given quantity of fluid to fill and thus producing low pressure which gives the clinical symptoms of shock. We must learn to distinguish between shock and collapse because in some respects the treatment is different. Crile has proven that shock is due to exhaustion of vasoconstrictor center. For example, any trauma involving a sensory nerve, if not too great, will produce a rise in blood pressure by stimulating the vasoconstrictor center, and causing it to send out more active vasoconstrictor impulses. Now follow up this injury with a second injury. Again the pressure rises, and again after a third injury, and so on, but each time the pressure rises to a less and less extent. Finally a stage is reached when no stimulation will cause reaction. This is exhaustion of the vasomotor center, or shock.

In collapse, stimulation of the vasomotor center will produce a response. Collapse thus differs from shock in that it is only a temporary suspension of the vasoconstrictor center. This may be illustrated by fainting, from violent mental impressions or from a sudden loss of a large quantity of blood. If in fainting the center is stimulated by dashing cold water on the face, by injections of strychnia or ammonia, the center generally will respond and in a comparatively short time act normally.

The causes of shock are anything that produces over-stimulation and consequent exhaustion of the vasoconstrictor center. Personal idiosyncrasy comes into play largely. Some individuals have more resisting power than others. Anything which tends to weaken the general resistance of the body also tends to weaken the resistance of the vasomotor center. A patient who is nervous and apprehensive about an operation is more liable to suffer from shock than one who takes things coolly. Unnecessary exposure to draughts during an operation or drenching the patient for long periods with solutions will tend to weaken the resistance and so predispose to shock; damp towels, unnecessary exposure of legs, arms or trunk act in same way. Organs that are well supplied with sensory nerves, as the ovary or the testicle, when injured, produce shock more readily than others. The immediate cause of surgical shock is some chemical or mechanical trauma to the sensory nerves.

The predisposing causes of collapse are practically the same as those of shock. But the direct causes may differ. Sudden loss of blood may cause surgical collapse. A severe injury to a highly nervous organ may send such sudden and overwhelming impulses to the vasomotor center as to produce temporary suspension of its function. While a small hemorrhage, extending over quite a period, is an active cause of both shock and collapse, a sudden severe loss is more liable to be followed by collapse. Collapse was very frequently seen in the days of preanesthetic surgery, when an operation was quickly performed with but little regard for immediate hemostasis.

The symptoms of shock are due to malnutrition of the vital centers resulting from lowered blood pressure. The skin is cold and pale. There are beads of sweat on the forehead, there is rapid shallow breathing, the pupils are dilated and the pulse is weak, thready and running. If after an operation the patient is restless, is acutely conscious of everything about, has a cold, clammy and pale skin, a sub-normal temperature, the diagnosis of shock is made easily.

The symptoms of collapse, such as pallor of the skin, weak, rapid pulse, and subnormal temperature, are identical with those of shock. A Tallquist hemoglobin test takes but two to three minutes and may help in making a diagnosis of hemorrhage. In collapse the symptoms usually come on suddenly, while in shock they appear gradually. It is usual to have unconsciousness or delirium in collapse, but not in

shock. The history is of great importance, that is, whether the condition which is present is due to sudden loss of blood, to intense violence upon some highly organized organ, or to trauma extending over some period of time.

The treatment of surgical shock and collapse should be very largely by prophylaxis. The anesthetizer should give as little anesthetic as possible. In certain brain and abdominal cases the operator and the anesthetist should work together, the depth of the narcosis increasing and diminishing as indicated by the operative manipulations. Small amounts of the anesthetic are needed except in abdominal cases, liver and stomach cases and certain brain and eye cases. If the operator is unconsciously and unnecessarily handling highly organized parts, especially intestines, the narcosis should be deeper and the operator's attention called to the fact. All are familiar with partial or complete post-operative paralysis of the intestines due to too much handling even with rubber gloves or gauze, and with the difficulty of overcoming this. Fortunately, nose, throat and ear operators do not have these delicate sensory parts to handle excepting the larynx as in bronchoscopy, thus the patient has a very slight amount of anesthetic, and shock in these cases is practically unheard of. The anesthetist should notify the nurse to prevent any unnecessary exposure of the body, to keep up the external heat, but not overdo it. The mental apprehension and fear of the patient should be talked away. A long-continued Trendelenburg position, by throwing the abdominal contents against the diaphragm, mechanically retards the heart and so should be avoided. In line of preventive measures the "nerve-blocking" procedure of Crile should be used to lessen the shock, when operating on an extremity. As the shock impulses go through the sensory nerves, if these nerves can be blocked, the shock impulses may be cut off, so that if then the large nerve trunks are cut down on after anesthesia and are injected with 4-10 minims of 4% cocaine, the shock is slight.

Drug treatment: When the shock features decidedly predominate, I agree with Crile and Horsley that no drug is of any use except, possibly, adrenalin. Hypodermic stimulants are contra-indicated. There can be nothing done which will so augment shock and diminish the chances of recovery for the patient as to give any of the nitrite group (amyl nitrite, nitroglycerin, sodium nitrite), remedies which are often used. They are distinctly vasodilators, and what is needed is high pressure, whereas the dilators give low pressure, the important feature of shock. Probably some cases that would have recovered without treatment have proved fatal on account of such medication.

You may say that strychnia and the other stimulants give inhibition and high pressure through vasoconstriction, but remember that in shock there is a paralysis of the vasoconstrictor center and that this is caused by too

frequent stimulation. Strychnia stimulates the center exactly the same as mechanical and chemical causes, and by giving it, you try to stimulate a center already exhausted. This is practically sending in the same kind of impulses as produced the shock originally.

Adrenalin is the only drug to be used in this condition. It should be given with saline solution by intravenous infusion. The proportions of adrenalin are 1 1000 solution, one part in 200,000 parts of saline solution. Give it slowly and at 110-115° F. The favorable action of adrenalin in shock is due to the fact that it acts chiefly on the muscles and the local nerve apparatus of the vessels, and not on the vasoconstrictor center which so badly needs rest, thus causing increased blood pressure. Salt solution when alone, given intravenously under the skin or by rectum, is of little or no benefit in cases of shock as it does not raise the blood pressure. All other stimulating drugs, as strychnia, are out of the question for the same reason. Digitalis can be ruled out if for no other reason, for its slowness of action.

In collapse, drugs may be employed with advantage because the vasomotor center needs and can take stimulation to bring it to its proper condition. Strychnia may be used here. Alcohol is of some value in surgical collapse, but its stimulating effect is due to the chemical irritation which it causes. Why use drugs in collapse when cold water on the face, ammonia fumes, artificial respiration will do the work as well and quicker? Salt solution is indicated if the collapse is due to loss of blood. When shock and collapse are combined, the outlook is unfavorable, but treatment should be along the lines of shock.

Rhythmic traction of the heart, by the hand in the abdomen and pressing against diaphragm, should be tried in desperate cases.

To sum up, I think that in cases of shock or collapse during operations drugs are used too freely and without a clear understanding of the reasons why they are given.

In etherizing give as little anesthetic as possible. If an emergency arises find out what it is due to. In collapse due to hemorrhage give saline solution, in shock give no drugs hypodermically, but put adrenalin and salt solution into a vein.

Clinical Department.

DEPARTMENT FOR DISEASES OF THE THROAT,
MASSACHUSETTS GENERAL HOSPITAL.

CLINICAL MEETINGS JAN. 31 AND FEB. 28, 1906.

DISCUSSION ON THE TREATMENT OF SYPHILIS.

General Treatment.—DR. J. T. BOWEN: Iodide of potash should be given where there is a definite local lesion occurring after the early stages. It has no action on the virus of the disease. Mercury is a specific; that is, it has a specific action upon the virus. These two drugs have each its definite indication, and it is seldom necessary or advisable to use them both at the same time. Their combined use, the so-called mixed treatment, as a routine method of treating syphilis is unscientific and is liable to confuse the proper use of the essential drug. No one should treat syphilis until a definite diagnosis can be made. In the early stages this generally means the appearance of the roseola, macula or mucous patches, when mercury is indicated. If after a year or more a local lesion arises, something breaks down, then iodide is indicated. This acts quickly upon the local lesion, and this action is not hastened by giving mercury at the same time. After the local lesions are healed, then a thorough course of mercury should be begun. But if during a course of treatment with injections a local lesion arises indicating iodide, this may be given at the same time. It is seldom necessary to give more than ten grains of iodide of potash three times a day for any lesion of the skin or mucous membrane. This does not apply to late lesions of the nervous system.

The most effective method which I have found for giving mercury is by injections. The subcutaneous method is much used abroad and is probably equally effective if properly done, especially if the bichloride is used. The insoluble salts are liable to cause local trouble.

DR. J. P. CRILE: If the disease should appear some years after it had been acquired and the patient had never been treated, what should be the treatment?

DR. BOWEN: First iodide, then mercury.

DR. CRILE: When should both be given?

DR. BOWEN: In a precocious case, as when a deep lesion appears the first year.

DR. F. C. CONN: In an old case in which a gummy develops would it not save time to begin mercury with the iodide?

DR. BOWEN: Possibly, but the separate indications are distinct.

DR. C. J. WARD: I have seen good results on the skin by local injections. Might not that be useful on mucous membrane?

DR. CONN: On the tongue possibly. It would be difficult to apply to the pharynx. Is the objection to giving both drugs absent for a year or a year and a half?

DR. BOWEN: Mercury soon fails to have a better effect later if it has not been given earlier. With the exception of late gummy disease, iodide is preferred to give iodide when mercury is indicated.

DR. WARD: I have given with good results. If iodide is given when mercury is indicated, the patient becomes used to it, and has to give a large amount of local lesions to purify the system. I do not know if it is better to omit everything for a year and then start again.

DR. D. C. GREEN: Should iodide be omitted when the local lesion is healed?

DR. WARD: Certainly. The iodide does not cure

the disease. But in old cases it may be well sometimes to give iodide as there may be unscen lesions, as of the arteries.

DR. A. COOLIDGE, JR.: In old cases after the local lesions have disappeared under iodide, is it not better to give mercury whether the patient has been treated before or not?

DR. BOWEN: Certainly; but it is often difficult to keep the patient at it. The iodide does not ward off subsequent attacks. We do not know how mercury acts upon the virus of the disease, and it seems to become less effective as the disease becomes older.

DR. COOLIDGE: If it becomes possible to diagnose syphilis positively at the time of the chancre, by the presence of the spirocheta, would it be desirable to begin treatment without waiting for secondary symptoms?

DR. BOWEN: Decidedly, begin at it once.

It has been said, and my experience is the same, that extra genital chancre is more likely to be followed by severe and obstinate late symptoms, nervous and otherwise. There are many cases with undoubted late lesions, where the early lesions have entirely escaped notice.

DR. COOLIDGE: I have for some years only seldom given iodide and mercury at the same time. Ten grains of iodide of potash three times a day is in most cases a sufficient dose to heal late deep-seated lesions in the nose and throat with a rapidity and thoroughness which is one of the wonders of medicine. A great objection to combining the two drugs is the difficulty of regulating the dosage, where the mixture is not well tolerated by the patient. Either of them may produce accidental effects which makes its use difficult to regulate, and the useful one should not be hampered by the poisonous effects of the other.

Local Treatment. — DR. COOLIDGE: In treating the superficial lesions of the fauces and mouth, which occur especially in the earlier stages of syphilis, we should carefully distinguish those appearances which are due solely to the disease, from those which are caused by a local sepsis engrafted upon the mucous patch. I think that we may say that the syphilitic patch itself is seldom painful, nor of foul odor, and that it is not helped by local irritating nor otherwise energetic treatment. But this patch may become infected, as may any other lesion which weakens the epithelium of the mucous membrane, by a variety of micro-organisms which infest the mouth and throat, and in almost all cases it is this local infection which demands local treatment. Treatment should, therefore, be directed towards cleansing the surface and preventing as far as possible the growth of micro-organisms, but anything which tends to injure normal mucous membrane or otherwise weaken its natural protective power should be carefully avoided. Local applications should be made to diseased areas only, and these should never be strong enough to destroy underlying living tissue. A mouth wash and gargle or spray should then be used, as cleansing as possible without being irritating.

If there is a pseudo-membrane overlying the diseased areas, these may be wiped clean and painted with a solution of chromium tri-oxide or nitrate of silver, of a strength sufficient to penetrate superficially, not to cauterize. For a wash to be used frequently by the patient, solutions of borax or boric acid, peroxide of hydrogen or some alkaline and aromatic solution may be given.

The patient is generally taking mercury at this stage and the question often arises whether the local condition is in part due to this drug and whether this should be temporarily stopped. Unless there is tenderness

of the gums or other distinct signs of mercurial poisoning, I think it is better to try local treatment and not to stop the general treatment unless the local trouble proves obstinate.

For the typical mucous patch, which is superficial, not covered with a white pseudo-membrane and seldom painful, local applications are not needed. A cleansing wash is, of course, always desirable. The deeper infiltrations as seen especially on the tongue require constitutional rather than local treatment, but these seem often to do well under a solution of chromium tri-oxide, painted so as to discolor the tissue, but not to the point of leaving an ulcer.

For the late deeply infiltrating and ulcerating gummatous lesions local applications can seldom be applied with advantage, although it may be necessary to remove necrotic tissue. These lesions are generally accompanied by surprisingly little pain or secondary sepsis. They fortunately yield very quickly to iodide of potash internally.

DR. CLARK: I should like to ask what strength of chromic acid solution is used.

DR. COBB: I have been looking up some of the older authorities on syphilis in order to see what changes have taken place in local treatment. Nitrate of silver, chromic acid and several other caustics were in use then as now. More powerful caustics gave very disagreeable pain, lasting many hours.

In order to test the efficiency of local treatment I have painted one side, in cases of bilateral efflorescence of mucous patches and left the other untouched, with the result that much greater improvement in the locally treated side was noticed at the next visit.

DR. J. L. GOODALE: I think chromic acid is of more value than an antiseptic mouth wash. When a mouth wash is used and nothing else, the mucous patches frequently get into an indolent condition, and have a pale, flabby appearance. They respond very readily to chromic acid, and I think 50% is as good as a stronger solution. I have found that 50% or weaker solutions have a selective action on the eroded membrane. Where there is even a very superficial erosion the acid will give rise to a yellowish patch which stands out very distinctly against the normal mucous membrane of the vicinity which is not stained.

DR. H. P. MOSHER: In late syphilis after all other manifestations have long since cleared up, superficial ulcerations often alternating with patches of leukoplakia persistently recur at the sides and the tip of the tongue. The slightest irritation brings them back. They worry the patient because he thinks that the disease is still active, they worry the physician because he cannot cure them. I have been accustomed to use mild solutions of chromic acid on them. At times I have used almost pure chromic acid.

DR. COOLIDGE: In regard to Dr. Clark's question, I have used from 10 to 50% solution in water. The proper strength to use is the one which is strong enough to take hold of the diseased part, and not to destroy the normal epithelium.

PAPILLOMA OF THE LARYNX.

DR. J. P. CLARK showed a case of papilloma of the larynx in a boy ten years old. Tracheotomy had been done two years previously, and the tube was still in and to be kept in until the period of active growth of the papilloma was over or until the boy is old enough to allow periodic intra-laryngeal removal under cocaine if necessary. The boy comes in at stated times for observation. An attempt will be made this spring to remove what remains of the papilloma through the Kirstein autoscope, if the appearance of the growth seems to warrant it.

LATERAL DEFLECTION OF THE NASAL BONES.

Dr. A. COOLIDGE, JR.: A case of marked deflection of the nasal bones to the right corrected by Dr. Mosher's method.¹ An obstructing deviation of the septum had been previously corrected by the submucous operation, with good results. Under ether a short incision was made through the skin opposite the lower part of the suture between the nasal bone and nasal process on each side, the nasal bones cut with a narrow chisel along this line and across their base, below the attachments to the frontal. The skin is so movable that the nasal bones may be chiseled without injuring the skin except for the two small incisions corresponding to the breadth of the chisel. These leave no noticeable scar. It is generally necessary to break portions of the nasal processes also, to fit the nasal bones in their new position.

SUBCUTANEOUS CORRECTION OF ROMAN NOSE.

Dr. D. C. GREEN: As the result of periostitis following trauma this patient had a marked Roman nose. The scar which is present was also the result of the accident. The operation for correcting the deformity was as follows: An incision was made within the nose through the mucous membrane over the lower edge of the left nasal bone. The nasal bone was freed from the skin above and the mucous membrane below and made to present the same as the cartilage of the septum is made to present in submucous resection. Both bones were treated in this way. Especial attention was given to the skin over the deformity. When everything was free a median strip including the deformity and a bit of the septum under it was taken out, leaving a gap. Then each nasal bone was chiseled free along its outer border and the bones pressed together so that they met again in the median line without deformity. The bones stood in place so readily that no splint was necessary. The profile of the girl's nose to-day is straight.

REMOVAL OF THE TONSILS FOR RHEUMATISM.

Dr. H. P. MOSHER: This patient, a girl about twenty-two, has had repeated attacks of articular rheumatism. The x-ray plates show distinct changes in one wrist. Along with the rheumatism the patient has had recurring attacks of bilateral tonsillitis. The tonsils were thoroughly removed hoping that they might be the portal of entry for the infection. They were of moderate size and of the so-called non-draining variety. The immediate effect of the operation was to precipitate a fresh attack of rheumatism. On section the tonsils showed what they show in most of these cases, that is, but little—simply here and there evidences of chronic inflammation about some of the crypts.

A CASE OF TURBINOMY.

Dr. G. H. POWERS, JR.: In this case the lower turbinates almost totally obstructed the nose. I trimmed the turbinates with scissors cutting a strip of mucous membrane about 1 inch wide from end to end. It is only two days since the operation so there is still oozing. There was very little bleeding. In about five days healing will be complete. The case shows how little reaction you ordinarily get. Turbinotomy seems to me the most safe method of reducing the size of large turbinates. One or more strips may be taken from a turbinate according to demands of individual cases.

OGSTON-LUC OPERATION.

Dr. J. P. CLARK: A case of frontal sinus empyema operated on three years ago by the Ogston-Luc method. The empyema has been entirely cured by the operation. The interesting point in the case is the absolute lack of visible scar. Even on close inspection it is difficult to find any external traces of the operation.

BULLO'S MIDDLE TURBINATE.

Dr. H. P. MOSHER: The patient had a large, cellular, middle turbinate which before operation reached nearly to the inferior meatus. In 90% of cases the middle turbinate has one or more cells. It is a fairly common anatomical variation to have the middle turbinate so large from the overgrowth of the cells in it, that it not only obstructs the middle meatus but presents at the vestibule. In beginning the treatment of disease in the ethmoid region it is essential to know the size and condition of the related sinuses. The x-ray will give this information. For instance, in this case, the plates showed that the frontal sinus did not reach the brow but had remained little developed in the ethmoid labyrinth. Had there been pus the operator would learn at once from this finding that the frontal sinus need not be considered.

A CASE OF ACUTE INFLAMMATION OF THE LEFT FRONTAL SINUS, ETHMOID LABYRINTH AND ANTRUM.

Dr. Mosher: At the present time the patient is free from all symptoms. When he came to the hospital six weeks ago there was pus in the middle meatus and he had the pain of a general left-sided sinusitis. The plates showed that the frontal, the ethmoid region and the antrum were opaque as compared with the other side, thus confirming the clinical diagnosis. The usual treatment, the removal of the anterior end of the middle turbinate and washing out the antrum speedily cleared up the pain and the discharge.

KILIAN'S OPERATION FOR EMPYEMA OF THE FRONTAL SINUS.

Dr. Mosher: This patient gave a history of left-sided nasal discharge of pus with pain over the left antrum and the left frontal for one year. X-ray plates which were taken one month before the patient's turn came round for entering the hospital showed that the whole left side was opaque. On the strength of this and because the frontal was small, and, further, because I had satisfied myself on previous cases that the Kilian operation gives no deformity in a small sinus beyond the scar, I performed on this man what might be called an exploratory Kilian operation. The anterior internal angle of the floor of the frontal sinus had narrowed away. There was no pus in the sinus and no pus was found in the ethmoid cells. Therefore, the question came up whether the pus had drained away between the time that the plates were taken and the operation or were the plates unreliable. In three other cases which gave the same x-ray pictures as this case I found on operating pus in the frontal and ethmoid. More experience is needed on this point. The patient has no deformity and the greater part of the scar is hidden by the eyebrow.

The arch of the palate was very high and the uvula was high also and much retracted. Owing to this I could not get into the antrum except at the top under the lower ram of the orbit. In doing this the inferior orbital artery was injured and gave annoying bleeding. The operation was finished by clearing the antrum of pus and entering it, and making a larger opening up to the inferior meatus from the antrum into the nose. The subsequent history of the case has shown that the

¹ Laryngoscope, January, 1905.

deep alveolar prolongation of the antrum caused by the high arch makes the opening into the inferior meatus drain poorly. For this reason the fistula in the canine fossa will be slow in closing.

DISCUSSION.

DR. COOLIDGE: There is great need that we should know more than we do now about the etiology of empyema of the frontal sinus, in order that we may attack it intelligently. In the case of the antrum we are sometimes able to find the cause of an empyema. There may be a foreign body in it, or a source of pus in connection with a tooth, or tooth socket, or the antrum may be acting as a reservoir of pus from the ethmoid or frontal. We seldom know anything about the cause of pus in the frontal. If in any case it arises from one focus, as it sometimes does in the antrum, it could probably be cured by attacking that focus, with a less extensive operation and with more certainty of relief than by blindly opening the whole sinus and removing as much as we can remove. At least it would be of great help in the choice of an operation.

DR. COBB: I can heartily indorse Dr. Coolidge's remarks. We know from Dr. C. G. Coakley's experience that diseased bone is seldom found in the frontal sinus, and it is a matter of common knowledge that the antrum seldom contains sequestra. Of the ethmoid we know less, but we do know that curettage of the cells and breaking down of bone which contains foul-smelling pus has more than once resulted in complete cure of the ethmoid, and, without additional treatment, of the antrum as well. Can we draw the conclusion that the ethmoid is the center from which antrum and frontal are infected? Until the pathology of the ethmoid is better understood, perhaps not, but the possibility is certainly worthy of consideration.

A PRELIMINARY REPORT ON THE POST-OPERATIVE RESULTS OF ADENOIDS AND TONSILS.

DR. I. D. KERR: Of 142 cases operated upon at this hospital during the past six months for adenoids and tonsils, I find that 7% more occur among males than in females, and that the average age operated upon is seven and one-half years.

The general condition of the patient was found to be good in 58% of the cases; fair in 34%; poor in 21%. Open mouths were found in 72%; high arches in 53%; crowded teeth in 26%; deflected septa in 14%. The tonsils were large in 46% of the cases; moderately large in 33%. Adenoids present and large in 85%.

The principal reasons for which these cases were called to notice and referred for operation were:

Mouth breathing in 61 cases; difficult breathing in 20 cases; enlarged tonsils in 19; frequent tonsillitis 11; cervical adenitis, 13; nasal discharge, 3; catarrhal laryngitis, 2; earache, 2; impediment in speech, 2; cough, 1.

In these 142 cases, it was found before operation that mouth breathing was a prominent symptom in 78% cases,—two thirds of these cases being constant mouth breathers while one third were periodic mouth breathers.

By operation 96% of these cases have been benefited, mouth breathing persisting in only 4% of the cases.

Snoring was found present in 72%; operation shows a decrease in this symptom to 4%. Restlessness at night, present in 68%; after operation present in only 1%. Recurrent colds, 82%; after operation, 81%. Cough, 16%; after operation, 17%.

Euresthesia was present in 7% of the cases and persisted in 2% of the cases after operation.

Deafness, found in 32%; after operation, 6%. Earache 26%; after operation, 13%.

In 13 cases of cervical adenitis, operation was followed by a marked diminution in the size of the glands in all but one case and in this case the glands remained the same size.

There were 3 cases of cervical adenitis reported as following the operation and 5 cases of otitis media.

Three cases of discharge from the middle ear before operation are reported as clearing up immediately after the operation.

Of 3 cases of dullness at school, 1 shows a marked improvement, 1 a slight improvement and the third none at all.

Of 3 cases of impediment in speech, one has shown much improvement.

One case of asthma reports much improvement following the removal of large tonsils and adenoid.

Four cases of chronic bronchitis have been greatly improved by operation.

Two cases of catarrhal laryngitis show improvement. One case of rheumatism shows no improvement in this symptom after removal of tonsils.

These cases have all been seen once or twice, from two weeks to six months after the operation.

The improvement in some has been so rapid that of 107 cases seen for the first time within two weeks following the operation, over one third have shown an entire subsidence of all the symptoms.

In conclusion, I think the vast majority of the cases operated upon for adenoids and tonsils show a marked improvement following the operation. Their general condition is improved, their breathing easier, the appetite increased; they are less restless and less nervous; snoring has ceased and sleeping is much improved.

Children appear brighter, talk more distinctly and seem to take more active interest in their school work.

Medical Progress.

RECENT PROGRESS IN OBSTETRICS.

BY W. L. BURRAGE, M.D.

PYELONEPHRITIS IN PREGNANCY.

ERNST RUPPANNER¹ reviews the two factors which are necessary for the production of a pyelonephritis, a bacterium which can produce inflammation and soil favorable for its growth. The bacillus coli communis is the common cause and the streptococcus and the staphylococcus may also act in this way. The infection generally comes from the bladder, and pressure on the ureter by the pregnant uterus is a favoring cause because of the trauma which is inflicted, also the stasis of the urinary current caused by the closure of the lumen of the ureter. Pressure on the right ureter is more frequent and right pyelonephritis is more common. Infection may come also from the blood or from the bowel contents. Previously diseased kidneys are more prone to pyelonephritis than healthy ones.

The disease usually begins during the middle months of pregnancy. It may be manifest with chills and fever and much pain, a sudden attack, or it may come on gradually. There may be

¹ Münchener medicinische Wochenschrift, No. 6, 1906, p. 254.

remissions, when symptoms are absent. Frequency of micturition is a constant symptom, whether there is cystitis or not. The urine is acid, with a slight trace of albumin, a little pus, blood, calcic oxalate crystals and bacteria, but no casts until the later stages of the disease. The kidney affected is tender to pressure and there is muscular rigidity, but no tumor can be felt in a majority of cases. The life of the mother or child is not directly jeopardized and the condition of the kidney improves after delivery. In 20 per cent. of his 91 cases, Cathala noted that spontaneous delivery took place. The author had this issue in one of his own cases at the Basel City Hospital for Women.

The best treatment in most cases is rest in bed in the horizontal position, as under these conditions the uterus does not press so deeply into the pelvis.

For the purpose of disinfecting the urine, the author obtained the best results from the administration of urotropin and salol. He saw, also, good effects from helmitol and aspirin; when there is cystitis, irrigation of the bladder is called for. Alkaline mineral waters are useful. Cases are reported in the literature in which artificial delivery was necessary; this must be a rare occurrence. Surgical interference in pyelonephritis of pregnancy is limited to an occasional nephrotomy. Pregnancy is, however, no longer a contra-indication to operations on the kidney.

RESEARCHES ON SYPHILIS OF THE PLACENTA.

V. Wallich and C. Levaditi² having made microscopic studies of the placenta in cases of syphilis, come to the conclusion that, from the anatomical-pathological point of view, spirochaete have been found in a majority of cases in the fetal portion of the placenta, and that rare parasites have been distinguished in the maternal portion of the placenta, it being impossible to say whether the latter micro-organisms penetrated into the placenta before or after delivery. The spirochaete have a perivascular arrangement, which is comparable to the location of the parasites found in the organs of the new-born subjects of hereditary syphilis, and in chancre. From the clinical point of view, the spirochaete have been found in the placenta only in the cases where there were evidences of syphilis in the fetus. Therefore, it is difficult to diagnose from a histological examination of the placenta with reference to the presence or absence of spirochaete, syphilis of the parents, or to make a prognosis as to the future health of the child.

THE PHYSIOLOGY OF UTERINE CONTRACTIONS.

E. M. Kurdinowsky¹ reports from the physiological laboratory of Professor Geyle of Zurich extensive observations which he has made upon the contractile functions of the uterine muscle. His conclusions are as follows: (1) Heat and cold

are the most constant and the most vigorous of the stimuli to uterine contractions, more especially sudden changes of temperature. (2) Thermic stimuli produce the same effect in their different forms, namely, strong contractions of the uterine muscle becoming tetanic in character; moist heat being more effective than dry. (3) Cold has a more powerful effect than heat and the contractions are of a sharper and more tetanic character, and tetanus of the uterus is more common after stimulation by cold than by heat. (4) Increase in the temperature of the blood increases the contractile activity of the uterus.

In the same number of the *Archiv*, Kurdinowsky gives the results of his experiments to settle the question of the influence of asphyxia and anemia upon uterine contraction. He considers that asphyxia lessens to a marked degree the reflex and contractile excitability of the uterine muscle. The intestines of animals contracted energetically when, under the same conditions, there was no effect on the uterus.

In the case of pregnant animals the same result was noted in anemia. Where the uterus was deprived of a part of its blood the uterine muscle failed to respond to stimuli. Variations in the blood pressure in the same individual seemed to have no effect on the uterine contractions.

THE VALUE OF ESTIMATING THE HEMOGLOBIN IN THE BLOOD OF PREGNANT WOMEN.

L. Devraigne¹ calls attention to the importance of investigating the condition of the blood in practical obstetrics, with special reference to the cases which have lost blood through placenta previa or other causes. He uses the apparatus of Gowers-Sahli and does not consider that a laboratory is necessary. From a clinical point of view the percentage of hemoglobin is more important than the number of the blood corpuscles. Many analyses of the blood in different abnormal conditions of pregnancy are given by the author. A low percentage of hemoglobin calls for the interruption of pregnancy.

The technique of the examination is simple.

DISENGAGEMENT OF THE ARM IN VERSION.

Apfelstedt² of Berlin, dwells on the need of careful manipulation of the child's arm during version to avoid delivering a dead child or one with a broken arm. In breech deliveries, to prevent the extension of the arms, he operates as follows: The left hand is introduced into the vagina and the right is placed on the fundus uteri externally. The membranes are ruptured and the left hand is passed over the nearest shoulder of the child, along the forearm to the elbow and seizes the arm so that the elbow and forearm lie in the palm of the operator's hand. The child's arm is then brought down, extended over the hip into the vagina until it reaches a position of abduction. After a brief interval of rest the corresponding foot is seized and brought

² *Archiv für Gynäkologie*, 1905, Bd. LXXX, Hft. 2.

¹ *Chirurgische Monat*, 1906.

² *Berliner klinische Wochenschrift*, No. 50, p. 1557, 1905.

into the vagina, the right hand on the outside all the time aiding in the manipulations. The rest of the delivery is accomplished in the usual way.

PUERPERAL ECLAMPSIA.

Under this heading John F. Moran⁶ gives the statistics of the 28 cases of eclampsia occurring in the last 2,035 confinements in the Columbia Hospital of Washington, D. C. The proportion of eclampsia was therefore one in every 72 confinements. Fifty per cent were black; the ages ranged from forty-four to sixteen; primiparae, 21; multiparae, 5; not given, 2. Convulsions occurred antepartum in 57%, intrapartum, 25%; post-mortem, 10.5%; not given, 7%; greatest number of convulsions, 56; earliest convulsions at five months' gestation; latest, tenth day after labor. Cephalic presentation in 26, breech in one case.

Prenatal symptoms were present in 23. Artificial delivery was resorted to in 15, natural delivery in 13, abdominal Cesarean section in 1, vaginal Cesarean section and forceps in 2, induction of labor and forceps in 1, manual delivery of breech in 1 and forceps in 10 cases. Venesection was practiced in two instances.

Maternal mortality, 7; infants died within three days, 7; stillborn, 7; unknown, 1.

The author is firmly convinced that the practice of giving anesthetics continuously or intermittently, extending over a period of some hours, adds to the inherent gravity of the disease and is largely responsible for the high mortality. He prefers to use morphine hypodermically on account of the certainty of dosage and rapidity of action. He also uses chloral hydrate, veratrum viride, nitroglycerin and venesection to control the convulsions.

Careful observation of pregnant patients is advised, for the purpose of becoming familiar with the hepatic and renal functions. In the case of the patients coming to the hospital there were very few data to be obtained as to these functions.

HEBOTOMY OR PUBIOTOMY.

A. Dührssen⁷ is favorably inclined toward hebotomy (sawing the ramus of the pubes on either side of the median line). He has collected 115 cases with 6 deaths reported in the literature. He presents a case, giving a photograph of the external genitalia and an x-ray plate taken fourteen days after delivery. There was a scar in the labium majus and moderate separation of the fragments of the pubic bone with callus formation. He considers the operation simple and advises against suturing the wound in the soft parts. Version is preferred to forceps after hebotomy and he counsels anticipating the actual beginning of labor by the operation lest delay destroy the life of the child.

Five articles on the subject of extramedian symphysectomy appear in the *Zentralblatt für*

Gynäkologie for Feb. 24, 1906. Max Henkel of Othausen's clinic reports a case of contracted pelvis and central placenta previa; pubiotomy or hebotomy, vaginal Cesarean section, version and extraction.

He thinks that hebotomy should not be performed when the true conjugate diameter is 6.75 cm. or less with a flat pelvis, or 7.5 cm. with a generally contracted pelvis. The operation is easy and simple, but should be performed only in selected cases. If a woman with an abnormally small pelvis has been in labor for a long time and has a temperature, he advises perforation of the living child, even in the case of a primipara, rather than sawing the os pubis, as the danger of secondary injury to the great veins and the bladder which lie behind the pubic bone, is considerable. He thinks the operation is contra-indicated in eclampsia and should not be done by the general practitioner, as severe hemorrhage and other complications have occurred, even in the hands of experienced operators. Henkel's operation was successful and required just thirteen minutes to perform, including the suture of the uterus. The patient had a contracted pelvis, the true conjugate measuring 7.75 to 8 cm. The previous pregnancies had been terminated by perforation of the fetus or abortion. A living child was obtained and there was no excessive hemorrhage.

Krämer, of Giessen, contributes illustrative cases to show that hebotomy can be used to supplement the other methods of artificial delivery, as the Waleher pendulous pelvis position, high forceps, etc. He gives an x-ray picture of Rosenfeld's experiments with hebotomy on the cadaver, showing great separation of the fragments of the pubic bone, the external portion being raised by contraction of the rectus muscle.

Seeligmann, of Hamburg, discusses the preferable technic, and advises that the operation be performed in a private house and that the secondary suture of the pelvic bones should be made thirty hours after the hebotomy, the patient being anesthetized a second time.

F. Jessen reports a case in which the Gigli saw broke during the operation and he was unable to complete it, finishing with a symphysectomy. There was excessive hemorrhage when the point of the saw came through the labium majus. It was controlled by suture.

Kannegiesser, of Dresden, attributes his success with hebotomy to his subcutaneous technic. A needle is first introduced from above and worked down behind the os pubis to emerge through the skin of the labium. The Gigli saw is drawn through the wound by a thread attached to the needle. Care is taken not to have the wound in the skin over that in the bone, the skin being drawn to one side.

The same author in another place⁸ reports 21 cases with x-ray photographs taken at varying intervals after operation. There was separation of the bone through the foramen ovale in several cases. Bone formation about the ends of the

⁶ American Journal of Obstetrics, May, 1906.

⁷ Berliner klinische Wochenschrift, No. 49, p. 1521, 1905.

⁸ Archiv für Gynäkologie, Bd. 78, Heft, 1, 1906.

separated fragments of the os pubis was to be noted in some instances at intervals of several months after the hebotomies and a partial callus was seen in one case thirty-one days after. As a rule no bone had formed in the fissures, and separation of the fragments was very considerable as shown by the x-ray plates. Kannegrasser advises that the ends of the bone be brought into apposition and wired at the time of delivery, before the patient is out of ether, unless better results with this operation are obtained.

Reports of Societies.

RHODE ISLAND MEDICAL SOCIETY.

NINETY-FIFTH ANNUAL MEETING.

At a meeting of the Council and House of Delegates, held in Providence, R. I., May 23, 1906, the following were elected officers for the ensuing year:

Christopher F. Barker, Newport, president; Charles V. Chapin, Providence, first vice-president; Frank B. Fuller, Pawtucket, second vice-president; Stephen A. Welch, Providence, secretary; George S. Mathews, Providence, treasurer.

Standing Committee of Arrangements: W. B. Cutts, P. Williams, H. G. Partridge. On Publication: G. D. Hersey, C. M. Golding, G. T. Swarts. On the Library: H. G. Miller, G. D. Hersey, G. W. Porter, G. L. Collins, F. L. Day. Curator: W. J. McEw. On Nomenclature: H. C. Putnam, E. B. Harvey, L. F. C. Garvin. On Legislation: G. T. Swarts, W. F. Gibson, W. L. Munro, C. F. Barker, S. A. Welch. On Building: H. G. Miller, J. W. Mitchell, R. F. Noyes, F. H. Peckham, F. T. Rogers. Auditors: E. B. Harvey, W. A. Risk. On Medical Education: G. T. Swarts, C. V. Chapin, J. M. Peters.

It was voted that the September meeting be held in Woonsocket.

The annual report of the secretary, Dr. Stephen A. Welch, showed that the total membership was 365 of these 329 were resident members, 24 non-resident and 12 honorary.

The annual report of the treasurer, Dr. George S. Mathews, showed that the total receipts for the year were \$1,724.85, and the expenses \$1,687.37, with cash on hand March 1, 1906, amounting to \$340.49.

The reports of the councilors of the district societies showed that each of the local societies had had a prosperous and successful year.

Dr. George D. Hersey for the Library Committee, reported that 295 books had been added during the year and some 400 health reports, the latter the gifts of Drs. C. V. Chapin and G. T. Swarts.

Dr. G. T. Swarts, for the Committee on Medical Legislation, reported that the only medical legislation enacted was an act to regulate the sale of certain narcotics, known as the Anti-Narcotic Bill.

The general session was held in the Truro Hotel, Providence, on Thursday, May 31, 1906.

For the trustees of the Fiske Fund, Dr. Halsey DeWolf reported that the prize of \$250 for the best essay on the "Etiology and Diagnosis of Epidemic Cerebrospinal Meningitis," had been awarded to Dr. Archibald William Fyfe, of New York City.

The subject chosen for the year 1906-07 is "Diet in Typhoid Fever." The prize is \$250.

The subject for 1907-08 is "Has Surgical Treatment Lessened the Mortality from Appendicitis?" The prize is \$200.

For the Trustees of the Chase-Wiggin Fund, Dr. George S. Mathews reported that a prize of \$75 was offered for the best essay on "Tobacco and Its Evil Effects on the System."

Dr. A. L. Stanwood, of Maine, and Dr. F. B. Lund, of Massachusetts, were introduced as delegates.

Dr. Henry Rolf Brown, in behalf of the California Physicians' Relief Fund, spoke of the need of physicians in San Francisco.

A motion to appropriate a sum of money to this fund was referred to the Council who subsequently voted \$100 to this object.

As additional delegates to the meeting of the British Medical Association the president named Drs. George L. Collins, Frank E. Peckham and Stephen A. Welch.

The following papers were read, by Dr. WILLIAM F. BARRY.

THE PHYSIOLOGY AND DISORDERS OF SLEEP.

And by Dr. FRANK E. PECKHAM,

THE TREATMENT OF FRACTURES OF THE NECK AND SHAFT OF THE FEMUR.

The annual address was given by the president, Dr. CHRISTOPHER F. BARKER, on the

PHYSICIAN'S OBLIGATION.

At the annual dinner Dr. Herbert Terry was anniversary chairman.

Addresses were given by Dr. C. F. Barker and Prof. J. Irving Manatt, of Brown University.

Recent Literature.

The Pathology of the Eye. Vols. 1 and 2. By J. HENRIER PARSONS, Assistant Ophthalmic Surgeon, University College Hospital, Curator and Pathologist, Royal London (Moorfields) Ophthalmic Hospital, New York. G. P. Putnam's Sons. 1904-1905.

While for several years there has been a plethora of textbooks on clinical ophthalmology, an adequate textbook in English devoted exclusively to the pathology of the eye has been entirely lacking. In fact it has been only within the past three years, during which the treatises of Greeff and Ginsberg made their appearance, that such a textbook in any language has been available. Although written in English, Parsons's work is more complete than either of the two German ones, a rather unusual circumstance. The author has already shown himself well qualified to deal with his subject on the grounds both of practical experience and critical judgment. The completed work is to consist of four volumes, only the first two of which have appeared. These take up the pathological histology of the various ocular structures, considered separately. The other two volumes are to deal with the general pathology of the eye, that is, with pathological processes involving the eye as a whole, such as glaucoma. The first two volumes follow in a general way the plan of Ginsberg. The normal histology of a part is first reviewed before the pathological changes are considered. The work is profusely illustrated, chiefly with photographs. While the latter are excellent in their way, well

executed drawings would no doubt be more acceptable to many. As the writer himself anticipates, his deductions will not in all cases meet with universal acceptance. However, disputed questions are as a rule discussed sufficiently fully for the reader to draw his own conclusions, and the complete bibliography at the end of each section enables him readily to refer to original sources for further information. Parsons's book will be read with interest by the clinician, and will be of value as a book of reference to the special pathologist. It will also be appreciated by the general pathologist who is occasionally called upon to examine eye specimens and who is, naturally enough, unfamiliar with the recent advances in the special pathology of the eye.

F. H. V.

Surgical Nursing and Principles of Surgery for Nurses. By RUSSELL HOWARD, M.B., M.S. (London), F.R.C.S. (England). Lecturer on Surgical Nursing at the London Hospital, etc., London. Edward Arnold, 1905.

This book of 300 odd pages is based on a series of lectures on surgical nursing, given to the "probationers" at the London Hospital. The author intends to present concisely the principles or essentials on which modern surgical treatment is based, and at the same time enumerate the details important from the nurse's standpoint. That is, to teach the principles which the nurse must understand in order to render the surgeon efficient aid.

The introductory chapters treat of general subjects and some surgical pathology, hemorrhage, shock, asphyxia, burns and scalds; following this the preparation for operations, operative room details, and postoperative treatment. The remaining chapters describe special operations and the special details of the postoperative care concluding with chapters on bandaging, infants and massage.

The impression one receives by reading this volume is, that it is a book, the chief value of which would be to its author's students. For others not familiar with the routine of the London Hospital it will have only a secondary value, for the facts are at times presented in such a way that much must be supplied to make the text complete. For example, in describing intravenous infusion the nurse is simply told to have ready six pints of boiled water. This is rather scanty information for the preparation of a liquid intended to be introduced directly into the blood current, unless the surgeon intends to superintend all the other necessary minutiae, or that the nurse has received, or is to receive, the necessary additional information in some other part of her hospital course.

At times, details of technique which are the work of the surgeon rather than the nurse are described; while sometimes the details necessary to enable her to work intelligently are omitted.

However, one must not think from the above that this book contains nothing of value for, quite the contrary, there are many important

facts scattered through its pages which are concisely and correctly presented, but it is a book having a local value and is not adapted for general use in this country.

The Treatment of Diseases of the Eye. By DR. VICTOR HANKE, of Vienna. Translated by J. HERBERT PARSONS, B.S., D.Sc., F.R.C.S., and GEORGE COATS, M.D., F.R.C.S. London: Hodder and Stoughton. Chicago: W. T. Keener and Co. 1905.

The avowed intention of the author, who is the first assistant of Professor Fuchs, is to supply the general practitioner and student with such hints and indications as may be necessary for the successful treatment of diseases of the eye. The question of diagnosis, differential in particular, has received more than ordinary attention, while description of operative procedure, so frequently found in even the smaller treatises of this class, has been very sensibly omitted, as it was thought better to merely mention briefly such surgical treatment as might be considered advisable, thereby emphasizing the importance of placing matters of operative technique in more practised hands. As it is practically a *résumé* of Professor Fuchs's clinical methods and experience, special workers in this branch of medicine may find its pages worthy of their attention. The translators have followed the original text closely although occasionally they have substituted British pharmacopoeial preparations for the Austrian. There are 214 pages of reading matter, without illustration, supplemented by a good index. It is compact and of convenient size.

A Textbook of Physiology for Medical Students and Physicians. By W. H. HOWELL, Professor of Physiology in the Johns Hopkins University. Pp. 905. Philadelphia and London: W. B. Saunders & Co. 1905.

It is a pleasure to record a publication so scholarly as Professor Howell has produced in this new textbook. Here one finds a work evidently based on an acquaintance with the original sources, and bearing internal evidence that the writer has kept his reading of these sources up to date and has read with careful judgment. The aim of the book is twofold: to present the facts and theories of physiology simply and clearly; and to present, not the whole subject but such part as seems most important. The great mass of physiological literature is thus reduced for the beginner by elimination rather than by condensation. What should be eliminated and what included are questions which different men will decide differently, but from the point of view of a teacher in a medical school it would seem that little fault could be found with Professor Howell's selection. The large number of original illustrations and the frequent references to the experimental sources of the science are features which add the element of authority to the entertaining and lucid exposition which characterizes the book.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JUNE 28, 1906.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico. \$6.00 per year for all other countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 207, Paddock Building, 101 Fremont Street, Boston.

THE MASSACHUSETTS MEDICAL SOCIETY AND HOMEOPATHY.

It is a sign of progress that the Massachusetts Medical Society has so far modified its rules of admission that homoeopaths may become members of the society under the same conditions that apply to practitioners of the regular school. The modifications in the by-laws which have rendered this change possible we published in our issue of last week in the official report of the councillors' meeting. Hereafter all persons will be admitted to the Massachusetts Medical Society who can give satisfactory evidence of moral character and an educational equipment sufficient to pass the examination prescribed by the society. Candidates for admission must, however, give proof that they have studied medicine at an authorized medical school recognized by the councillors of the society and have received a diploma from such school. They must also not profess to treat diseases by an exclusive system. If a candidate can satisfactorily meet these requirements, he may hereafter become a member of the Massachusetts Medical Society without question as to his therapeutic theories. The therapeutic question is left absolutely to the individual conscience, and no questions will be asked as to his method of treatment, provided the broader question of non-exclusiveness is met. There are at present eight homoeopathic schools recognized by the councillors of the society, the graduates of which, naturally, owing to the altered by-laws, are candidates for admission to the society.

It follows from the foregoing that no special

insistence will hereafter be laid upon what has come to be known as regular practice. It is felt, and we think properly, that many who call themselves and are regarded as homoeopaths differ in no essential respect in their practice from those who make no profession of exclusiveness. If such practitioners are desirous of joining the Massachusetts Medical Society, the opportunity is now open to them, and no doubt, as time goes on, many will avail themselves of this opportunity. According to the existing law of Massachusetts the state defines what constitutes regular practice, and those who successfully pass the State Board examinations are legally entitled to practice medicine without further question. It has appeared, therefore, to the councillors of the Massachusetts Medical Society that the sharp distinction between so-called regular and homoeopathic practitioners may, with profit, be allowed to lapse to the end that the medical profession may present a more united front.

In relation to the general question we have recently had occasion to say that medicine, both on its practical and theoretical side, should offer a solid front against the encroachments of rampant quackery. Recognizing therefore the somewhat contentious distinction which now exists between practitioners in good standing, the councillors of the Massachusetts Medical Society have felt that progress would be gained by ignoring the differences which have hitherto excluded homoeopathic practitioners and permitting them to join the society under conditions to which we believe no right-minded man can object. This final action was not taken without much discussion and consideration. No doubt there are two sides to the question, and it may well be so long as the homoeopaths cling to a principle of treatment which the great body of scientific men have rejected. The situation, therefore, continues to offer material for argument, but we are convinced that neither side can treat the question in general good will, and much better than the action of the Massachusetts Medical Society.

MEDICAL INSPECTION OF PUBLIC SCHOOLS.

In our issue of May 22, 1906, we have already referred to the efforts of the Massachusetts Medical Society to secure recognition of the regular medical school graduates as medical inspectors of the public schools. In our issue of June 11, 1906, we have reported that the Massachusetts Medical Society has been successful in securing recognition of the regular medical school graduates as medical inspectors of the public schools. In our issue of June 11, 1906, we have reported that the Massachusetts Medical Society has been successful in securing recognition of the regular medical school graduates as medical inspectors of the public schools.

the legislators would be influenced by the many arguments in its favor. It will, perhaps, be remembered that his Excellency, Governor Guild, in his inaugural address under the heading of "School Inspection," called attention to the urgent need of action in this matter. On that occasion he made the following statement:

"The work of the State Board of Education shows satisfactory progress, as usual. I would suggest, however, that you consider legislation contemplating a more general medical inspection of school children, as now practiced in some localities, notably for the discovery of infectious diseases and physical defects. A child may be a dullard at school and a failure in life because of undiscovered defects in eyesight or hearing. There are, to quote one line of work only, children now struggling for education through pain,—ailing little creatures, backward in their lessons, tortured with racking headaches,—who only need relief of a complaining set of nerves by a pair of properly adjusted glasses, to transform them to healthy, happy children, capable of assimilating all the benefits of their school work."

It must be a source of great gratification to all concerned in the furthering of this most excellent bill that it received the signature of the Governor June 20, and, therefore, has now become a law. That this is a step in the right direction cannot for a moment be questioned. It has become a commonplace of observation to say that medicine of the future must be largely prophylactic, and nowhere can this prophylaxis so well be practiced as in our public schools where disease and defect must inevitably early make their appearance. It is furthermore significant that very many affections relating to the eyes, muscular system or to the nervous system are easily remediable, if taken in time. Such medical inspection as is proposed by this bill should not only call attention to the more obvious ailments, which it is intended primarily to correct, but should also, as experience accumulates, do much toward rendering the classification of school children more exact and comprehensive. It will, no doubt, as time goes on, bring to the front many problems which may now be more or less definitely recognized, but which will demand careful study properly to solve, extending over the observation of many cases. The state is certainly to be congratulated upon the passage of this most salutary bill, due in no small measure to the active interest of Governor Guild, as well as of a large number of public spirited citizens who have realized our shortcomings in respect to school inspection.

REPORT OF THE HENRY PHIPPS INSTITUTE.

THE second annual report of the Henry Phipps Institute for the Study and Prevention of Tuberculosis has recently appeared covering the year from Feb. 1, 1904, to Feb. 1, 1905. In spite of the fact that the year's work was carried on in temporary quarters and under great difficulties, the volume before us shows a large amount of extremely careful work, both of a theoretical and practical sort. Many interesting points in this much discussed subject of tuberculosis are brought forward. It has been shown, for example, that the character of the street in which patients live is not a significant determining factor in the development of tuberculosis. Persons living on blind alleys do not present a large percentage of cases under treatment. It appears, however, that those who live in open spaces are less susceptible to the disease than those who live on ordinary streets. It has also been shown that the ratio of black to white tuberculous persons presenting themselves for treatment has decreased during the current year, in spite of the fact that, as generally known, negroes are particularly prone to the disease. This is regarded as an important social problem, inasmuch as the negroes are careless in their habits, uncleanly, and will constitute a menace if not brought under control by strict supervision. Attention is again drawn to the importance of the relationship between alcoholism and tuberculosis. Alcohol has at times been regarded as a preventive of the disease, a matter which may be regarded with some doubt. In any case, the alcohol evil and the tuberculosis problem should be considered together, whatever their exact etiological relation may be. In general, the opening section of the report, written by Dr. L. F. Frick, contains many statistics of value, which naturally will become of increasing significance as other figures from the same standpoint are added, year by year.

An interesting statement regarding the neurological work, under the supervision of Dr. D. J. McCarthy, is given. Notes have also been made of the mental attitude in tuberculosis. It appears from this investigation that the proverbial idea of the hopefulness of the outcome on the part of persons afflicted with the disease is not to be forthwith accepted. It is also reasonable to suppose that the great publicity given to tuberculosis at the present time must have modified the general mental attitude of the individual as well as of the community toward it.

Being better understood, its seriousness is, no doubt, more frequently recognized.

Work of value is being done at the Institute on immunization in tuberculosis. It will be remembered that Prof. Edward Maragliano presented a lecture last year in connection with the Phipps Institute, on the "Specific Therapy of Tuberculosis and Vaccination against the Disease." The claims were made that a specific therapy for tuberculosis is possible and that animals might be immunized against tuberculosis as in other infectious diseases with good reason to hope that this might later be applied to man. As a result of this lecture investigations have been faithfully carried on in this line at the Institute, but without any definite conclusions as yet. Dr. Leonard Pearson, however, reports that work upon the immunization of cattle has been most encouraging. This portion of the report will in general be of much interest to students of tuberculosis, representing as it does recent experimental work along lines which at least give promise of future results.

MEDICAL NOTES.

DEATH OF A PHYSICIAN FROM SLEEPING SICKNESS.—It is reported that Lieutenant Tulloch, one of the physicians accompanying the Commission of the Royal Society to Uganda for the purpose of studying sleeping sickness, died in London, June 20, from the disease, as the result of an accidental inoculation.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, June 27, 1906, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 11, scarlatina 32, typhoid fever 12, measles 50, tuberculosis 35, smallpox 0.

The death-rate of the reported deaths for the week ending June 27, 1906, was 15.43.

BOSTON MORTALITY STATISTICS. The total number of deaths reported to the Board of Health for the week ending Saturday, June 24, 1906, was 158, against 201 the corresponding week of last year, showing a decrease of 43 deaths and making the death-rate for the week 13.85. Of this number 84 were males and 74 were females; 155 were white and 3 colored; 84 were born in the United States, 72 in foreign countries and 2 unknown; 30 were of American parentage, 112 of foreign parentage and 16 unknown. The

number of cases and deaths from infectious diseases reported this week is as follows: Diphtheria, 41 cases and 2 deaths; scarlatina, 11 cases and 2 deaths; typhoid fever, 7 cases and 2 deaths; measles, 55 cases and 1 death; tuberculosis, 41 cases and 28 deaths; smallpox, no cases and no deaths. The deaths from pneumonia were 8, whooping cough 2, heart disease 20, bronchitis 5 and marasmus 3. There were 6 deaths from violent causes. The number of children who died under one year was 21; the number under five years 36. The number of persons who died over sixty years of age was 35. The deaths in public institutions were 51.

There were 2 cases and 2 deaths reported from cerebrospinal meningitis during the week.

HARVARD MEDICAL ALUMNI ASSOCIATION.

The annual meeting of the Harvard Medical Alumni Association was held June 26 at twelve o'clock at the Harvard Medical School. Dr. F. B. Mallory spoke on the future of the new Harvard Medical School, and Dr. Malcolm Storer also addressed the association. As heretofore the association met at Cambridge on Commencement Day.

APPOINTMENT OF PHYSICIANS BY BOSTON SCHOOL COMMITTEE. At a recent meeting of the Boston School Committee the following physicians were appointed to consider the curriculum and hours of the first three grades of the primary school from a medical standpoint: Dr. A. C. Jelly, Dr. J. S. Stone, Dr. L. P. O'Donnell, Dr. G. S. C. Badger, Dr. J. E. Goldthwait, Dr. J. F. Young and Dr. E. P. Joslin.

"THIRD-RAIL EYE." A recent decision of the Massachusetts Supreme Court regarding the so-called "third-rail eye" will probably prove of much importance. Sometime ago suit was brought against the Boston Elevated Railway Company for alleged injury to the eye from a particle of steel coming from the third rail during the passage of a train overhead. After much litigation the Supreme Court has ruled that the original verdict should stand. This evidently opens the way for a series of suits of the same general character.

NEW YORK.

SMALLEST INFANT ON RECORD. The smallest infant on record at Bellevue Hospital, a premature child weighing twelve ounces, was recently received at that institution and placed in an

incubator. Although it was well-formed and seemed to have some chance of surviving, it lived but a day or two.

NEW YORK BAY POLLUTION COMMISSION. — Mayor McClellan has announced his appointment of the members of the New York Bay Pollution Commission created by the recent legislature. The head of the commission is Dr. Daniel Lewis, who, for a number of years, was president of the State Board of Health, and among the other commissioners are Dr. George A. Soper, the well-known sanitary expert, and Prof. Olin H. Landreth, of Union College. It would appear that the best men have been selected for these positions, without any regard to political considerations.

DINNER TO RETIRED POLICE SURGEON. — On June 19 the Board of Police Surgeons gave a complimentary dinner to the recently retired president of the board, Dr. Stephen G. Cook, in recognition of his thirty-four years' faithful service as a police surgeon. The new president, Dr. John J. Quigley, presided, and among those present was the head of the Police Department, General Bingham, who gave interesting medical reminiscences of his army life and told some of his experiences in a Buffalo hospital, where his leg was amputated.

GIFT TO AMERICAN MUSEUM OF NATURAL HISTORY. — The skeleton of the famous race horse *Synsby*, which recently died at the Sheepshead Bay track, will probably be presented to the American Museum of Natural History, New York. It is stated that when the noted English horse, *Ormonde*, was sold to the Argentine Republic, there was a stipulation to the effect that when he died his skeleton should be returned to England as a gift to the British Museum, where it now is; while in America the mounted skeletons of two other famous race horses, *Eclipse* and *Lexington*, are serving science and students of natural history, in the Smithsonian Institution at Washington.

UROTROPIN QUESTIONED. — The mind of the Collector of the Port of New York has been for some time considerably exercised over the matter of hexamethylenaminotetramine, more familiarly known as urotropin. Being convinced that this preparation contains alcohol, he demanded importation duty on the basis of fifty-five cents a pound. The importers, contending that there was no alcohol in it, appealed to the Board of General Appraisers, and the board upheld the collector in his position. The importers then

carried their case to the courts, and Judge Pratt, in the United States Circuit Court, has now, much to their relief, rendered a decision to the effect that the drug does not contain alcohol.

ETHICS OF THE ALLIED PROFESSIONS. — A symposium on the "Ethics of the Allied Professions" was held on June 18, at the New York College of Pharmacy, the medical profession being represented by Dr. Reynold Webb Wilcox, Professor of Medicine in the New York Post-Graduate Medical School, and Drs. F. E. Stewart and John P. Davin, the medical press by Dr. H. Edwin Lewis, the pharmaceutical press by Messrs. Mayo and E. C. Goetting, the pharmacists by Drs. William C. Alpers and William C. Anderson, and the manufacturing chemists by Parke, Davis & Co. and W. H. Schiefflin & Co. In the course of his remarks Professor Wilcox said: "It is a lamentable fact that the young doctor nowadays is relatively less fitted to practice the art of healing than the young doctor of ten years ago. The theoretical work in the medical schools is enormously out of proportion to the practical. The average student, when he comes out of college to practice his profession, knows little or nothing about compounding prescriptions. If he does not become a peddler of Smith's heart tablets or Jones's hypophosphites, he becomes a therapeutic nihilist, and then is surprised when his patients wander off into Christian Science." Dr. Stewart argued for the elimination of the proprietary system, and concluded by saying: "The medical and pharmaceutical professions are certainly allied. They twain should be one flesh, and what God has joined together let no patent medicine man put asunder."

MORTALITY DURING MAY. — The weekly reports of the Health Department show that the mortality in the city during the month of May represented an annual death-rate of 18.53, as against 19.79 in April, and 16.92 in May, 1905. In May of last year, the number of deaths was unusually small. Among the diseases in which there was a decline in fatality were the following: The weekly average of deaths from measles decreased from 51 in April, to 35.5 in May; the weekly average of deaths from influenza, from 8 to 4; from epidemic cerebro-spinal meningitis, from 29.5 to 26.5; from pulmonary tuberculosis, from 182.75 to 177.25; from acute bronchitis, from 31.25 to 22.5; from pneumonia, from 164.5 to 114.25; from bronchopneumonia, from 141 to 107.5; from cancer, from 58.25 to 54; from organic heart diseases, from 117.25 to 101.25; and from Bright's disease

and nephritis, from 127.25 to 121.75. Among the diseases which showed an increased mortality were the following: The weekly average of deaths from scarlet fever increased from 14.75 to 26.25; from diphtheria and croup, from 43 to 47.75; from whooping-cough, from 4 to 5.5; from diarrheal diseases, from 42.75 to 55.5; and from diarrheals under two years of age, from 38.5 to 48.25. During the month there were 5 deaths from smallpox, the largest mortality from this disease reported in any one month for several years. The corrected death-rate, excluding non-residents and infants under one week old, was 17.17.

QUARANTINE REGULATIONS AFFECTING CUBAN PORTS. — On June 23, the new quarantine regulations affecting Cuban ports which have been ordered by Health Officer Doty went into effect. According to these, all passengers on steamships arriving from such ports who are not provided with certificates to the effect that they are immune to yellow fever are to be held for observation until five days have elapsed since their departure from Cuba. Dr. Doty explains that this precaution is taken for the purpose of keeping yellow fever out of the Southern States, as a person with the disease in his system might come from Havana in three days, and, if allowed to land, could, by taking a fast train, be in New Orleans before the expiration of the five-day limit. Passengers on vessels from other ports than Havana, from which the time of passage is five days or longer, will, if they show no signs of infection, be permitted to land after the usual inspection common to all vessels is made at quarantine.

CAMP FOR SICK BABIES. — An out-of-door camp for sick babies is to be started on the bluff extending from 64th to 65th streets on the East River front. John D. Rockefeller has given the use of the land, which adjoins the site of the Rockefeller Institute and will, it is said, contribute largely to the expenses of the undertaking. The camp, which is to be known as the Junior Sea Breeze, will be under the management of the New York Association for Improving the Condition of the Poor, which maintains the Sea Breeze hospital and fresh air resort at Coney Island. There will be accommodations for about one hundred infants in open tents, with porches in front. Three of the tents will be reserved for seriously ill patients, who will remain in them day and night, while in the others the children will be largely cared for by their own mothers during the hours of daylight. It is not likely

that there will ever be enough places at the seashore for all the sick babies of the city in the summer months, and one object of this enterprise is to teach the mothers how to properly care for their infants in hot weather. Among the prominent physicians who will be on the consulting staff of the camp are Health Commissioner Darlington and Drs. John W. Brannan, Henry D. Chapin, W. P. Northrup. The quarters for the nurses will be in the old Schermerhorn mansion, which is still standing on the estate purchased by Mr. Rockefeller for the institute for medical research which bears his name. It is understood that the babies' camp is only a temporary enterprise, which is to be conducted as a demonstration, in the hope that the city will reserve portions of the recreation piers for similar purposes, and that other breathing spaces also will be so utilized.

Miscellany.

CRIMINAL ANTHROPOLOGY AND THUG SKULLS.

At the last meeting of the Royal Society of Edinburgh last week, Sir William Turner, K.C.B., submitted Part 3 of his "Contributions to the Craniology of the People of the Empire of India." Amongst the skulls, of which he exhibited photographs, were specimens of Thugs, who, Sir William explained, made it their business to frequent the great highways of India and become friendly with travellers, with a view to setting upon them and strangling them. They did this with so much care and forethought that no one ever escaped. Large numbers of people disappeared and no one knew what became of them, as the Thugs buried their victims with such secrecy that the burial places could not be discovered. The attention of the Government was at last directed to the matter and the system is now believed to be at an end. A number of the skulls of these Thugs found their way to Edinburgh, several of which had been presented to him. Altogether he had examined 15. This practice was hereditary in families and the people who practised it regarded it as a religious duty — that they were offering sacrifices to the particular goddess they worshipped. They read nowadays in *lashed* and other journals of the "criminal" type of skull. The criminal was believed to have marks on the skull which showed him to be a morally degraded person. In these skulls they had a means of investigating the species of criminal type because neither the last people whose families had for generations been devoted to crime and of such a thing as a criminal type prevailed they would expect to find it in them. Exhibiting a photograph of one of the Thug skulls Sir William said it was exceedingly well

formed. There was a well-arched forehead, and no want of symmetry. He did not consider that in these skulls of the Thugs there was any evidence whatever to support the view that there was a definite type of criminal skull. Sir William also described two skulls which had been sent him by a former pupil who was with the Thibet expedition. He pointed out that one, that of a Thibetan proper, was Mongolian in type; and the other, that of a Kham warrior, was of the long-headed type. The fighting of the Thibetans was very poor in the early stages of the expedition. They were so afflicted with monastic institutions that there was not much courage in them. The people of Kham, however, were different. They were warriors, and it was found that the fighting was more severe after the Kham warriors joined the Thibetan people. There seemed to be a physical correspondence between the people of the Kham country and the people of Upper Burma.—*British Medical Journal*.

Correspondence.

DIAGNOSIS OF SUBDELTOID BURSTITIS.

227 BEACON STREET, BOSTON, MASS.,
June 19, 1906.

Mr. Editor: Your issue of June 14 contains a letter from Dr. Dawbarn, of New York, concerning the diagnosis of subdeltoïd burstitis.

I feel very grateful to Dr. Dawbarn for his kind allusion to my paper published in your issue of May 31 and for his suggestion as to the diagnosis of subdeltoïd burstitis. Nevertheless, I am inclined to think that his communication gives a false impression and that the sign which he regards as "pathognomonic" is, perhaps, misnamed "pathognomonic," because it is only of value in a small proportion of the cases. The word "pathognomonic" implies that all cases of subdeltoïd burstitis have this sign. Dr. Dawbarn, I am sure, really means that cases which have this sign are cases of subdeltoïd burstitis. It is certainly very valuable in those cases in which muscular spasm or actual adhesions do not prevent the passage of the greater tuberosity under the acromion, but unfortunately those cases in which the tuberosity will not pass under the acromion form the majority of the cases one sees. For instance, in the cases which I have alluded to as type III it is of considerable service, for in these cases the arm can be abducted normally and the tender point will pass under the protection of the acromion process. This is not the case, however, in the types which I have described as I, II and IV. In type I (the acute cases) the sign is sometimes of use because the scapulo-humeral spasm does not entirely lock the motion in which the tuberosity passes under the acromion process; in other acute cases, however, the spasm is so great that the tender point is prevented from passing under the acromion and tenderness may still be elicited in abduction. In type II (the adherent cases), actual adhesions prevent the passage of the tuberosity under the acromion so that this sign cannot be used. In other cases the adhesions are entirely painless with no tenderness.

I want to thank Dr. Dawbarn, however, for alluding to this point because it is certainly of considerable value in mild acute cases and certain chronic cases in which motion is not greatly restricted. I must submit, however, that it is not "pathognomonic" and that a large majority of the cases do not exhibit this sign, because muscular spasm or actual adhesions prevent the passage of the tender point under the acromion.

Truly yours,

E. A. CODMAN, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JUNE 16, 1906.

SOCIETY NOTICE.

OFFICERS OF THE LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY.—Wendell C. Phillips, president, New York, N. Y.; Vice-presidents: C. G. Coadley, M.D., chairman Eastern Section, New York, N. Y.; John M. Ingersoll, M.D., chairman Middle Section, Cleveland, Ohio; W. C. Bane, M.D., chairman Western Section, Denver, Colo.; J. M. Ray, M.D., chairman Southern Section, Louisville, Ky. Secretary, Thomas J. Harris, M.D., 117 East 40th St., New York City. Treasurer, Edwin W. Day, M.D., 71 Westinghouse Building, Pittsburgh, Pa.

RECENT DEATHS.

JOHN ALEXANDER TANNER, M.D., M.M.S.S., died in Dorchester, June 21, 1906, aged fifty-three years.

DR. WILLIAM DUFF BULLARD, of New York, died on June 20. He was the son of Dr. William M. Bullard, and was born in New York City in 1872. He was graduated from Amherst College in 1892, and from the College of Physicians and Surgeons, New York, in 1895. He served as interne in the New York Post-Graduate Hospital, and later was made adjunct professor of surgery in the Post-Graduate Medical School. He resigned this position in 1900, and at the time of his death was an assistant surgeon at the Hospital for Ruptured and Crippled.

DR. THOMAS DE L. BURCKHALTER, of New York, died from cardiac disease at St. Vincent's Hospital in that city on June 20. He was thirty-two years old, and a native of Aiken, S. C., and was graduated from the Carolina Medical College in 1885. He removed to New York some time ago, and for three years was assistant resident physician at the Willard Parker Hospital for contagious diseases. A few months since he resigned that position to become an inspector in the Health Department.

DR. KARL EDWARD BEHN, surgeon of the Hamburg-American steamship "Graf Waldersee," died from cardiac disease on that vessel on June 16, and was buried at sea. He was forty-five years of age, and had been in the medical service of the Hamburg-American Line for ten years.
